
• **Fig. 33.2** (A) Gram stain appearance of *Campylobacter jejuni* subsp. *jejuni* from a colony on a primary isolation plate. Note seagull and curved forms *(arrows)*. (B) Appearance of *C. jejuni* subsp. *jejuni* in a direct Gram stain of stool obtained from a patient with campylobacteriosis. *Arrows* point to the seagull form.

blood free (CCDA) is a modified agar that does not include blood. The blood is replaced with charcoal, sodium pyruvate, and ferrous sulfate. The medium supports growth of most *Campylobacter* spp. An additional blood-free media is **charcoal-based selective medium (CSM)**.

Cultivation

Stool

Successful isolation of *Campylobacter* spp. from stool requires selective media and optimal incubation conditions. Cultures should not be performed from formed stool for diagnostic purposes. Recommended inoculation of two selective agars is associated with increased recovery of the organisms. Reports indicate that CVA and CCDA demonstrate a higher recovery rate than blood-based media. Because *Campylobacter* and *Arcobacter* spp. have different optimum temperatures and atmospheric requirements, two sets of selective plates should be incubated, one at 42°C and one at 37°C with increased hydrogen. Extended incubation may be required (48 to 72 hours) before there is evidence of visible growth. In addition, *Campylobacter* spp. such as *C. concisus, C. upsaliensis, C. ureolyticus,* and *C. sputorum,* are not routinely isolated due to the nonthermophilic nature and/or inhibition by antibiotics included in the commonly used selective media.

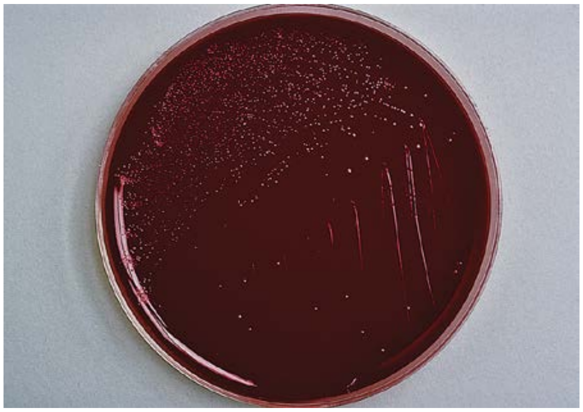
A filtration method can also be used in conjunction with a nonselective medium to enhance recovery of *Campylobacter* and *Arcobacter* spp. A filter (0.45 to 0.65-μm pore-size polycarbonate or cellulose acetate) is placed on the agar surface, and a drop of stool is placed on the filter. The plate is incubated upright. After 60 minutes at 37°C, the filter is removed and the plates are reincubated in a microaerobic atmosphere. The organisms are motile and capable of migrating through the filter, producing isolated colonies on the agar surface and effectively removing contaminating stool microbiota. *C. concisus, A. butzleri, A. cryaerophilus,* and *Helicobacter cinaedi* have been isolated after 5 to 6 days of incubation using the filter technique. An enrichment broth may be used for the recovery of *Arcobacter* or *Campylobacter* species from stool such as Preston enrichment, Campy-thio, and *Campylobacter* enrichment broth. The clinical advantage and cost-effectiveness of the use of enrichment broth has not been evaluated.

Blood

Campylobacter spp. are capable of growth in less than 5 days in most blood culture media, although they may require extended incubation periods of up to 2 weeks for detection. Subcultures should be incubated in 5% O_2, 10% CO_2, and 80% N_2 (microaerobic) environment. Turbidity may not be visible in blood culture media; therefore subcultures at 24 to 48 hours to a nonselective blood agar medium or microscopic examination using acridine orange stain may be necessary. The presence of *Campylobacter* spp. in blood cultures is effectively detected through carbon dioxide monitoring. Isolation from sources other than blood or feces is extremely rare. Recovery of the organisms is enhanced by inoculation (minced tissue, wound exudate) to a nonselective blood or chocolate agar plate and incubation at 37°C in a carbon dioxide–enriched, microaerobic atmosphere. Selective agars containing cephalosporin, rifampin, and polymyxin B may inhibit growth of some strains and should not be used for isolation from sterile sites.

Atmosphere

Campylobacter spp. require a microaerobic environment as previously indicated; however, not all species will grow in this environment. Some species, including *Campylobacter sputorum, C. concisus, C. mucosalis, C. curvus, C. rectus,* and *C. hyointestinalis* require increased hydrogen concentration for optimal growth. A gas mixture of 10% CO_2, 6% H_2, and 84% N_2 using an evacuation-replacement system such



• **Fig. 33.3** Colonies of *Campylobacter jejuni* after 48 hours of incubation on a selective medium in a microaerobic atmosphere.

as the Anoxomat, Advanced Instruments, Norwood, MA (Chapter 40) is sufficient for growth of these organisms.

Approach to Identification

Plates should be examined for characteristic colonies, which are gray to pink or yellow gray and slightly mucoid; some colonies may exhibit a tailing effect along the streak line (Fig. 33.3). Colony morphology varies with the type of medium used for isolation. Suspicious-looking oxidase-positive colonies observed on selective media incubated at 42°C may be presumptively identified as *Campylobacter* spp., usually *C. jejuni* or *C. coli*. A wet preparation of the organism in broth can be examined for characteristic darting motility and curved morphology on Gram stain. Most isolates of *C. jejuni* subsp. *jejuni* can be distinguished from other *Campylobacter* species by the presence of sodium hippurate hydrolysis. *Campylobacter fetus* is incapable of growth at 42°C, and optimal growth is 37°C. Susceptibility or resistance to cephalothin and nalidixic-acid are no longer recommended for species identification due to the increasing fluoroquinolone resistance present in clinical isolates of *Campylobacter* spp. Table 33.2 provides characteristics for biochemical differentiation of the common clinically relevant organisms included in this chapter.

Almost all the pathogenic *Campylobacter* spp. are oxidase positive and catalase positive. Laboratories will commonly report stool isolates as "*Campylobacter* spp." Because *C. coli* and *C. jejuni* are similar, biochemically, molecular methods or MALDI-TOF is required to differentiate hippurate negative *C. jejuni.*

Most *Campylobacter* spp. are asaccharolytic, unable to grow in 3.5% NaCl, although strains of *Arcobacter* appear more resistant to salt and, except for *A. cryaerophilus,* unable to grow in ambient air requiring incubation in 10% O_2, 10% CO_2, and 80% N_2 at 37°C. Growth in 1% glycine is variable. Other tests useful for identifying these species are the rapid hippurate hydrolysis test, production of hydrogen sulfide (H_2S) in triple sugar iron agar slants, nitrate reduction, and hydrolysis of indoxyl acetate. Indoxyl acetate disks are available commercially. Cellular fatty acid analysis is useful for species identification. This method is not available in routine clinical microbiology laboratories.

Because *Campylobacter* and *Arcobacter* are difficult to identify using biochemical and phenotypic tests, nucleic acid (NAATS)–based amplification of the 16S and 23S ribosomal ribonucleic acid (rRNA) gene along with a variety of other targets and direct sequencing of the PCR products have successfully been used to identify most *Campylobacter* species. The assays accurately discriminate related taxa, including *Campylobacter, Arcobacter,* or *Helicobacter* species.

In addition to molecular methods, matrix-assisted laser desorption ionization time-of-flight mass spectrometry (MALDI-TOF MS) is increasingly being used to identify *Campylobacter* spp. Identification has been reported with 99% to 100% accuracy for *C. jejuni, C. coli, C. fetus* subsp. *fetus, Campylobacter lari,* and *A. butzleri.*

Serodiagnosis

Serodiagnosis is not widely applicable for the diagnosis of infections caused by these organisms.

Antimicrobial Susceptibility Testing and Therapy

C. jejuni and *C. coli* demonstrate variable susceptibility to many antimicrobial agents, including macrolides, tetracyclines, chloramphenicol, aminoglycosides, and quinolones. Erythromycin has been the drug of choice for patients with severe gastroenteritis (severe dehydration, bacteremia), with ciprofloxacin as an alternative therapeutic option. Ciprofloxacin resistance has been reported as high as 26.7% to 35.6% in *C. jejuni* and *C. coli,* with 25% to 50% resistance to erythromycin. Previously, fluoroquinolones were the antibiotic therapy most commonly prescribed for *Campylobacter* infection; however, a rapidly increasing proportion of *Campylobacter* strains worldwide have been identified as fluoroquinolone resistant. Parenteral therapy (not taken through the alimentary canal but by an alternate route, such as intravenously) is used to treat systemic *C. fetus* infections. *Arcobacter* spp. demonstrate variable resistance patterns to macrolides and fluoroquinolones.

The Clinical Laboratory Standards Institute (CLSI) recognizes broth microdilution and disk diffusion and ETEST (bioMérieux, Inc.) screening methods for susceptibility testing. Methodologies and breakpoints may vary; it is important to review the criteria used in the laboratory's region. Because of emerging resistance to fluoroquinolones, susceptibility testing is recommended for patients with *Campylobacter* spp. gastroenteritis. Susceptibility testing should be performed on all isolates from sterile fluids and body sites.

Prevention

No vaccines are available for *Campylobacter* spp. Infections caused by *Campylobacter* spp. are acquired by ingesting contaminated foodstuffs or water. Proper preparation and cooking of all foods derived from animal sources, particularly poultry, will decrease the risk of transmission. All milk

should be pasteurized and drinking water chlorinated. Care must be taken during food preparation to prevent cross-contamination from raw poultry to other food items.

Helicobacter spp.

General Characteristics

Approximately 39 species are included in the genus *Helicobacter*, the majority of which colonize mammalian stomachs or enterohepatic regions (intestine, liver, and biliary tract). The genus *Helicobacter* consists of curved, helical or spiral, or fusiform microaerophilic, gram-negative rods with or without periplasmic fibers, with the majority of species exhibiting urease activity. The organisms may appear coccoid or spheroidal if cultivated for long periods or in suboptimal growth conditions.

Epidemiology and Pathogenesis

Helicobacter pylori's primary habitat is the human gastric mucosa. The organism is distributed worldwide and although acquired early in life in underdeveloped countries, the exact mode of transmission is unknown. An oral-oral, fecal-oral, and a common environmental source have been proposed as possible routes of transmission, with familial transmission associated with *H. pylori* infections. Research studies suggest mother-to-child transmission as well as among siblings and other household contacts as the most probable cause of intrafamilial spread. In industrialized nations, antibody surveys indicate that approximately 50% of adults older than 60 years are infected by *H. pylori.* Gastritis incidence increases with age. *H. pylori* has occasionally been cultured from feces and dental plaque, thereby suggesting a fecal-oral or oral-oral transmission.

The habitat for *H. heilmannii* and closely related species (*H. heilmannii-like* or HHLO) appears to be the human gastrointestinal tract with one or more species (*H salomonis, H. felis, H. suis*) of zoonotic origin. *H. heilmannii*, HHLO, and *H. pylori* may be normal microbiota of the human host. Additional enterohepatic species inhabit the intestinal and hepatobiliary tract of birds and mammals, such as *H. bilis, H. canadensis, H. canis, H. cinaedi, H. fennelliae,* and *H. pullorum.*

H. pylori is capable of colonizing the mucous layer of the antrum, cardia, and corpus of the stomach and areas of the gastric metaplasia of the proximal duodenum but fails to invade the epithelium. Motility allows *H. pylori* to escape the acidity of the stomach and burrow through and colonize the gastric mucosa in close association with the epithelium. In addition, the organism produces urease that hydrolyzes urea-forming ammonia (NH_3), significantly increasing the pH around the site of infection. The change in pH protects the organism from the acidic environment produced by gastric secretions. *H. pylori* also produces a protein called CagA and injects the protein into the gastric epithelial cells. The protein subsequently affects host cell gene expression, inducing cytokine release and altering cell structure, and interactions with neighboring cells, enabling *H. pylori* to successfully invade the gastric epithelium. Individuals who demonstrate positive antibody response to the CagA protein are at increased risk of developing both peptic ulcer disease and gastric carcinoma. Other possible virulence factors include adhesins for colonization of mucosal surfaces, mediators of inflammation, and a cytotoxin capable of causing damage to host cells (Table 33.3). Although *H. pylori* is noninvasive, untreated colonization persists despite the host's immune response.

TABLE 33.3 **Genes and Their Possible Role in Enhancing the Virulence of *Helicobacter pylori***

Gene	Possible Role
VacA	Exotoxin (VacA) Creates vacuoles in epithelial cells, decreases apoptosis, and loosens cell junctions
CagA	Pathogenicity island Encodes a type IV secretion system for transferring CagA proteins into host cells
BabA	Encodes outer membrane protein: mediates adherence to blood group antigens on the surface of gastric epithelial cells
IceA	Presence associated with peptic ulcer disease in some populations

Spectrum of Disease

H. pylori causes gastritis, peptic ulcer disease, and gastric cancer. However, most individuals tolerate the presence of *H. pylori* for decades with few, if any, symptoms. Infection with this organism is also a risk factor for the development of atrophic gastritis, gastric ulcer disease, gastric adenocarcinomas, and gastric mucosa–associated lymphoid tissue (MALT) lymphomas.

Enterohepatic helicobacters have been identified in association with human disease including *H. fennelliae, H. canis, H. cinaedi,* and *H. pullorum.* These isolates are transmitted from animals to humans and may be isolated from human blood or fecal samples. *H. cinaedi* and *H. fennelliae* have been isolated in cases of proctocolitis, gastroenteritis, neonatal meningitis, skin rashes, and bacteremia in immunocompromised patients. HHLO have been isolated in association with human cases of mild to moderate gastritis, peptic ulcer, and gastric MALT.

Laboratory Diagnosis

Specimen Collection, Transport, and Processing

Tissue biopsy material of the stomach for detection of *H. pylori* should be placed directly into transport media such as Stuart's transport medium, *Brucella* broth with 20% glycerol, or Portagerm pylori media (bioMérieux, Inc., Durham, NC) to prevent drying. Specimens for biopsy may be refrigerated up to 24 hours before processing; tissues should be minced and gently homogenized. If longer storage is required, samples should be frozen at −70°C in a 10% glycerol–containing medium.

Fecal specimens may be used for stool antigen tests but cannot be used for routine culture of gastric helicobacters. These samples should be tested immediately and stored at −20°C or according to the manufacturer's recommendations. Repeated freezing and thawing of specimens should be avoided. Enterohepatic helicobacters may be processed for culture using campylobacter protocols as previously described in this chapter.

Blood samples for serologic diagnosis of *Helicobacter* spp. infection may be collected, transported, and processed by standard methods. Gastric juice has been used for nucleic acid detection and culture of *H. pylori.*

Direct Detection

Gastric biopsy specimens that are preserved in 10% formaldehyde or paraffin-imbedded tissue are often used for the histopathologic diagnosis of *H. pylori* infection. Pathologists use the Warthin-Starry or other silver stains to examine biopsy specimens. Squash preparations of biopsy material can be performed and stained with rapid Giemsa stain, fluorescent acridine orange stain, or Gram stain. Gram stain using an alternate secondary stain, 0.5% carbolfuchsin or 0.1% basic fuchsin, enhances recognition of the bacteria's typical morphology. However, because of the presence of bacterial atypical morphologies, the results may not be interpreted correctly. Sampling error may occur during processing, resulting in no identification of the organisms.

Presumptive evidence of the presence of *H. pylori* in biopsy material may be obtained by placing a portion of crushed tissue biopsy material directly into urease broth, onto commercially available urease agar kits, or on a paper strip containing a pH indicator. These tests are collectively referred to as rapid urease tests (RUTs). A positive test is considered indicative of the organism's presence. The CLOtest (Kimberly-Clark, Neenah, Murray Hill, NG) is an example of an agar-gel based RUT (Fig. 33.4).

Another noninvasive indirect test to detect *H. pylori* is the urea breath test (UBT). This test relies on the presence of *H. pylori* urease. The patient ingests nonradioactively labeled natural isotope (^{13}C) urea, and if the organism is present, the urease produced by *H. pylori* hydrolyzes the urea to form ammonia and labeled bicarbonate that is exhaled as $^{13}CO_2$; the $^{13}CO_2$ is detected by a special spectrometer. This test has excellent sensitivity and specificity. EIA *H. pylori* stool antigen tests (Premier Platinum HpSA, Meridian Diagnostics, Inc., Cincinnati, OH, or IDEIA Hp StAR, Oxoid Ltd., Basingstoke, United Kingdom) and rapid immunochromatographic point of care assays using monoclonal antibodies (ImmunoCard STAT! HpSA, Meridian Bioscience, Cincinnati, OH, or *RAPID* Hp StAR, Oxoid Ltd., Basingstoke, United Kingdom) have been introduced to directly detect *H. pylori.*

Nucleic Acid Detection

A variety of nucleic acid–based methods have been developed to directly detect *H. pylori* and HHLO in clinical specimens and to identify bacterial strains and host genotype characteristics, bacterial density in the stomach, and antimicrobial resistance patterns. Polymerase chain amplification and fluorescence *in situ* hybridization using species-specific probes has enhanced the diagnosis and detection in gastric biopsy specimens. Amplification targets include the 16S RNA, 23S rRNA *ureA, glmM, vacA,* and *cagA* genes. Interpretation of nucleic acid–based methods should be used in conjunction with other diagnostics methods. There are no methods available for the detection of enterohepatic *Helicobacter* species of clinical relevance at the time of this writing.

Varieties of methods are under development for the direct detection of *H. pylori* nucleic acids in feces. These techniques are problematic in that DNA is often degraded when passing through the gastrointestinal tract as well as the presence of a variety of amplification enzyme inhibitors in feces. Potential new methods are expected to be placed in clinical trials and submitted for FDA approval that would not only detect the organism but also the presence of mutations that confer macrolide resistance.

Cultivation

Stool specimens submitted for culture of enterohepatic helicobacters such as *H. bilis, H. canadensis, H. canis, H. cinaedi, H. fennelliae,* and *H. pullorum* are inoculated onto selective media used for *Campylobacter* isolation but without cephalothin, such as Campy-CVA. *H. cinaedi, H. canis,* and *H. fennelliae* have been occasionally isolated from commercial blood culture systems in patients suspected of bacteremia. The recovery of *H. pylori* from tissue biopsy specimens, including gastric antral biopsies; nonselective agar media, including brain heart infusion agar, and *Brucella* agar with 5% sheep blood; **Wilkins Chalgren agar;** and trypticase soy agar have resulted in successful recovery of the organisms. The combination of a selective agar (Columbia agar with an egg yolk emulsion, supplements, and antibiotics) and a nonselective

agar (modified chocolate agar with Columbia agar, 1% **Vitox,** and 5% sheep blood) was reported as the optimal combination for recovering *H. pylori* from antral biopsies. Incubation up to 1 week in a humidified, microaerobic environment (4% O_2, 5% CO_2, 5% H_2, and 86% N_2 atmosphere) at 35°C to 37°C may be required before growth is visible.

Approach to Identification

Colonies of *Helicobacter* spp. may require 4 to 7 days of incubation before growth is observed. Colonies may appear as small, translucent, circular colonies or swarming phenotypes from some gastric isolates. Culture plates should be reviewed daily for a minimum of 10 days before a negative culture is reported. Organisms are identified presumptively as *H. pylori* by the typical cellular morphology and positive results for oxidase, catalase, and RUT. *H. pylori* and some enterohepatic species may be definitively identified by using a similar approach to *Campylobacter* spp. However, on subculture these organisms may lose their classic morphology, making identification difficult. MALDI-TOF has been successfully used to identify *H. pylori* from cultures of gastric biopsy specimens (Table 33.4).

Serodiagnosis

Serologic diagnosis is also available for *H. pylori.* The immune response typically presents with a rise in immunoglobulin M (IgM), followed by immunoglobulin G (IgG) and immunoglobulin A (IgA), although 2% of patients fail to seroconvert. Numerous serologic EIAs designed to detect IgG and IgA antibodies to *H. pylori* are commercially available. Reported performance of these assays varies depending on the reference method used to confirm *H. pylori* infection, the antigen source for the assay, and the population studied. In addition to variability in assay performance, the clinical utility of IgA testing in these assays is controversial. In some cases, IgA has demonstrated a much lower sensitivity and specificity than IgG for the detection of *H. pylori* infections. These assays are incapable of differentiation of active versus past *H. pylori* infections. As of this writing, there are no serologic assays for the routine diagnosis of HHLO or enterohepatic *Helicobacter* spp.

Antimicrobial Susceptibility Testing and Therapy

Except for metronidazole and clarithromycin, most laboratory susceptibility assays are unsuccessful in predicting clinical outcome. Routine testing of *H. pylori* isolates' susceptibility to metronidazole is recommended using the ETEST and agar or broth dilution methods.

Therapy for *H. pylori* infection is problematic. *H. pylori* readily becomes resistant when metronidazole, clarithromycin, azithromycin, rifampin, or ciprofloxacin is prescribed as a single agent. Current regimens recommend triple-drug therapy including a proton pump inhibitor, clarithromycin, and either amoxicillin or metronidazole. An alternative treatment for *H. pylori* infection includes fluoroquinolone, levofloxacin, and a rifamycin (rifabutin). Similar treatments have demonstrated successful therapy in patients with gastritis and peptic ulcer disease associated with HHLO. No guidelines exist for the treatment of enterohepatic helicobacters.

Prevention

No vaccines are available for *H. pylori.*

CASE STUDY 33.1

A 10-year-old male became ill a few days after a Fourth of July picnic where fried chicken was served. He complained of diarrhea, abdominal pain, and fever. Symptoms continued over the next week, and he was seen at the local clinic. Blood was found in his stool, and cultures were ordered. He was treated with ampicillin but switched to azithromycin (a macrolide similar to erythromycin) for 5 days when the culture results were reported.

Questions

1. At 42°C in a microaerobic environment, water droplet–type oxidase- and catalase-positive colonies were isolated. A Gram stain showed gram-negative rods with seagull-shaped morphology. What rapid test is used to confirm the identity of this bacterium?
2. What follow-up testing would be required if the hippurate hydrolysis is negative?
3. What is the most likely route of transmission to the patient in this incident?

Chapter Review

1. *Campylobacter* are:
- **a.** Small, curved, motile, gram-positive bacilli
- **b.** Small, curved, motile, gram-negative bacilli
- **c.** Small, curved, nonmotile, gram-negative bacilli
- **d.** Small, curved, nonmotile, gram-positive bacilli

2. *Campylobacter* species produce the following syndromes in immunocompetent patients *except:*
- **a.** Endocarditis
- **b.** Febrile systemic disease
- **c.** Periodontal disease
- **d.** Gastroenteritis

3. *C. jejuni* and *C. coli* are usually transmitted by:
- **a.** Food
- **b.** Milk
- **c.** Water
- **d.** All of the above

4. Which *Campylobacter* species has been recognized as the most common causative agent of gastroenteritis in the United States?
- **a.** *C. lari*
- **b.** *C. fetus*
- **c.** *C. coli*
- **d.** *C. jejuni*

5. Which of the following has been recognized in postinfection complications of a *C. jejuni* infection?
- **a.** Guillain-Barré syndrome
- **b.** Chronic pulmonary disease
- **c.** Encephalitis
- **d.** Endocarditis

6. *Campylobacter* species should be grown at what temperature?
- **a.** 25°C
- **b.** 37°C
- **c.** 42°C
- **d.** 37°C and 42°C

7. A positive hippurate hydrolysis is a characteristic of:
- **a.** *C. coli*
- **b.** *C. jejuni*
- **c.** *C. lari*
- **d.** *C. fetus*

8. *Campylobacter* infection may be prevented by which of the following?
- **a.** Thoroughly cooking all foods
- **b.** Pasteurized milk
- **c.** Chlorinated water
- **d.** All of the above

9. All of the following agars may be used to isolate *Helicobacter except:*
- **a.** Campy-CVA
- **b.** CCDA
- **c.** Thiosulfate-citrate-bile salts-sucrose (TCBS)
- **d.** CSM

10. *H. pylori* may be identified presumptively by which positive tests?
- **a.** NO_3, hippurate, catalase
- **b.** Oxidase, indoxyl acetate, NO_3
- **c.** Oxidase, catalase, rapid urea
- **d.** NO_3, catalase, growth at 25°C

11. True or False

_____ Hippurate hydrolysis can be used to differentiate *C. jejuni* from all other *Campylobacter* species.

_____ *Campylobacter* causes febrile systemic disease, periodontal disease, and gastroenteritis in humans.

_____ *Campylobacter* is most commonly transmitted via respiratory droplets.

_____ Stool specimens should be plated on MacConkey, Hektoen enteric (HE), and sorbitol-MacConkey (SMAC) agar for optimal recovery of *Campylobacter* species.

_____ Curved, microaerophilic, gram-negative rods showing strong urease activity are suggestive of *Campylobacter* species.

_____ Enterohepatic helicobacters may be isolated using the standard laboratory procedures for the isolation of *Campylobacter* spp.

_____ *H. pylori* causes gastritis, peptic ulcer disease, and gastric cancer.

12. Matching: *Match the correct term with the appropriate description.*

_____ microaerobic
_____ Guillain-Barré
_____ Cary-Blair
_____ seagull-winged
_____ darting motility
_____ *H. pylori*
_____ CCDA
_____ demyelination

a. removal of the myelin sheath from a nerve
b. long, polar flagella
c. requires less oxygen
d. neurologic syndrome
e. a selective agar
f. urea diagnostic test in broth
g. helix-shaped morphology
h. transport medium

34

Legionella

OBJECTIVES

1. Define the general characteristics of *Legionella* spp.
2. List sources for *Legionella* in the environment, including those that are naturally occurring and those that are man-made.
3. State the means of transmission for *Legionella* spp.
4. Describe the life cycle of *Legionella*, and explain how it avoids destruction by the host.
5. Compare and contrast the three primary clinical manifestations of *Legionella,* including signs and symptoms.
6. List the appropriate specimen collection, transport, and processing techniques for *Legionella* spp.
7. Outline the different types of testing for *Legionella,* including sensitivity and specificity.
8. Explain the chemical principle for buffered charcoal–yeast extract (BCYE) with and without inhibitory agents and the proper use for each.
9. Describe the morphology of the *Legionella* spp. when grown under optimal growth conditions, including oxygenation, temperature, and length of incubation.
10. State the drugs of choice for effective therapy.

GENUS AND SPECIES TO BE CONSIDERED

Legionella dumoffii
Legionella micdadei
Legionella longbeachae
Legionella pneumophila
  L. pneumophila subsp. *pneumophila*
  L. pneumophila subsp. *fraseri*
  L. pneumophila subsp. *pascullei*
Legionella spp.

Legionella belongs to the family *Legionellaceae,* which includes a single genus, *Legionella,* comprising approximately 59 species and 3 subspecies. *Legionella pneumophila* is the causative agent of **Legionnaires' disease,** a febrile and pneumonic illness with numerous clinical presentations. *Legionella* was discovered in 1976 by scientists at the Centers for Disease Control and Prevention (CDC) who were investigating an epidemic of pneumonia among Pennsylvania State American Legion members attending a convention in Philadelphia. There is retrospective serologic evidence of *Legionella* infection as far back as 1947. Bacteria resembling *Legionella* that are capable of living in amoebae have been designated as ***Legionella*-like amoebal pathogens (LLAPs).** *Legionella lytica,* one of the LLAPs, has been shown to cause human disease.

General Characteristics

All *Legionella* spp. are mesophilic (20°C to 42°C), obligately aerobic, faintly staining, thin, gram-negative, fastidious bacilli. *Legionella* do not grow on routine media and require a medium supplemented with iron, L-cysteine, branched-chain fatty acids, and ubiquinones and buffered to pH 6.9 for optimal growth. The organisms are asaccharolytic and utilize protein for energy generation. The overwhelming majority of *Legionella* spp. are motile. There are approximately 26 species of *Legionella* documented as human pathogens in addition to *L. pneumophila*. There have been more than 500 strains of *L. pneumophila* that have been completely sequenced, which indicates that the species is genetically diverse. The gene sequence for the lipopolysaccharide core and the O side chain for serogroup 1 demonstrates a predominance in clinical isolates of *L. pneumophila.* Box 34.1 is an abbreviated list of some of the species of *Legionella.*

Epidemiology

Legionellae are ubiquitous and widely distributed in the environment. As a result, most individuals are exposed to *Legionella* spp.; however, few develop symptoms. In nature, legionellae are found primarily in aquatic habitats and thrive at warmer temperatures; these bacteria can survive extreme ranges of environmental conditions for long periods; studies have shown that *Legionella* spp. are capable of survival for several months in free-flowing water. The organisms exist in microbial biofilms as intracellular parasites of free-living amoebae including *Acanthamoeba* and *Naegleria* spp. *Legionella* spp. have been isolated from most natural water sources investigated, including lakes, rivers, and marine waters, as well as moist soil. Organisms are also widely distributed in man-made facilities, including air-conditioning ducts and cooling towers; potable water; large, warm-water plumbing systems; humidifiers; whirlpools; and technical-medical equipment in hospitals. *L. longbeachae*, first isolated in Long Beach, California, is found predominantly in potting soil and compost.

Legionella infections are acquired exclusively from environmental sources; no person-to-person spread has been documented. Inhalation and aspiration of infectious aerosols (1–5 µm in diameter) are considered the primary means of transmission. Exposure to these aerosols can occur in the workplace or in industrial or health care settings; for example, nebulizers filled with tap water and showers have been implicated.

Legionella rubrilucens
Legionella sainthelensi
Legionella steelei
Legionella tucsonensis
Legionella wadsworthii

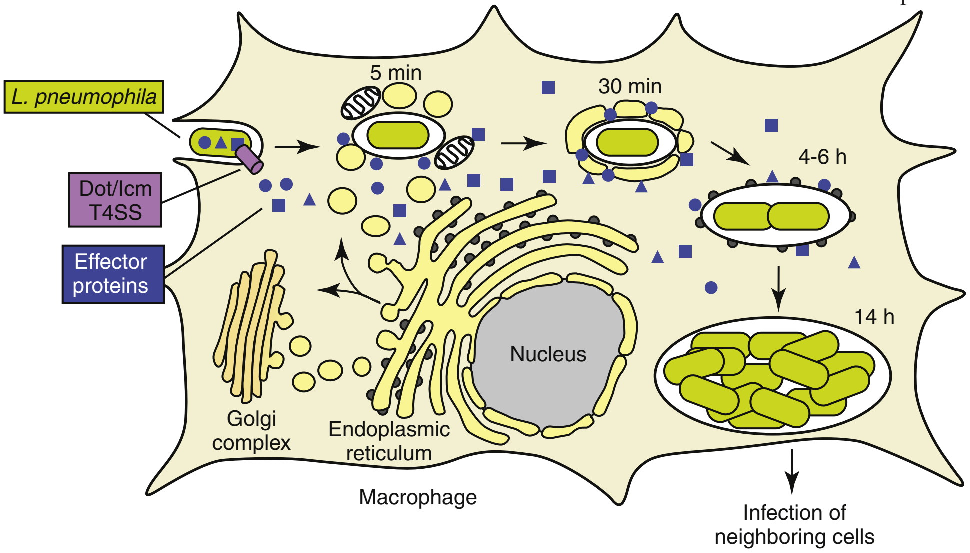
Pathogenesis and Spectrum of Disease

The virulence mechanisms of *Legionella* spp. are an important factor in the ability to infect and subsequently multiply within amoebae (*Acanthamoeba* and *Naegleria* spp.); *Tetrahymena* spp., a ciliated protozoan; and certain host cells. The organism can also multiply within biofilms, well-organized microcolonies of bacteria usually enclosed in polymer matrices that are separated by water channels that remove wastes and deliver nutrients. This contributes to the organism's survival in the environment. In addition, *L. pneumophila* exists in two well-defined, morphologically distinct forms in Hela cells: (1) a highly differentiated, cystlike form that is highly infectious, metabolically dormant, and resistant to antibiotics and detergent-mediated lysis and (2) a replicative intracellular form that is structurally similar to agar-grown bacteria. The existence of the cystlike form may account for the ability of *L. pneumophila* to survive for long periods between hosts (amoebae or humans).

L. pneumophila is considered a facultative intracellular pathogen. The organism causes disease by infecting human monocytes, predominantly alveolar macrophages. Once inside the macrophage, the organism is able to avoid destruction by the host's phagocytic cells and multiply. Molecular analysis of *L. pneumophila* has demonstrated that the organism's genome contains eukaryotic-like gene sequences that in effect subvert the normal eukaryotic cellular functions for intracellular survival. The pathogenesis of *L. pneumophila* has been extensively studied; however, little is known about the pathogenic mechanisms associated with other *Legionella* spp.

Legionella have a similar life cycle in both protozoa and human macrophages, as illustrated in Fig. 34.1:

- Binding of microorganisms to receptors on the surface of eukaryotic cells
- Penetration of microorganisms into phagocytes
- Escape from bactericidal attack
- Formation of a **replicative vacuole** (a compartment within the cell where bacterial replication occurs)



• Fig. 34.1 *Legionella pneumophila* cellular trafficking and growth mechanism inside a human macrophage. (Modified from 2009 annualreport.nichd.nih.gov/ump.html.)

- Intracellular multiplication and killing of the host cell

There are differences in the mechanisms used to enter and exit from the respective type of host cell. After infection, organisms are taken up by phagocytosis primarily in alveolar macrophages. Almost immediately following phagocytosis, *L. pneumophila* injects hundreds of pathogenicity effector molecules into the host macrophage using a type IVB secretion system (Dot or Icm). Strains that do not have the type IVB secretion system are avirulent. A type IVB secretion system has been identified in *Legionella dumoffii.* Once inside the host macrophage, the microorganism survives and replicates within a specialized, membrane-bound vacuole by resisting acidification and evading fusion with lysosomes. After replication, the organisms will kill the phagocytes, releasing them into the lungs. The organisms will again be phagocytized by a mononuclear cell, and multiplication of the organism will increase.

Many bacterial pathogens use secretion systems as a part of how they cause disease. *L. pneumophila* utilizes the type IVB secretion system, referred to as **defective organelle trafficking (Dot)** or **intracellular multiplication (Icm)**, to "trick" the eukaryotic macrophage into transporting the organism to the endoplasmic reticulum. In eukaryotic cells, most proteins secreted or transported inside vesicles to other cellular compartments are synthesized at the endoplasmic reticulum (ER) (Fig. 34.1). This Dot/Icm secretion system in *L. pneumophila* consists of 27 genes. Bacterial type IV secretion systems are bacterial devices that deliver macromolecules such as proteins across and into cells. After entry but before bacterial replication, *L. pneumophila,* residing in a membrane-bound vacuole, is surrounded by a ribosome-studded membrane derived from the host cell's ER and mitochondria. Thus, by exploiting host cell functions, *L. pneumophila* is able to gain access to the lumen of the ER, which supports its survival and replication where the environment is rich in peptides. A second type II secretion system has also been implicated in the virulence of some strains of *Legionella.* The **type II secretion system** carries numerous genes for enzymatic degradation, including lipases, proteinases, and a number of proinflammatory or tissue destructive proteins. The type II secretion system produces a number of novel proteins that permit growth of the organism in low temperatures, is required for biofilm establishment, sliding motility, and intracellular infection. Mutations within the type II secretion system result in decreased infectivity of the organism. *Legionella* is the only intracellular pathogen known to possess a functional type II secretion system. Several additional bacterial factors have also been identified as crucial for intracellular infection; some of these are listed in Box 34.2.

Finally, several cellular components and extracellular products of *L. pneumophila,* such as an extracellular cytotoxin that impairs the ability of phagocytic cells to use oxygen and various enzymes (e.g., phospholipase C), have been purified and proposed as virulence factors.

The sequestering of *Legionella* within macrophages also makes it difficult to treat the infection effectively with antimicrobial agents. Therefore, a competent cell-mediated immune response is also important for recovery from *Legionella* infections. Humoral immunity appears to play an insignificant role in the defense against this organism.

Legionellosis is a spectrum of clinical presentations, ranging from asymptomatic infection to severe, life-threatening diseases. Serologic evidence exists for the presence of asymptomatic disease, because many healthy people tested possess antibodies to *Legionella* spp. Table 34.1 provides a

• BOX 34.2 Examples of *Legionella pneumophila* Factors Crucial for Intracellular Infection

- Macrophage infectivity potentiator
- Genes encoding for the type II secretion systems required for intracellular growth
- Type IV pili
- Flagella
- Dot/Icm type IVB secretion system

TABLE 34.1 Disease Spectrum Associated With *Legionella* spp.

	Epidemiology	Disease
Pneumonia (Legionnaires' disease)	Community and nosocomial, health care–associated transmission (inhalation of aerosolized particles); immunocompromised patients, particularly in cell-mediated immunity; rarely occurs in children	Acute pneumonia indistinguishable from other bacterial pneumonias; clinical syndrome may include nonproductive cough, myalgia, diarrhea, hyponatremia, hypophosphatemia, and elevated liver enzymes.
Pontiac fever	Community setting associated with employment (industrial or recreational) or other group	Self-limiting, febrile illness; symptoms may include cough, dyspnea, abdominal pain, fever, and myalgia; pneumonia does not occur.
Extrapulmonary	Rare, metastatic complications from underlying pneumonia; incidents of inoculation into sites via punctures have been identified; therapeutic bathing; highly associated with immunocompromised patients	Abscesses have been identified in the brain, spleen, lymph nodes, muscles, surgical wounds, and a variety of tissues and organs.

From Bennett J, Dolin R, Blaser M: *Principles and practice of infectious diseases,* ed 9, Philadelphia, 2020, Elsevier-Saunders.

more detailed description of the following three primary clinical manifestations:

- Legionnaires' disease is a severe pneumonia with a case fatality rate of 10% to 20%. It is a global public health issue. Legionnaires' disease occurs in sporadic, endemic, and epidemic forms. The incidence of the disease varies greatly and appears to depend on the geographic area, but it is estimated that *Legionella* spp. cause less than 1% to 5% of cases of pneumonia.
- A mild, self-limited, nonfatal, influenza-like (e.g., fever, headache, malaise) respiratory infection known as **Pontiac fever.**
- Other rare extrapulmonary sites, such as wound abscesses, encephalitis, or endocarditis.

The disease can affect anyone but principally affects those who are susceptible because of age, illness, immunosuppression, or other risk factors, such as heavy smoking. The clinical manifestations after infection with a particular species are primarily caused by differences in the host's immune response and perhaps by inoculum size; the same *Legionella* spp. gives rise to different expressions of disease in different individuals.

L. longbeachae is the second most common cause of legionellosis. Infections associated with *L. longbeachae* are particularly common in Australia, but cases have been documented in other countries including the United States. The infection is most likely due to inhalation or aspiration of contaminated dust compost or soil and can be very serious, often leading to hospitalization and sometimes death. *Legionella micdadei* is believed to be associated with approximately 60% of Legionnaire's disease not caused by *L. pneumophila* or *L. longbeachae*. This organism has been predominantly isolated from immunocompromised patients.

There are a few bacteria that grow within amoebae and are closely related phylogenetically based on 16S ribosomal ribonucleic acid (rRNA) gene sequencing to *Legionella* species: LLAPs. Several LLAPs have been assigned to the *Legionella* genus. One LLAP has been isolated from the sputum of a patient with pneumonia after the specimen was incubated with the amoeba *Acanthamoeba polyphaga.* Serologic surveys of patients with community-acquired pneumonia suggest LLAPs may be occasional human pathogens.

Laboratory Diagnosis

Although culture remains the gold standard for the diagnosis of Legionnaires' disease, it is currently diagnosed with a urinary antigen test that is highly accurate for *L. pneumophila* serogroup 1. The use of selective culture media yields a high sensitivity and specificity. Other diagnostic tests, including serotyping and nucleic acid sequencing are used to fully characterize clinical isolates of *Legionella* spp.

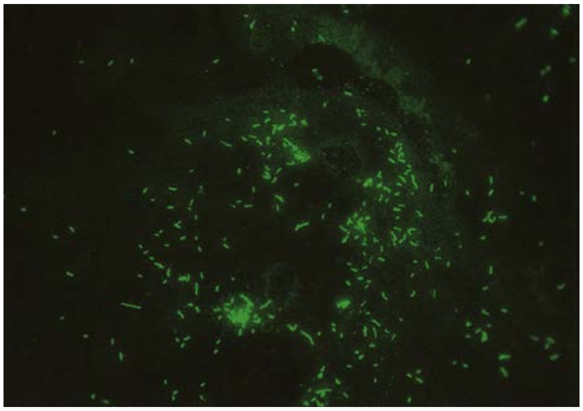
Specimen Collection and Transport

Specimens from which *Legionella* can be isolated include respiratory tract secretions of all types, including expectorated sputum, additional lower respiratory specimens including pleural fluid, bronchoscopy specimens, and lung biopsy specimens. Rare sources associated with infection include other sterile body fluids, such as pericardial fluid and specimens from kidney, liver, spleen, myocardium, respiratory sinuses, skin, soft tissues, wounds, peritoneal fluid, joint fluids, bone marrow, and intestine. Because sputum from patients with Legionnaires' disease is usually nonpurulent and may appear bloody or watery, the grading system used for screening sputum for routine cultures may not be applicable. Patients with Legionnaires' disease usually have detectable numbers of organisms in their respiratory secretions, even for some time after antibiotic therapy has been initiated. If the disease is present, the initial specimen is often likely to be positive. However, additional specimens should be processed if the first specimen is negative, and suspicion of the disease persists. Pleural fluid has not yielded many positive cultures in studies performed in several laboratories, but it may contain organisms and should be processed if available. Urine for antigen collection should be collected in a sterile container. The sample should be transported to the laboratory and refrigerated if a delay in processing occurs. Specimens should be transported without holding media, buffers, or saline, which may inhibit the growth of *Legionella.* The organisms are hardy and are best preserved by maintaining specimens in a small, tightly closed container to prevent desiccation and transporting them to the laboratory within 30 minutes of collection. If a longer delay is anticipated, specimens should be refrigerated. If moisture of the specimens cannot be ensured, 1 mL of sterile broth may be added. Samples collected for *Legionella* spp. nucleic acid testing do not require special collection or processing.

Specimen Processing

All specimens for *Legionella* culture should be handled and processed in a class II biologic safety cabinet (BSC). When specimens from nonsterile body sites are submitted for culture, selective media or treatment of the specimen to reduce the numbers of contaminating organisms is proposed. Brief treatment of sputum specimens with hydrochloric acid before culture has been shown to enhance the recovery of legionellae. However, this technique is time consuming and is recommended for specimens from patients with cystic fibrosis. Respiratory secretions may be held for up to 48 hours at 5°C before culture; if culturing is delayed longer, then the specimen may be frozen.

Tissues are homogenized before smears and cultures are performed, and clear, sterile body fluids are centrifuged for 30 minutes at 4000 × *g*. The sediment is then vortexed and used for culture and smear preparation. Blood for culture of *Legionella* may be processed with the lysis-centrifugation tube system (Isolator, Alere, Inc., Waltham, MA) and plated directly to **buffered charcoal–yeast extract (BCYE) agar.** Specimens collected by bronchoalveolar lavage are quite dilute and therefore should be concentrated at least tenfold by centrifugation before culturing.



• **Fig. 34.2** Fluorescent antibody–stained *Legionella pneumophila.*

Direct Detection Methods

Several laboratory methods are used to detect *Legionella* spp. directly in clinical specimens.

Microscopy

Legionella spp. are small, gram-negative coccobacilli or short rods when directly observed in a clinical specimen. However, in indirect microscopy when examining an isolate from artificial culture media, the organism appears as long, filamentous bacilli. *Legionella* spp. have a thin cell wall and stain poorly in the Gram procedure if neutral red or safranin is used as the counterstain. This characteristic is related to the composition of the cell walls, which have large amounts of branched-chain cellular fatty acids. Because of their faint staining, intracellular form in human tissues and large amounts of proteinaceous material in clinical specimens, *Legionella* spp. are not usually detectable directly in clinical material by Gram stain. The use of 0.1% fuchsin substituted for safranin in the Gram-stain procedure may enhance the visibility of the organisms. Organisms can be observed on histologic examination of tissue sections using silver stains. However, these stains generally lack sensitivity and produce significant artifacts making interpretation highly complex. *L. micdadei* stains with acid-fast stain in fresh and formalin fixed tissue.

Direct immunofluorescent microscopy is the most sensitive and specific method for the detection of *L. pneumophila* in respiratory samples and tissue. The sensitivity of the DFA test ranges from 25% to 75%, and its specificity is greater than 95%. If positive, organisms appear as brightly fluorescent rods (Fig. 34.2). The high complexity of the test and lack of highly reproducible sensitivity discourage many laboratories from offering DFA testing, and it is rarely used except during autopsies.

Antigens

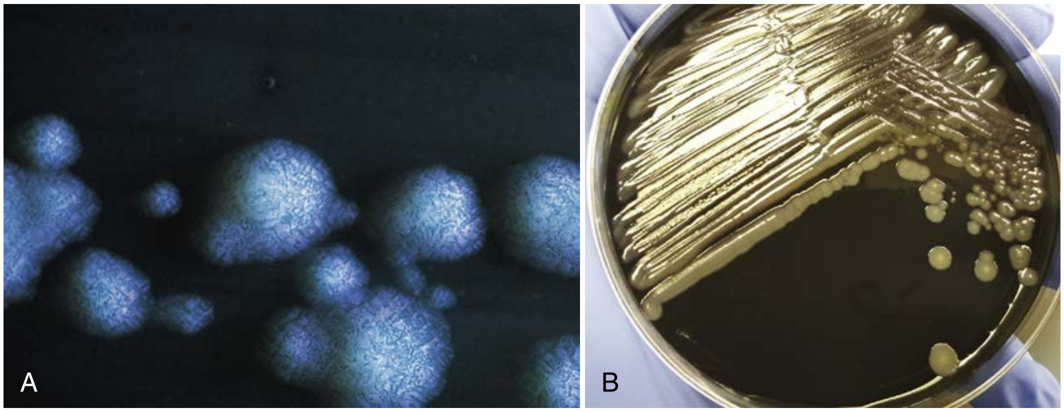
Microtube-based enzyme immunoassay (EIA) methods can be used to serologically diagnose *L. pneumophila* serogroup 1 in tissues. Several EIA serologic diagnostic kits are commercially available, with sensitivity ranging from 80% to 90% and a specificity of about 98%. The sensitivity of kits for testing antibody from other serotypes is still unknown.

Rapid detection of *Legionella* antigen in urine and other body fluids has been accomplished by commercially available EIA kits and by immunochromatography (ICT); however, the ICT have demonstrated up to a 40% decrease in sensitivity compared to the microtube-based immunoassays. Detecting the antigen in urine allows for early diagnosis of the infection. The antigen is detectable in most patients between 1 and 3 days after the onset of symptoms and may persist for some weeks or months. The urine antigen assays are 90% to 99.9% specific, which is similar to the traditional culture method, but may have greater sensitivity than culture. Compared with other diagnostic methods, the advantages of urinary antigen detection are striking. Specimens are easily obtained, the antigen is detectable very early in the course of disease, and the test is rapid and specific. A rapid immunochromatographic assay for detecting *L. pneumophila* serogroup 1 antigen in urine is also available. This assay detects urinary antigen within a very short time and does not require laboratory equipment. Concentration of urine improves the sensitivity of both the EIA and immunochromatographic assays without decreasing their specificity. A drawback of the immunochromatographic urine antigen assay is that it only detects the presence of antigen of *L. pneumophila* serogroup 1, which constitutes 80% to 90% of all *Legionella* infections. In addition, false positives may occur in urine in the presence of rheumatoid-like factors, urinary sediment, and freeze thawing of urine. All positive urine antigen tests should be confirmed. The urine sample should be clarified by brief centrifugation and boiled for 5 to 15 minutes (dependent on protocol) to remove rheumatoid-like factors.

Nucleic Acid Detection

Polymerase chain reaction (PCR) assays have been extensively used to detect deoxyribonucleic acid (DNA) from environmental and clinical samples, particularly those from the respiratory tract. Traditionally, the rRNA (16S and 23S) genes and the macrophage infectivity protein (*mip*) gene have been used for assays targeting the *Legionella* genus and the serogroup 1 target (*wzm*) gene for *L. pneumophila*–specific assays. Assays for *Legionella* and *L. pneumophila* using real-time PCR platforms have also been described. With respiratory samples, *Legionella* PCR has a reported specificity of more than 99% and sensitivity of 80% to 100%. An important feature of *Legionella* PCR is that the method can potentially detect all serogroups of *L. pneumophila* and other species and is therefore useful in the early diagnosis of infections, particularly in health care–associated cases and outbreak investigations.

Although no FDA-cleared nucleic acid–based tests are available in the United States, they are available in Europe. Nucleic acid amplification tests have demonstrated an 11% increase in positive yields over urine antigen testing. This may be a result of the predominance of serogroup I and the Pontiac subgroup in infections. NAAT may also demonstrate improved sensitivity in immunocompromised patients because of the low sensitivity of urine testing in these patients.

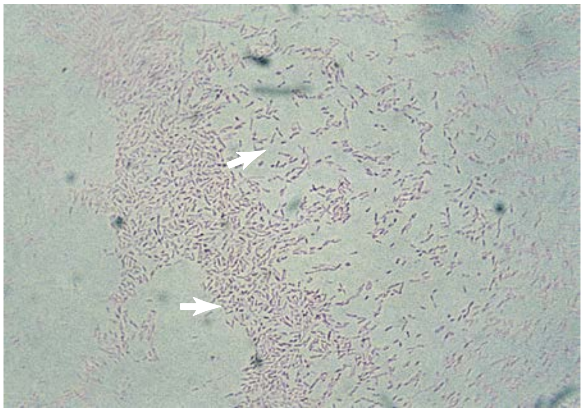


• Fig. 34.3 (A) Colonies of *Legionella pneumophila* demonstrating the cut-glass internal granular speckling. (B) Colonies of *Legionella pneumophila* on buffered charcoal–yeast extract agar demonstrating blue-green glistening. (Photo courtesy Brooks Murillo-Kennedy, Houston, TX.)

Cultivation

The specimen should be processed for cultivation by diluting the specimen 1:10 in tryptic soy broth or distilled water to reduce inhibition by tissue and serum factors or decontamination for sputum and respiratory specimens to remove contaminating and inhibitory normal microbiota. Decontamination to reduce contaminating microbiota in sputum and respiratory samples should be completed using a 1:10 dilution of a low pH KCl-HCl buffer (pH 2.2) and incubating at room temperature for 4 minutes prior to plating. An alternative method for decontamination is heading at 50°C for 30 minutes. Primary isolation of *Legionella* spp. should be carried out by inoculating a nonselective media and two different selective media. Specimens for recovery of *Legionella* should be inoculated to at least one BCYEα agar plate containing L-cysteine and α-ketoglutarate without inhibitory agents. This medium contains charcoal to detoxify the medium, remove carbon dioxide (CO_2), and modify the surface tension to allow the organisms to proliferate more easily. BCYEα is also prepared with ACES buffer (N-[2-Acetoamido]-2-aminoethanesulfonic acid) and the growth supplements cysteine (required by *Legionella*), yeast extract, alpha-ketoglutarate, and iron. Additional selective media, such as the BCYEα with polymyxin B, anisomycin (to inhibit fungi), and cefamandole, is recommended for specimens, such as sputum, that are likely to be contaminated with other human microbiota. Less selective media containing polymyxin B, anisomycin, and vancomycin should be used to isolate *Legionella* spp. other than *L. pneumophila*. *L. micdadei* has been recovered from BCYEα supplemented with bovine serum albumin from a guinea pig spleen, but no data is available for direct culture from human specimens. BCYEα with natamycin, aztreonam, and vancomycin has been used to isolate *L. longbeachae* from environmental samples.

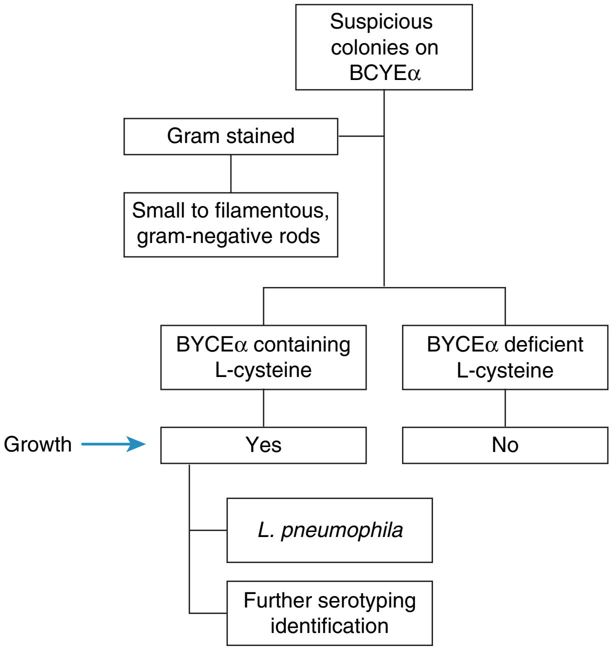
Culture plates are incubated at 35°C to 37°C in a humid atmosphere for up to 14 days and are examined every 3 or 4 days. Even the detection of one or a few colonies is sufficient to confirm the diagnosis. Some *Legionella* spp. may be stimulated by increased 2% to 5% concentration of CO_2, including *Legionella sainthelensi* and *Legionella oakridgensis.* The low level of CO_2 will not prevent the growth of *L. pneumophila.* If this concentration is not possible, incubation in air is preferable to 5% to 10% CO_2, which may inhibit some legionellae, specifically *L. pneumophila.* At 5 days, colonies are 3 to 4 mm in diameter, gray-white to blue-green, glistening, convex, and circular and may exhibit a cut-glass type of internal granular speckling (Fig. 34.3). A Gram stain yields thin, gram-negative bacilli (Fig. 34.4).



• Fig. 34.4 Gram stain of a colony of *Legionella pneumophila* showing thin, gram-negative bacilli *(arrows).*

Approach to Identification

Because *Legionella* spp. are biochemically inert, and many tests produce equivocal results, extensive biochemical testing is of little use. Definitive identification generally requires the facilities of a specialized reference laboratory. Using a long-wave UV light in a dark room, suspect colonies of *L. pneumophila* will appear pale yellow-green with diffusion of the pigment into the medium. It is important to note that some young colonies will not fluoresce. Other species of *Legionella* will fluoresce a brilliant bluish white or a brilliant red. *L. pneumophila* colonies should be Gram stained, using 0.1% fuchsin as the counterstain, to determine whether bacteria are small to filamentous, gram-negative rods. Colonies should be plated to two media, including a BYCEα plate



Suspicious colonies on BCYEα
Gram stained

Further serotyping identification

• **Fig. 34.5** Presumptive identification of *Legionella pneumophila* in culture.

containing L-cysteine and one made without. *L. pneumophila* will only grow on the BYCEα L-cysteine media, providing a more definitive identification. In addition, if only a small amount of growth is present on the primary medium, the growth may be emulsified in sterile water and used for subculturing, staining, and serologic identification. *F. tularensis* is the only other gram-negative bacterium that demonstrates L-cysteine growth dependence; however, the colonial morphology is opaque and homogenous. In addition, some serotyping reagents for *Legionella* spp. will cross-react with *F. tularensis*. Once the isolate has been determined to be L-cysteine dependent, further identification is completed using serotyping. Many different bacteria, including *Bordetella pertussis* have been reported to cross-react with serologic reagents used for the characterization and identification of *Legionella* spp. It is important to correlate all diagnostic testing with cellular and colonial morphology to avoid misidentification of other bacteria as *Legionella* spp. Gram-negative rods that demonstrate the colonial morphology and L-cysteine growth dependency may be presumptively reported as *Legionella* spp. If the organism is reactive in the serogroup 1 typing assay, the organism may be presumptively identified as *L. pneumophila* (Fig. 34.5).

Further identification of isolates can be completed using matrix-assisted laser desorption ionization time-of-flight mass spectrometry (MALDI-TOF MS) or DNA sequencing. MALDI-TOF MS databases include either no *Legionella* spp. or only *L. pneumophila.* This method is unable to distinguish serogroup designations. The research use only database in MALDI-TOF MS systems has been successfully used to identify 80% to 90% of isolates being tested in reference laboratories. Upon completion of sufficient data collection, the MALDI-TOF MS databases may be used to identify the organism upon FDA clearance.

Serodiagnosis

Most patients with legionellosis have been diagnosed retrospectively by detection of a fourfold rise in anti-*Legionella* antibody with an indirect fluorescent antibody (IFA) test. Serum specimens should be tested no closer than 2 weeks apart. Diagnostic efficacy associated with serologic testing increases with the collection and testing of acute and convalescent paired sera. Convalescent sera should be collected at 4, 6, and 12 weeks after the appearance of the disease. Disease is confirmed by a fourfold rise in titer to more than 128. A single serum with a titer of more than 256 and a characteristic clinical picture may be presumptive for legionellosis; however, because as many as 12% of healthy persons yield titers as high as 1:256, this practice is strongly discouraged. Unfortunately, individuals with Legionnaires' disease may not exhibit an increase in serologic titers until as long as 10 weeks after the primary illness, or they may never display significant antibody titer increases. It is essential to correlate serologic findings with the patient's clinical presentation because of the variation in antibody response associated with legionellosis. Most patients will develop a classic IgM, IgG, and IgA response. However, some patients may develop antibodies for a single class (in other words, IgG, IgM, or IgA only). Commercially prepared antigen-impregnated slides for IFA testing are available from numerous suppliers.

Antimicrobial Susceptibility Testing and Therapy

In vitro susceptibility studies are not predictive of clinical response and should not be performed for individual isolates of legionellae. Antimicrobial agents such as quinolones, tetracycline, and the macrolides (e.g., clarithromycin and azithromycin) are active against *L. pneumophila*. Penicillins, cephalosporins of all generations, and aminoglycosides are not effective and should not be used. Low-level resistance to ciprofloxacin was recently identified; however, the clinical significance is unclear. Macrolides and quinolones have also demonstrated effective treatment for infections with *L. micdadei, L. dumoffii,* and *L. longbeachae.*

Prevention

Although under development, a vaccine against *Legionella* infections is not currently available. The effectiveness of other approaches to the prevention of *Legionella* infections, such as the elimination of its presence from cooling towers and potable water, is uncertain.

Legionellosis is a notifiable disease in most industrialized countries. An important piece of information for surveillance of the disease is the history of exposure. The incubation period for legionellosis is normally between 2 and 10 days. Thus, during an outbreak, an exposure history for 2 weeks before the onset of illness should be obtained from the patient. In the presence of a pneumonic illness, a laboratory diagnosis will support clinical suspicion of the infection and help classify the case. Many countries have developed guidelines or regulations for the control of *Legionella* in water systems and for the prevention of legionellosis.

Visit the Evolve site for a complete list of procedures, review questions, and case studies.

CASE STUDY 34.1

A 6-month-old female was diagnosed clinically with pneumonia. She was treated with intramuscular ceftriaxone followed by an oral cephalosporin for 3 days. The next day she was found to be unresponsive and rushed to the hospital. She was afebrile but tachypneic (increased breathing) and tachycardic (increased heart rate); she had an elevated white blood cell (WBC) count predominated with lymphocytes. A bronchoalveolar lavage was collected and was positive for *Legionella* by direct fluorescent antibody. A culture grew *Legionella pneumophila* serogroup 6 after 8 days. Despite appropriate therapy with erythromycin and rifampin, the infant's pulmonary disease was fatal. No underlying disease was found in the baby.

Questions

1. The *Legionella* urine antigen test was negative in this baby. What is the explanation for this finding?
2. The baby appeared to be a normal healthy infant. List as many risk factors as possible for acquiring *Legionella* pneumonia.
3. List the factors that hamper the laboratory diagnosis of *Legionella.*
4. In general, sputum sent to the laboratory to diagnose pneumonia will be purulent with mucus and increased polymorphonuclear WBCs. Describe the type of sputum observed with *Legionella* infection.

ADVANCED CASE STUDY 34.2

A 78-year-old male retired executive presented to the clinic with a 3- to 5-day illness that consisted of a headache and diarrhea. Over-the-counter remedies and hydration were recommended as empiric therapy for viral gastroenteritis. Two days later his wife drove him to the clinic, because the man was too weak to drive. She reported that her husband had become confused and had a high fever for the past 24 hours. In addition, he had developed a dry cough and was complaining of feeling short of breath. The patient has a previous medical history of hypertension and dyslipidemia. He is a former smoker but has no structural lung disease and no history of heart failure.

Physical examination revealed a temperature of 102.5°F, blood pressure of 110/65 mm Hg, a pulse of 110 bpm, a respiratory rate of 26 breaths per minute, and an oxygen saturation of 86%. A lung examination revealed crackles bilaterally in both left and right lungs. There were no signs of heart murmur or cyanosis. The patient had no other significant physical findings. Chest x-ray revealed diffuse pulmonary infiltrates bilaterally. The patient was admitted to the hospital with a provisional diagnosis of pneumonia and potentially H1N1 influenza. The following laboratory results were obtained:

Laboratory Results

Chemistry	Patient	Reference Range
Arterial pH	7.35	7.35–7.45
P_{CO_2} (carbon dioxide partial pressure)	40	35–45 mm Hg
P_{O_2} (oxygen partial pressure)	60	75–85 mm Hg
HCO_3– (bicarbonate)	24	20–25 mmol/L
CRP (C-reactive protein)	12	<1 mg/dL
BNP (B-type natriuretic peptide)	100	9–86 pg/mL (male 75–83 years)
Hematology		
WBC (white blood cells)	14	5–10 × 10^9/L
RBC (red blood cells)	5.11	5–6 × 10^{12}/L
Hgb (hemoglobin)	15.5	13.5–17.5
Hct (hematocrit)	0.46	0.41–0.53 L/L

Chemistry	Patient	Reference Range
Platelets	120	150–400 × 10^9/L
Segmented neutrophils	85%	25%–60%
Lymphocytes	13%	20%–50%
Monocytes	2%	2%–11%
Eosinophils	0%	0%–8%
Basophils	0%	0%–2%

Questions

1. Evaluate the laboratory results as presented. Are there any unusual indicators here or in the patient's history that would signify a predisposition for unusual respiratory infections?
2. What additional laboratory tests would be indicated at this time?

After hospitalization, the patient continued to demonstrate a low sodium level of 120 to 123 mEq/L (reference range 135–145 mEq/L) despite rehydration efforts. His diarrhea and headache resolved by day 6 of his hospitalization, but his hypoxia increased. He was subsequently intubated and placed on mechanical ventilation for respiratory failure and continued to have a markedly elevated temperature of up to 104.3°F despite antibiotic treatment with cefotaxime and azithromycin. Repeat chest x-ray indicated an increase in infiltrates. His antibiotic treatment was broadened to include fungal and anaerobic antimicrobial agents, and the patient was placed in respiratory isolation. The following serologic test results were obtained: Influenza Rapid Antigen Test—negative; TB (tuberculin) skin test—negative; sputum by endotracheal suction for acid-fast bacteria—negative; mycoplasma IgM—<1:16 (negative); *Legionella* Urine Antigen Test—positive.

A diagnosis of *Legionella* pneumonia was made. The azithromycin was maximized to optimal dosing of 500 mg/day, and the additional antibiotic treatment was discontinued.

Eventually the patient was extubated and made a full recovery from the pneumonia.

3. What are the major factors in the patient's clinical history that would point to an atypical pneumonia related to *Legionella pneumophila* infection?

Chapter Review

1. *Legionella* can be spread by all of the following *except:*
   - **a.** Cooling towers
   - **b.** Person-to-person contact
   - **c.** Lakes
   - **d.** Humidifiers
2. All of the following are primary manifestations of Legionnaires' disease *except:*
   - **a.** Trench fever
   - **b.** Pontiac fever
   - **c.** Endocarditis
   - **d.** Pneumonia
3. Which of the following agars should be used for culturing *Legionella*?
   - **a.** CIN
   - **b.** BCYE
   - **c.** SMAC
   - **d.** XLD
4. What is the specimen of choice for isolating *Legionella*?
   - **a.** Stool
   - **b.** Urine
   - **c.** Cerebrospinal fluid (CSF)
   - **d.** Respiratory secretions
5. Which of the following is acceptable for therapy?
   - **a.** Fluoroquinolones
   - **b.** Penicillin
   - **c.** Cephalosporin
   - **d.** Aminoglycosides
6. *Legionella* injects proteins into the host cell by:
   - **a.** Dot/Icm
   - **b.** Viral multiplication
   - **c.** Damaging the epithelial cell lining the blood vessels
   - **d.** Inhibiting the host defense
7. *Legionella* can be definitively diagnosed by a:
   - **a.** Twofold rise in anti-*Legionella* antibody with an IFA
   - **b.** Single serum with a titer of 128
   - **c.** Monoclonal immunofluorescent stain
   - **d.** Gram stain
8. Which of the following is *not* a characteristic of *Legionella*?
   - **a.** Faintly staining, thin, gram-negative bacilli
   - **b.** Requires iron and L-cysteine supplements
   - **c.** Growth enhanced by microaerophilic conditions
   - **d.** Medium buffered to pH 6.9 for optimal growth
9. All of the following are true of *Legionella except:*
   - **a.** Thrives at warmer temperatures
   - **b.** Can survive up to 5 years in water
   - **c.** Has been isolated in rivers and lakes
   - **d.** Is acquired from environmental sources
10. **True or False**

    ______ Humoral immunity plays an important role in the defense against *Legionella.*

    ______ Sputum specimens should be treated with sulfuric acid before culturing.

    ______ Respiratory secretions may be held for 24 hours at room temperature before culturing.

    ______ Specimens collected by bronchial alveolar lavage should be concentrated tenfold before culturing.
11. **Matching:** *Match the correct term with the appropriate description.*

______ Legionnaires'
______ Pontiac fever
______ BCYEα
______ urine Ag test
______ Dot
______ Icm

a. self-limiting, nonfatal respiratory infection
b. defective organelle trafficking
c. intracellular multiplication
d. pneumonic illness
e. agar recommended for *Legionella* isolation
f. rapid detection by EIA

35

Brucella

OBJECTIVES

1. Identify the primary routes of transmission for *Brucella* spp.
2. List the occupations at risk for developing brucellosis.
3. Identify the signs and symptoms associated with brucellosis.
4. State two reasons why the microbiology laboratory should be notified when *Brucella* spp. infection is suspected.
5. Describe the media and incubation requirements to isolate *Brucella* spp.
6. Describe the differential characteristics of *Brucella abortus, Brucella melitensis, Brucella suis,* and *Brucella canis.*
7. Identify the species classified as select agents and discuss the reporting requirements as nationally notifiable conditions with respect to the Laboratory Response Network (LRN).

GENERA AND SPECIES TO BE CONSIDERED

Classified as Select Agents

Brucella abortus
Brucella melitensis
Brucella suis

Other Species

Brucella canis
Brucella ceti
Brucella microti
Brucella neotomae
Brucella ovis
Brucella papionis
Brucella pinnipedialis

The family *Brucellaceae* comprises three genera: *Ochrobactrum* (Chapter 22), *Mycoplana,* and *Brucella. Brucella* spp. are discussed in this chapter. Brucellae are free-living organisms that are subcategorized into 10 recognized species. Eight of the species are terrestrial, and four of those have been associated with human disease: *Brucella abortus* (seven biovars), *Brucella melitensis* (three biovars), *Brucella suis* (five biovars), and *Brucella canis.* Two marine species, *B. ceti* and *B. pinnipedialis*, are also known to cause human disease. Of the four terrestrial species known to cause human infection, all but *B. canis* are considered Category B select agents. Brucellosis is a reportable disease in all 57 states and territories; it is mandatory that disease cases be reported to state and territorial jurisdictions when identified by a health provider, hospital, or laboratory. Reporting requirements vary by jurisdiction. Brucellosis is also a nationally notifiable condition. Notification of brucellosis cases (without direct personal identifiers) to the Centers for Disease Control and Prevention (CDC) by state and territorial jurisdictions is voluntary for nationwide aggregation and monitoring of disease data. Clinical or diagnostic laboratories and other entities that have identified *B. suis*, *B. melitensis*, or *B. abortus* are required to immediately (within 24 hours) notify the CDC Division of Select Agents and Toxins (DSAT) (http://selectagents.gov).

General Characteristics

Brucellae are small, facultative, intracellular, nonmotile, aerobic, gram-negative coccobacilli or short bacilli that stain poorly by conventional Gram stain. Many isolates require supplementary carbon dioxide (CO_2) for growth, especially on primary isolation. *Brucella* spp. are closely related to *Bartonella, Rhizobium,* and *Agrobacterium* spp.

Epidemiology and Pathogenesis

The disease brucellosis occurs worldwide, especially in Mediterranean and Persian Gulf countries, India, and parts of Mexico and Central and South America. The organisms are capable of survival for extended periods (e.g., soil, 10 weeks; aborted fetuses, 11 weeks; bovine stool, 17 weeks; milk and ice cream, 3 weeks); they can survive in fresh cheese for several months. Animals are carriers and do not typically demonstrate symptoms of disease. The most prominent symptom in animals is the infectious abortion of the fetus. **Brucellosis** is a zoonosis and is recognized as a cause of devastating economic loss among domestic livestock.

Each of the *Brucella* spp. that are pathogenic for humans has a limited number of preferred animal hosts (Table 35.1). In the host, *Brucella* spp. tends to localize in tissues rich in erythritol (e.g., placental tissue), a four-carbon alcohol that enhances their growth. Humans become infected by four primary routes:

- Ingestion of infected unpasteurized animal milk products (most common means of transmission)
- Inhalation of infected aerosolized particles (laboratory-acquired infection is the most important source of transmission)

TABLE 35.1 ***Brucella* spp. and Their Respective Natural Animal Hosts**

Organism	Preferred Animal Host
Brucella abortus	Cattle and buffalos
Brucella melitensis	Sheep, goats, or camels
Brucella suis	Swine and a variety of wild animals
Brucella canis	Dogs
Brucella ovis	Rams (not associated with human infection)
Brucella microti	Red foxes (not associated with human infection)
Brucella neotomae	Desert and wood rats (not associated with human infection)
Brucella papionis	Baboons and bull frogs (not associated with human infection)
Brucella pinnipedialis	Marine mammals, seals (rare human infection)
Brucella ceti	Dolphins, cetaceans (rare human infection)

- Direct contact with infected animal parts through ruptures of skin and mucous membranes
- Accidental inoculation of mucous membranes by aerosolization

Rare cases of transmission by blood and bone marrow transplantation and by sexual intercourse, in addition to neonatal brucellosis, have been reported. Individuals considered at risk for contracting brucellosis include dairy farmers, livestock handlers, slaughterhouse employees, veterinarians, and laboratory personnel (public health, medical, and research). The organism has a very low infectious dose (100 organisms or fewer). Mishandling and misidentification of the organism is often associated with laboratory transmission of the organism.

Brucella spp. are facultative, intracellular parasites that are able to exist in both intracellular and extracellular environments. After infecting a host, brucellae are ingested by neutrophils, within which they replicate, causing cell lysis. Neutrophils containing viable organisms circulate in the bloodstream and are subsequently phagocytized by mononuclear phagocytic cells in the spleen, liver, and bone marrow. If the infection goes untreated, granulomas develop in these organs, and the brucellae survive in monocytes and macrophages. Brucellae show a tendency to invade and persist in the human host by inhibiting apoptosis (programmed cell death). Resolution of the infection depends on the host's nutritional and immune status, the size of the inoculum and route of infection, and the *Brucella* species causing the infection; in general, *B. melitensis* and *B. abortus* are more virulent for humans.

Survival and multiplication of *Brucella* in phagocytic cells are features essential to the establishment, development, and chronicity of the disease. *Brucella* spp. can change from a smooth to a rough colonial morphology based on the composition of the cell wall lipopolysaccharide O-side chain (LPS); those with a smooth LPS are more resistant to intracellular killing by neutrophils than those with a rough LPS. The smooth phenotype has been identified in *B. abortus* and *B. melitensis*. Brucellae ensure intracellular survival by interfering with the phagosome-lysosome fusion in macrophages and epithelial cells. In addition, like *Legionella* spp. (Chapter 34), brucellae use a type IV secretion system, VirB, for intracellular survival and replication. Unlike *Legionella* spp., however, brucellae modulate phagosome transport to avoid being delivered to lysosomes. Essentially, VirB is involved in controlling the maturation of the *Brucella* vacuole into an organelle that allows replication. In the mouse model, if nucleic acid mutations occur in this region, *B. abortus* is unable to establish chronic infections. In addition, *Brucella* spp. produce urease, which provides protection during passage through the digestive system when the organism is ingested in food products. Urease breaks down urea, producing ammonia, and neutralizes the gastric pH. Despite our current knowledge, many questions remain about the pathogenesis of disease caused by *Brucella* spp.

Spectrum of Disease

The clinical manifestations of brucellosis vary greatly, ranging from asymptomatic infection to serious, debilitating disease. For the most part, brucellosis is a systemic infection that can involve any organ of the body. Symptoms, which are nonspecific, include fever, chills, weight loss, night sweats, headache, muscle aches, fatigue, and depression. Lymphadenopathy and splenomegaly are common physical findings. After an incubation period of about 2 to 4 weeks, the onset of disease is commonly insidious. Complications can occur, such as arthritis, spondylitis (inflammation of the vertebrae), genital, pulmonary, and renal complications, and endocarditis. Neurobrucellosis occurs in approximately 3% to 5% of infections and can result in mild symptoms such as fever and headache to meningitis, coma, and paralysis. Relapse is considered an important feature of brucellosis; it is associated with delayed initiation of treatment, ineffective antibiotic therapy, and positive blood culture findings during the initial presentation.

Laboratory Diagnosis

Specimen Collection, Transport, and Processing

Samples for the diagnosis and identification of infections associated with *Brucella* spp. may be used for culture, serology, or nucleic acid–based testing. The gold standard for the definitive diagnosis of brucellosis is isolation of the organisms in cultures of blood; bone marrow; cerebrospinal fluid

(CSF); pleural, abdominal, and synovial fluids; urine; spleen or liver abscesses; or other tissues. Bone marrow or blood are considered the best specimens for culture. If processing is delayed, the specimen may be held in the refrigerator. Some research laboratories offer nucleic acid–based testing on blood (serum or whole blood), CSF, and bone marrow specimens for the identification of the organism.

It is essential that the clinical microbiology laboratory be notified whenever brucellosis is suspected:

- To ensure that specimens are cultivated in an appropriate manner for optimal recovery from clinical specimens
- To prevent accidental exposure of laboratory personnel handling the specimens, because *Brucella* spp. are considered category B select agents (specimen labels should indicate that *Brucella* spp. are a potential pathogen). All specimens should be handled using a BS-3 or BSL-2 with BSL-3 precautions.

Blood for culture can be collected routinely (Chapter 67) into most commercially available blood culture bottles and the lysis-centrifugation system (Isolator, Alere, Waltham, MA). For other clinical specimens, no special requirements must be met for collection, transport, or processing.

Within 2 hours of obtaining a high-confidence presumptive or confirmatory result, a Laboratory Response Network (LRN) Laboratory Director or a designee must notify:

- the State Public Health Laboratory Director,
- the State Epidemiologist,
- the Health Officer for the State Public Health Department,
- the CDC Emergency Operations Center (EOC), and
- the FBI Weapons of Mass Destruction (WMD) POC.

For emergency and non-emergency situations, LRN laboratories will submit data for all samples, including positive and negative results related to the event, within 12 hours of obtaining each result. The LRN is a national network of local, state, federal, military, and international public health, food testing, veterinary diagnostic, and environmental testing laboratories that provides laboratory infrastructure and capacity to respond to biological and chemical public health emergencies. More information on the LRN is included in Chapter 79.

Direct Detection Methods

Direct stains of clinical specimens are not particularly useful for the diagnosis of brucellosis.

Nucleic Acid Detection

Conventional and real-time polymerase chain reaction (PCR) assays are reliable and specific means of directly detecting *Brucella* organisms in clinical specimens. Sensitivity varies among assays, ranging from 50% to 100%. This variation is related to the differences in nucleic acid extraction procedures, specimen type, and detection formats. Several gene targets have been used, including a cell surface protein (BCS P31), a periplasmic protein (BP26), 16S ribosomal ribonucleic acid (rRNA), and transposon insertion sequence 711(IS711). Although nucleic acid–based testing can be used for rapid identification, standardization is needed to improve the use in routine laboratories.

Serodiagnosis

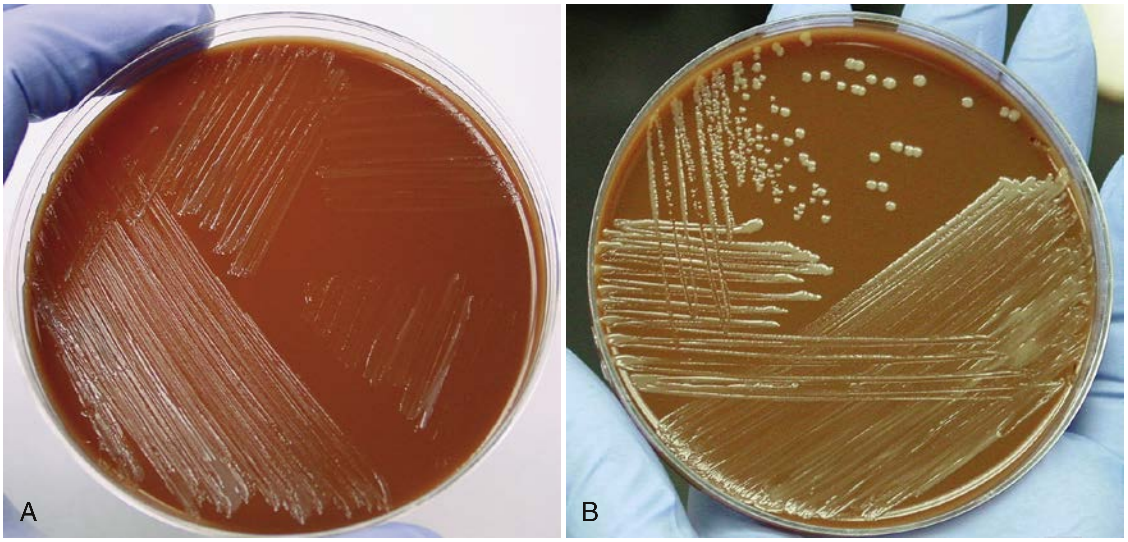
Because isolating brucellae is difficult, a serologic test is widely used (e.g., serum agglutination test [SAT] or microplate agglutination [MAT]). This technique detects antibodies to *B. abortus, B. melitensis,* and *B. suis;* however, the SAT does not detect *B. canis* antibodies. An indirect Coombs test is performed after the SAT. This test detects nonagglutinating or incomplete antibodies in complicated and chronic cases of brucellosis.

The serology associated with *Brucella* infection follows the classic antibody response: IgM appears initially, followed by IgG. A titer of 1:160 or greater in the SAT is considered diagnostic if this result fits the clinical and epidemiologic findings. The SAT can cross-react with class M immunoglobulins with a variety of bacteria, such as *Francisella tularensis* and *Vibrio cholerae.* Enzyme-linked immunosorbent assays (ELISAs) also have been developed. Purified LPS or protein extracts are primarily used in ELISAs. However, currently no reference antigen exists; therefore, it is important to identify the antigen used in the commercial system when evaluating test results. In patients with neurobrucellosis, ELISA offers significant diagnostic advantages over conventional agglutination methods.

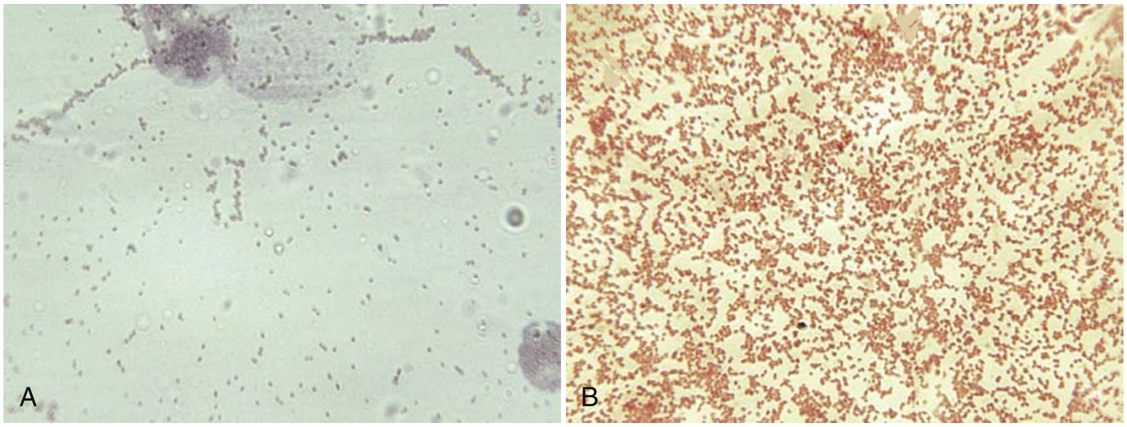
Additional serologic assays are commercially available, including a lateral flow dipstick for screening outbreaks and an immunocapture agglutination method. The immunocapture assay demonstrates sensitivity and specificity similar to a Coombs test and is less cumbersome to perform. The dipstick test has a high degree of sensitivity (>90%). Microarrays that contain numerous antigens are being evaluated for their efficacy in elucidating differential antibody responses from patients during different stages of disease. Serologic testing should be interpreted with care, as methods lack standardization of antigen preparation, methodologies, and detection.

Cultivation

Cultivation and identification of *Brucella* spp. remain the primary method used for laboratory diagnosis of brucellosis. Although most isolates of *Brucella* spp. grow on blood and chocolate agars (some isolates are also able to grow on MacConkey agar), more enriched agars and special incubation conditions generally are needed to achieve optimal recovery of these fastidious organisms from clinical specimens. Brucella agar or infusion base is recommended for specimen types other than blood. The addition of 5% heated horse or rabbit serum enhances growth on all media. Thayer-Martin or Martin-Lewis medium may be used to isolate the organisms from mixed cultures or contaminated specimens. Cultures should be incubated in 5% to 10% CO_2 in



• **Fig. 35.1.** Growth of *Brucella* spp. on chocolate agar after incubation for 2 days (A) and 4 days (B).



• **Fig. 35.2.** *Brucella melitensis* with traditional Gram stain (A) and Gram stain with 2-minute safranin counterstain (B) to allow easier visualization of the organism.

a humidified atmosphere; inoculated plates are incubated for up to 3 weeks before they are considered negative and discarded.

Commercial blood culture systems (e.g., BacT/Alert [bioMérieux, Durham NC], BACTEC [Becton Dickinson, Franklin Lakes, NJ], and lysis-centrifugation systems) all have successfully detected brucellae in blood. Other blood culture bottles, such as those with brain-heart infusion and trypticase soy broth support the growth of brucellae if the bottles are continuously vented and placed in a CO_2 incubator. Most isolates can be detected within 5 to 7 days using commercial systems. Bottles need not be incubated longer than 10 to 14 days. Culture bottles may not become turbid. All subculture plates should be held for a minimum of 10 days.

On culture, colonies appear small, convex, smooth, translucent, gamma-hemolytic, and slightly yellow and opalescent after at least 48 hours of incubation (Fig. 35.1). Rough variants may be seen with *B. canis.* The colonies may become brownish with age.

Approach to Identification

Brucellosis is the most commonly reported laboratory-acquired bacterial infection; therefore, all handling and manipulations of suspected *Brucella* spp. should be performed using BSL-3 precautions in a BSL-2 or higher biologic safety cabinet. Gram stain of the organisms reveals small coccobacilli that resemble fine grains of sand (Fig. 35.2). *Brucella* spp. are catalase and urease positive, and most strains are oxidase positive. *B. canis* may be oxidase variable. Other nonfermentative, urea-positive, oxidase- and catalase-positive, gram-negative coccobacilli that may be confused with brucellae are *Bordetella, Haemophilus, Psychrobacter, Paracoccus, Methylobacterium, Cupriavidus*, and *Oligella* spp. (Table 35.2).

Brucella spp. are differentiated by the rapidity with which the organism hydrolyzes urea, its relative ability to produce hydrogen sulfide (H_2S), its requirements for CO_2, and its susceptibility to the aniline dyes thionine and basic fuchsin (Table 35.3). For determination of the CO_2 requirement, identical plates of *Brucella* agar or brain-heart infusion agar

TABLE 35.2 Characteristics of Organisms That Resemble *Brucella* spp.

should be given equal inocula (e.g., with a calibrated loop) of a broth suspension of the organism to be tested. One plate should be incubated in CO_2 and the other plate in ambient air. Most strains of *B. abortus* do not grow in ambient air but show growth in CO_2. Presumptive identification can be reported based on the colonial morphology and a positive catalase, oxidase, urease, and slide agglutination reaction with specific *B. abortus* or *B. melitensis* antisera. *Brucella* spp. isolates should be sent to state or other reference laboratories for confirmation or definitive identification because most clinical laboratories lack the necessary media and containment facilities required for further analysis.

Subtyping of biovars may be performed using a variety of molecular techniques, including pulsed-field electrophoresis, random amplification of polymorphic DNA, amplified fragment length polymorphism, various PCR techniques, and multilocus DNA target sequence typing.

MALDI-TOF MS is an important and increasingly available tool in clinical microbiology laboratories because it allows a rapid and accurate identification of bacteria. MALDI Biotyper software is a convenient molecular method that can be used for diagnosing brucellosis. This method requires strict culture conditions and sample preparation to ensure correct identification. Accurate identification of *Brucella* species using MALDI-TOF MS has been achieved by constructing a *Brucella* reference library based on multilocus variable-number tandem repeat analysis (MLVA) data. MLVA is a technique that utilizes multiple repeat nucleic acid sequences that are distributed in different variations across an organism's genome. Comparing MS-spectra from *Brucella* species against a custom-made MALDI-TOF MS reference library can be used as a rapid identification method for *Brucella* species. This method was able to identify 99.3% of 152 isolates tested to the species level, and *B. suis* biovar 1 and 2 were identified as the correct biovar. This demonstrates that for *Brucella*, even minimal genomic differences between the biovars translate to specific proteomic differences and clearly identifiable spectra using MALDI-TOF MS.

Antimicrobial Susceptibility Testing and Therapy

Because of the fastidious nature of the brucellae and their intracellular localization, *in vitro* susceptibility testing is not reliable. In addition, the organisms rarely develop antibiotic resistance, and laboratory safety is a consideration. To prevent relapse of infection, patients with brucellosis undergo prolonged treatment (6 weeks) with antimicrobials that can penetrate macrophages and act in the acidic intracellular environment. Clear guidelines for treatment and duration of therapy remain unclear. Combination therapy with two or more antimicrobials results in fewer relapses than using a single antimicrobial. Doxycycline, rifampin, streptomycin, gentamicin, aminoglycosides, or ceftriaxone are some of the antimicrobials that are used to treat brucellosis. In some instances, surgical drainage may also be required to treat the localized foci of infection and prevent the development of disseminated infection.

Prevention

Successful vaccines against *Brucella* infection have been developed for livestock. However, the development of human vaccines has met with serious medical contraindications and low efficacy. The prevention of brucellosis in humans depends on elimination of the disease in domestic livestock as well as heating dairy products and related food to reduce disease transmission.

CASE STUDY 35.1

A 67-year-old female from the Middle East has total arthroplasty of the right knee, and 3 years later the same procedure is performed in the left knee. She seeks medical attention because of pain in her left knee. Her knee is aspirated, and a WBC count of 3.6 × 10^9/L is reported, but no organisms are seen on Gram stain. Coagulase-negative staphylococci are grown from joint fluid cultured in blood culture bottles after 3 days of incubation. A few tiny, poorly staining gram-negative bacilli are present on the direct blood and chocolate agar plates after 5 days of incubation, but not in the blood culture. The bacilli are oxidase and catalase positive. A repeat culture 2 weeks later grows only the gram-negative bacilli. Surgical debridement with appropriate antimicrobial therapy results in control of the infection.

Questions

1. When fastidious, gram-negative coccobacilli are isolated from a normally sterile site, what is the first step that should be taken in the laboratory?
2. What rapid test can expedite the identification of this fastidious coccobacillus? Describe the limitations associated with this method.
3. How did this patient acquire the infection with this organism?
4. How is the diagnosis confirmed?

Chapter Review

1. Organisms belonging to the genus *Brucella* are:
- **a.** Motile
- **b.** Gram-positive bacilli
- **c.** Anaerobic
- **d.** Facultative intracellular

2. Humans become infected with *Brucella* spp. by all of the following means *except:*
- **a.** Direct contact with infected animal parts
- **b.** Ingestion of unpasteurized milk
- **c.** Person-to-person contact
- **d.** Inhalation of infected aerosolized particles.

3. Which *Brucella* species may require CO_2 for growth, is urease positive in 2 hours, and is inhibited by thiamine dye?
- **a.** *B. abortus*
- **b.** *B. melitensis*
- **c.** *B. suis*
- **d.** *B. canis*

4. What titer in the SAT is considered diagnostic and correlates to the clinical findings?
- **a.** 1:1
- **b.** 1:4
- **c.** 1:80
- **d.** 1:160

5. Why should the microbiology laboratory be notified when brucellosis is suspected?
- **a.** It is pathogenic for humans.
- **b.** It is a vaccine-preventable disease.
- **c.** *Brucella* organisms are category B select agents.
- **d.** It is a zoonotic disease.

6. Which of the following *Brucella* spp. is *not* considered a bioterrorism agent?
- **a.** *B. abortus*
- **b.** *B. melitensis*
- **c.** *B. suis*
- **d.** *B. canis*

7. Resolution of a *Brucella* infection depends on what?
- **a.** Host's nutritional and immune status
- **b.** Size of inoculum
- **c.** Route of infection
- **d.** All of the above

8. When a specimen other than blood is tested, which agar is recommended?
- **a.** Blood agar
- **b.** Chocolate agar
- **c.** *Brucella* agar
- **d.** MacConkey agar

9. Which test should be used for screening patients in an outbreak of possible brucellosis?
- **a.** ELISA
- **b.** Laminate flow dipstick
- **c.** Immunocapture agglutination
- **d.** Coombs test

10. True or False

_____ *Brucella* spp. are capable of survival in soil for longer than 2 months.

_____ *Brucella* organisms tend to localize in tissue such as placental tissue.

_____ *B. canis* and *B. suis* are the most virulent species for humans.

_____ Isolation of *Brucella* organisms is a definitive diagnosis of brucellosis.

_____ Most strains of *B. abortus* show equal growth in air and in a candle jar.

11. Matching: *Match each term with the appropriate description.*

_____ facultative intracellular

_____ category B select agent

_____ brucellosis

_____ *Brucella* agar

_____ particle agglutination

_____ unpasteurized animal milk

_____ apoptosis

a. infection with *Brucella* spp.

b. contains additive of horse/rabbit serum

c. rapid test for presumptive *Brucella* infection

d. transmitted primarily by aerosols

e. most common means of *Brucella* transmission

f. can exist in extracellular and intracellular environments

g. programmed cell death

36

Bordetella pertussis, Bordetella parapertussis, and Related Species

OBJECTIVES

1. Describe the general characteristics of the *Bordetella* spp.
2. State the normal habitat and routes of transmission for *Bordetella pertussis* and *Bordetella parapertussis.*
3. Describe the three stages of pertussis, including the duration and symptoms.
4. Describe the proper collection and transport of specimens for the detection of bordetellae.
5. Explain the limitations of nucleic acid-based methods for detecting *B. pertussis,* including assay specificity and sensitivity.
6. Describe the optimal conditions for culturing *B. pertussis,* including specimens of choice for optimal recovery.
7. Outline the major tests used to identify and differentiate *B. pertussis* and *B. parapertussis.*
8. Correlate the patient's signs, symptoms, and laboratory results to identify the etiologic agent associated with infection.

GENERA AND SPECIES TO BE CONSIDERED

Bordetella ansorpii (putative species)
Bordetella avium
Bordetella bronchialis
Bordetella bronchiseptica (Chapter 24)
Bordetella flabilis
Bordetella hinzii
Bordetella holmesii
Bordetella muralis
Bordetella pertussis
Bordetella parapertussis (Chapter 20)
Bordetella petrii
Bordetella pseudohinzii (considered a proposed species)
Bordetella sputigena
Bordetella trematum (Chapter 20)

The genus *Bordetella* includes four primary human pathogens: *B. bronchiseptica, B. holmesii, B. pertussis,* and *B. parapertussis.* Three new species have been identified from human respiratory specimens: *B. bronchialis, B. flabilis,* and *B. sputigena.* These organisms have been identified in patients with cystic fibrosis (CF). *B. bronchiseptica* is reviewed in Chapter 24 because it grows on MacConkey agar. Although *B. parapertussis* and *B. holmesii* can also grow on MacConkey agar, they are discussed here with *B. pertussis* because they are associated with human upper respiratory tract infections, with almost identical symptoms, epidemiology, and therapeutic management. Additional *Bordetella* species may cause rare asymptomatic infections in immunocompromised patients; these include *B. hinzii, B. holmesii, B. petrii, B. trematum,* and *B. ansorpii* (described species that remains putative, not validly named). (See the chapter cross-references in the preceding table for information on organisms not discussed in this chapter.)

General Characteristics

General features of *Bordetella* spp. other than *B. pertussis* and *B. parapertussis* are summarized in Chapter 24. In contrast to *B. bronchiseptica, B. pertussis* and *B. parapertussis* are nonmotile and infect only humans. In the evolutionary process, these exclusive human pathogens have a close genetic relationship. They remain separate species based on their chemotaxonomic differences, pathogenesis, and host range.

Epidemiology and Pathogenesis

Before the introduction of the vaccine (and currently in nonimmunized populations), pertussis (whooping cough) periodically appears as an epidemic disease that cycles approximately every 2 to 5 years. Transmission occurs person-to-person through inhalation of respiratory droplets. Humans are the only known reservoir.

Pertussis is a highly contagious, acute infection of the upper respiratory tract caused primarily by *B. pertussis* and less commonly by *B. parapertussis.* The latter agent generally has a less severe clinical presentation both in duration of symptoms and in the percentage of identified cases. *B. holmesii* causes a pertussis-like illness, but little is known about the biology, virulence mechanisms, and pathogenic significance. Additional species of bordetellae, *B. bronchiseptica, B. petrii, B. avium, B ansorpii*, and *B. hinzii* are rarely isolated from the respiratory secretions of patients with respiratory illness. Pertussis occurs worldwide, with millions of cases reported annually. Although the incidence has decreased significantly since vaccination became widespread, outbreaks of pertussis occur periodically. *B. pertussis* infections appear to be endemic in adults and adolescents because of a natural decrease in immune protection from natural infections and vaccine-induced immunity; these infections may serve as the source of the epidemic cycles involving unvaccinated or partially immunized infants and children. CF patients often present with polymicrobial respiratory infections and may serve as a source for periodic outbreaks. The microbiome of CF patients demonstrates a high degree of variability; however, only six genera, including *Bordetella* spp., are routinely identified from CF specimens.

Pathogenesis

B. pertussis, the primary pathogen of whooping cough, uses several mechanisms to overcome the immune defenses of healthy individuals. The mechanisms are complex and involve the interplay of several virulence factors (Table 36.1). Some factors help establish infection, others are toxigenic to the host, and still others override specific components of the host's mucosal defense system. For example, when *B. pertussis* reaches the host's respiratory tract, the surface adhesins attach to respiratory ciliated epithelial cells and paralyze the beating cilia by producing a tracheal cytotoxin. The organism produces a major virulence factor, pertussis toxin (PT). PT enters the bloodstream, subsequently binding to specific receptors on host cells. After binding, PT disrupts several host cell functions, such as initiation of host cell translation; the inability of host cells to receive signals from the environment causes a generalized toxicity. The center membrane of *B. pertussis* blocks access of the host's lysozyme to the bacterial cell wall via its outer membrane. *B. pertussis* and *B. parapertussis* share two nearly identical virulence control systems encoded by the *bags (Bordetella virulence gene)* and *plrSR* (persistence in the lower respiratory tract) loci that are responsive to variation in environmental conditions. Because of this very complex system, *Bordetella* organisms appear to be able to alter phenotypic expression, enhancing transmission, colonization, and survival.

TABLE 36.1 **Major Virulence Determinants of *Bordetella pertussis***

Function	Factor/Structure
Adhesion (auto transporters)	Fimbriae (FIM), types 2 and 3: Serotype-specific agglutinins for colonization of respiratory mucosa Filamentous hemagglutinin (FHA): Mediates adhesion to the ciliated upper respiratory tract Pertactin (PRN): Mediates eukaryotic cell binding and is highly immunogenic Tracheal colonization factor Brk A[a]
Toxicity	Pertussis toxin (encoded by the ptx gene, an A/B toxin related to cholera toxin): Induces lymphocytosis and suppresses chemotaxis and oxidative responses in neutrophils and macrophages Adenylate cyclase hemolysin: Hemolyzes red cells and activates cyclic adenosine monophosphate, thereby inactivating several types of host immune cells Dermonecrotic toxin (exact role unknown) Tracheal cytotoxin (ciliary dysfunction and damage) Endotoxin (lipopolysaccharide) Type III secretion[b] *Bordetella*-secreted protein regulator (BSPR)[c]
Overcome host defenses	Outer membrane: Inhibits host lysozyme Siderophore production: Prevents host lactoferrin and transferrin from limiting iron

[a] Plays a role in pathogenesis by conferring serum resistance.

[b] This type of secretion allows *Bordetella* organisms to transport proteins directly into host cells; it is required for persistent tracheal colonization.

[c] This transcriptional regulator is involved in mediation of the type III secretion system during iron-starved conditions.

• BOX 36.1 **Factors Known to Affect the Clinical Manifestation of *Bordetella pertussis* Infection**

- Patient's age
- Previous immunization or infection
- Presence of passively acquired antibody
- Antibiotic treatment

Spectrum of Disease

Several factors influence the clinical manifestations of *B. pertussis* (Box 36.1). Classic pertussis is usually a disease of children and can be divided into three symptomatic stages: catarrhal, paroxysmal, and **convalescent.** During the **catarrhal stage,** symptoms are the same as for a mild cold with a runny nose and mild cough; this stage may last several weeks. Episodes of severe and violent coughing increase in number, marking the beginning of the **paroxysmal stage.** As many as 15 to 25 paroxysmal coughing episodes can occur in 24 hours; these are associated with vomiting and with "whooping," which is the result of air rapidly inspired into the lungs past the swollen glottis. Lymphocytosis occurs, although, typically, the patient has no fever and no signs and symptoms of systemic illness. This stage may last 1 to 6 weeks.

In addition to classic pertussis, *B. pertussis* can cause mild illness and asymptomatic infection, primarily in household contacts and in a number of unvaccinated and previously vaccinated children. Since the 1990s, a shift in the age distribution of pertussis cases to adolescence and adults has been observed in highly vaccinated populations. Adults and adolescents are now recognized as a reservoir for transmitting infection to vulnerable infants. Among these immunized individuals, a prolonged cough may be the only manifestation of pertussis; a scratchy throat, other pharyngeal symptoms, and episodes of sweating commonly occur in adults with pertussis. A number of studies have documented that 13% to 32% of adolescents and adults with an illness involving a cough of 6 days' duration or longer have serologic or culture evidence of *B. pertussis* infection. Organisms that may produce pertussis-like symptoms include adenoviruses, respiratory syncytial virus, human parainfluenza viruses, influenza viruses, and *Mycoplasma pneumoniae.*

Other *Bordetella* species have been associated with infection in immunocompromised patients. *B. bronchiseptica, B. holmesii,* and *B. hinzii* produce a pertussis-like respiratory illness. *B. trematum* has been isolated from individuals working with poultry, and *Bordetella ansorpii* has been associated with septicemia.

Laboratory Diagnosis

Specimen Collection, Transport, and Processing

Confirming the diagnosis of pertussis is challenging. Culture, which is most sensitive early in the illness, has been the traditional diagnostic standard for pertussis and shows nearly 100% specificity but varied sensitivity. Organisms may become undetectable by culture 2 weeks after the start of paroxysms. Nasopharyngeal aspirates (vacuum assisted), nasopharyngeal wash (syringe method), or a nasopharyngeal swab (calcium-alginate or Dacron on a wire handle) are acceptable specimens, because *B. pertussis* colonizes the ciliated epithelial cells of upper respiratory tract. Calcium-alginate swabs with aluminum shafts are not recommended for polymerase chain reaction (PCR) because they may inhibit the polymerase enzyme in PCR detection. Flocked swabs may be used but have not been validated for PCR or culture of *B. pertussis.* In addition, cotton swabs may be inhibitory to specimen growth and are not recommended. If possible, two nasopharyngeal swabs should be collected, one from each nostril. Specimens obtained from the throat, sputum, or anterior nose are unacceptable because these sites are not lined with ciliated epithelium. For collection, the swab is bent to conform to the nasal passage and held against the posterior aspect of the nasopharynx. If coughing does not occur, another swab is inserted into the other nostril to initiate the cough. The swab is left in place during the entire cough, removed, and immediately inoculated onto a selective medium at the bedside (Table 36.2) or placed in appropriate transport media. Samples should be collected before the administration of antibiotics.

Transport time is critical and should not exceed 48 hours. *B. pertussis* and *B. parapertussis* are highly sensitive to metabolites and other toxic substances present in microbiological media, requiring special fluid transport media. Half-strength Regan-Lowe agar enhances recovery when used as a transport and enrichment medium. Cold casein hydrolysate medium and casamino acid broth (available commercially) have proved to be effective transport media, particularly for the preparation of slides for direct fluorescent antibody staining. Dry swabs may be transported in ambient air for PCR testing.

TABLE 36.2 **Examples of Selective Media for Primary Isolation of *Bordetella pertussis* and *Bordetella parapertussis***

Agar Media	Description
Bordet-Gengou	Potato infusion agar with glycerol and sheep blood with methicillin or cephalexin[a] (short shelf-life)
Regan-Lowe[b]	Charcoal agar with 10% horse blood and cephalexin (4- to 8-week shelf-life)
Stainer-Scholte	Synthetic agar lacking blood products

[a] Cephalexin is superior to methicillin and penicillin for inhibiting normal respiratory flora.
[b] Regan-Lowe agar has been found to work best for recovery of *B. pertussis* from nasopharyngeal swabs.

Direct Detection Methods

Because of the limitations associated with culture and serologic diagnostic methods, significant effort has been put into developing nucleic acid amplification methods. Nucleic acid-based diagnostic tests for the direct detection of *B. pertussis* and *B. parapertussis* genes by various PCR procedures, including real-time PCR, have replaced DFA in the clinical laboratory. These assays have a diagnostic sensitivity at least comparable (and in most cases superior) to that of culture. Sensitivity of the assays appears to decrease with the duration of the cough, but they may be useful in diagnosis for up to 4 to 6 weeks. A word of caution: Positive results have been obtained with samples containing *B. holmesii* and *B. bronchiseptica* (Chapter 24) depending on the sequence targeted in conventional and real-time PCR assays. Most laboratories use transposon insertion sequence IS481 for *B. pertussis* and IS1001 for *B. parapertussis*; however, strains of *B. holmesii, B. parapertussis,* and *B. bronchiseptica* that carry IS481 have been identified, and thus, careful interpretation of results and correlation with the clinical presentation are required. The addition of transposon insertion sequence IS1002, which is closely related to IS481, and *recA* significantly improves the specificity of the nucleic acid amplification and species identification. (Table 36.3). Additional PCR assays are available for the detection of the PT promoter, PT, *recA*, filamentous hemagglutinin and the porin genes. However, because these are single-copy genes and not multicopy insertion sequences, assay sensitivity is reduced. Nasopharyngeal swabs (rayon or Dacron swabs on plastic shafts) and aspirates are the two types of samples primarily used for pertussis PCR; calcium-alginate swabs are unacceptable, as previously mentioned, because they inhibit PCR-based detection.

TABLE 36.3 **Sequences Used to Differentiate *Bordetella* spp.**

Organism	IS481	IS1001	IS1002	*RecA*

• **Fig. 36.1** Growth of *Bordetella pertussis* on Regan-Lowe agar.

Cultivation

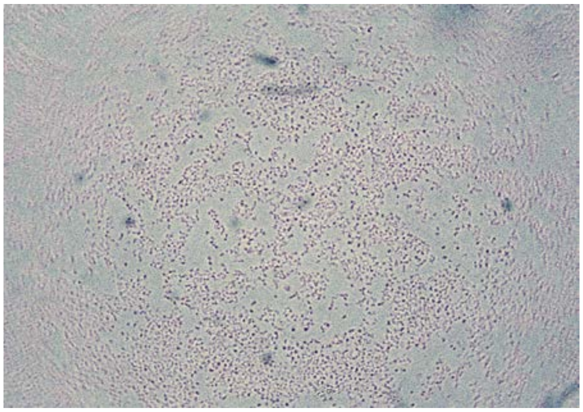
Cultivation is generally 100% specific; however, it has been replaced with PCR in most laboratories for routine diagnosis. Plates are incubated at 35°C in a humidified atmosphere without elevated carbon dioxide for up to 12 days. Most isolates are detected in 3 to 7 days; *B. parapertussis* appears in 2 to 3 days. Colony morphology is not distinct for the identification of other *Bordetella* spp.

Regan-Lowe agar, Bordet-Gengou agar, and Stainer-Scholte synthetic medium are suitable culture media. Regan-Lowe agar contains beef extract, starch, casein digest, and charcoal supplemented with horse blood. Bordet-Gengou agar is a potato fusion base containing glycerol and either sheep or horse blood. Most media contain cephalexin as an additive for suppression of contaminating organisms. Young colonies of *B. pertussis* and *B. parapertussis* are small and shiny, resembling mercury drops; colonies become whitish gray with age (Fig. 36.1).

Sensitivity of culture approaches 100% in the best of hands and depends on the stage of illness at the time of specimen collection, the technique used for specimen collection, specimen adequacy and transport, and culture conditions.

Approach to Identification

A Gram stain of the organism reveals minute, faintly staining coccobacilli singly or in pairs (Fig. 36.2). Use of a 2-minute safranin "O" counterstain or a 0.2% aqueous basic fuchsin counterstain enhances their visibility. *Bordetella* spp. characteristics are presented in Table 36.4. Whole-cell agglutination reactions in specific antiserum can be used for species identification. 16S rRNA gene sequencing or ribotyping and matrix-assisted laser desorption ionization time-of-flight mass spectrometry (MALDI-TOF MS) are often used to identify these organisms.



• **Fig. 36.2** Typical Gram stain appearance of *Bordetella pertussis*.

Serodiagnosis

Although several serologic tests are available for the diagnosis of pertussis, including agglutination and enzyme immunoassay, the enzyme-linked immunosorbent assay (ELISA) or bead-based assays are recommended for serologic diagnosis at this time.

The current most reliable serologic test available for diagnosis is an anti-PT (antibody to pertussis toxin) ELISA that has been used with acute and paired convalescent sera successfully in older children, adolescents, and adults. A titer greater than 100 to 125 IU/mL has been reported as a reliable indicator of exposure of patients to PT-producing bacteria. Serological assays cannot distinguish infection versus vaccine-induced immunity for *B. pertussis* and is unable to detect infection with *B. parapertussis.*

Antimicrobial Susceptibility Testing and Therapy

Laboratories currently do not perform routine susceptibility testing of *B. pertussis* and *B. parapertussis* because the organisms remain susceptible to some penicillins or the macrolides (clarithromycin, azithromycin), ketolides, quinolones, and other antibiotics, such as tetracyclines, chloramphenicol, and trimethoprim-sulfamethoxazole. Three erythromycin-resistant isolates of *B. pertussis* have been discovered; therefore, continued surveillance of *B. pertussis* is advised. Both *B. pertussis* and *B. parapertussis* are resistant to most oral cephalosporins and *B. bronchiseptica* is resistant to many penicillins, cephalosporins, and trimethoprim-sulfamethoxazole. Routine antimicrobial susceptibility testing for *Bordetella pertussis* and *B. parapertussis* is not recommended due to the lack of standardization; however, testing for other *Bordetella* isolates should be reported based on the laboratories' procedures for other fastidious gram-negative bacilli.

TABLE 36.4 **Characteristics That Differentiate the Major Isolates of *Bordetella* spp.**

Characteristic	*B. hinzii*	*B. holmesii*	*B. pertussis*	*B. parapertussis*	*B. bronchiseptica*
Oxidase	+	(+)	+	–	+
Motility	+	–	–	–	+
Nitrate	–	–	–	–	+
Urease	–	–	–	+ (24 h)	+ (4 h)
Growth					
Regan-Lowe agar	ND	2–3 days	3–4 days	2–3 days	1–2 days
Blood agar	–	+	–	+	+
MacConkey agar	+	(+)	–	–	+

ND, not determined; (+), <10% positive.

Prevention

Whole-cell vaccines to prevent pertussis, made from various *B. pertussis* preparations, are manufactured in many countries and are efficacious in controlling epidemic pertussis. As recommended by the Centers for Disease Control and Prevention (CDC), the United States uses three different formulas for diphtheria, tetanus, and pertussis vaccines. Children should receive five doses of DTaP vaccine before they are 6 years of age. Adolescents between 11 and 12 years of age, and adults, who have never received the vaccine, should receive a single dose of Tdap. Expectant mothers should receive a Tdap during pregnancy between 27 and 36 weeks. This should also be given to any children 7 to 10 years of age who are not fully immunized against pertussis. Capital letters in the vaccine indicate full strength doses of the vaccine components (D) diphtheria, (T) tetanus, and (P) pertussis. Lowercase letters indicate reduced doses that are used in adolescent and adult formulations. The lowercase *a* indicates that the pertussis component is acellular or simply a part of the organism. Td vaccine can be given as a booster for adults every 10 years. Prompt recognition of clinical cases and treatment of contacts and cases are also very important in preventing the transmission of *B. pertussis* and *B. parapertussis;* viable organisms can be recovered from untreated patients for 3 weeks after the onset of cough. To prevent nosocomial outbreaks, patients with suspected or confirmed pertussis should be placed on droplet precautions.

Visit the Evolve site for a complete list of procedures, review questions, and case studies.

CASE STUDY 36.1

A 36-year-old female surgeon is discharged from hospital after an uncomplicated delivery of a healthy second child. Three days after arriving home, she awakes with a fever, malaise, and nonproductive cough. An induced sputum specimen grows *Pseudomonas aeruginosa.* She is admitted to the hospital and treated with ceftazidime and tobramycin. Her white blood cell count on admission is 13,500/mm^3, and scattered, coarse rhonchi are heard on deep inspiration. The rest of the family is in good health. The Infectious Disease Service (IDS) does not believe that the patient has *Pseudomonas* pneumonia and suggests that a nasopharyngeal aspirate be collected for *Bordetella pertussis* PCR, even though the patient is feeling better. The laboratory performs the test, and the result is positive. Subsequent culture on Regan-Lowe medium is positive for the organism (Fig. 36.1).

Questions

1 Why was the IDS so interested in having the diagnosis correct in a patient whose disease was improving?
2 Pertussis in young and older adults is underdiagnosed. What are some of the reasons?
3 Why is the pertussis PCR assay so sensitive?
4 What biochemical tests uniquely identify *B. pertussis?*

Chapter Review

1. The primary pathogen of whooping cough is:
- **a.** *B. bronchiseptica*
- **b.** *B. holmesii*
- **c.** *B. pertussis*
- **d.** *B. parapertussis*

2. What is the specimen of choice for culturing *B. pertussis*?
- **a.** Throat
- **b.** Nasopharyngeal swab
- **c.** Sputum
- **d.** Anterior nose

3. Which selective media should *not* be used for primary isolation of *B. pertussis*?
- **a.** Bordet-Gengou
- **b.** Modified Jones-Kendrick charcoal
- **c.** Regan-Lowe
- **d.** Buffered charcoal yeast extract agar

4. Which specimen is *not* acceptable for *B. pertussis* nucleic acid amplified testing?
- **a.** NP rayon swab
- **b.** NP Dacron swab
- **c.** NP calcium-alginate swab
- **d.** NP aspirate

5. Pertussis cultures:
- **a.** Can be considered negative after 3 days of incubation
- **b.** Should be incubated in CO_2
- **c.** Resemble mercury droplets
- **d.** Should be incubated at room temperature

6. A PCR sample for *B. pertussis* tests positive for IS1001 from an NP sample. The technologist should:
- **a.** Repeat the test
- **b.** Confirm with serology (ELISA-specific test)
- **c.** Report as positive
- **d.** Collect a new specimen

7. An NP sample for *B. pertussis* is IS481, IS1001 positive in the PCR assay. The technologist should:
- **a.** Repeat the test
- **b.** Confirm with serology (ELISA-specific test)
- **c.** Report as positive
- **d.** Collect a new specimen

8. The most reliable serologic test for the diagnosis of *B. pertussis* in adults and adolescents is:
- **a.** Complement fixation
- **b.** Agglutination
- **c.** Anti-PT ELISA
- **d.** Enzyme immunoassay (EIA)

9. An organism is cultured on Bordet-Gengou agar and grown at 35°C in a humid atmosphere. The organism is detected at 72 hours. This organism is most likely:
- **a.** *B. pertussis*
- **b.** *B. parapertussis*
- **c.** *B. holmesii*
- **d.** More information is required.

10. Which of the following is *not* an effective transport medium for *Bordetella* spp. when the specimen will be sent overnight to a reference laboratory?
- **a.** Cold casein hydrolysate
- **b.** Half-strength Regan-Lowe agar
- **c.** Fluid-transport medium
- **d.** Dry swab in air for PCR testing

11. True or False

_____ *B. pertussis* infections are endemic as a result of waning natural infection and vaccine-induced immunity.

_____ *B. pertussis* organisms paralyze the cilia with tracheal cytotoxins.

_____ *Bordetella* organisms are detectable by culture for up to 2 months after the start of paroxysms.

_____ Any adult who has never received a Tdap, should be vaccinated with DTap.

_____ *B. holmesii* has been cultured in individuals working with poultry.

12. Matching: *Match each term with the appropriate description.*

_____ whooping cough	a. decreasing severity of coughing spells
_____ catarrhal stage	b. severe and violent cough
_____ paroxysmal stage	c. potato infusion agar
_____ convalescent stage	d. charcoal agar
_____ Regan-Lowe	e. classic pertussis
_____ Bordet-Gengou	f. pertussis toxin
_____ PT	g. mild cold, runny nose

37

Francisella

OBJECTIVES

1. List the media of choice for optimal recovery and cultivation of *Francisella tularensis*.
2. Describe the optimal incubation conditions for *F. tularensis*.
3. Describe the normal habitat and mode of transmission of *Francisella* spp.
4. Describe the symptoms of tularemia, and differentiate the various clinical presentations, including ulceroglandular, glandular, oculoglandular, oropharyngeal, systemic (typhoidal), and pneumonic tularemia.
5. Describe the clinical presentations that can be associated with non-*tularensis Francisellaceae*.
6. Differentiate *F. tularensis* from other potential biothreat agents with similar clinical findings.

GENERA AND SPECIES TO BE CONSIDERED

Francisella tularensis
    subsp. *tularensis* (type A)
    subsp. *holarctica* (type B)
    subsp. *mediasiatica*
Francisella halioticida
Francisella hispaniensis
Francisella noatunensis
Francisella novicida
Francisella persica
Francisella philomiragia

The family *Francisellaceae* includes two genera, *Francisella* and *Allofrancisella. Allofrancisella* spp. are environmental organisms that are not associated with disease. *Francisella tularensis* is the cause of tularemia, an acute fatal illness that affects animals and humans. Additional species of *Francisella* cause opportunistic infections in immunocompromised patients.

Tularemia is a reportable disease in all 57 states and territories; it is mandatory that disease cases be reported to state and territorial jurisdictions when identified by a health provider, hospital, or laboratory. Reporting requirements vary by jurisdiction. Tularemia is also a nationally notifiable condition. Notification of cases of tularemia (without direct personal identifiers) to the Centers for Disease Control and Prevention (CDC) by state and territorial jurisdictions is voluntary for nationwide aggregation and monitoring of disease data. Clinical or diagnostic laboratories and other entities that have identified *F. tularensis* are required to immediately (within 24 hours) notify the CDC Division of Select Agents and Toxins (DSAT). http://selectagents.gov.

Francisella organisms are facultative, intracellular pathogens that require cysteine, cystine, or another sulfhydryl and a source of iron for enhanced growth. This indicates that the organisms require a complex medium for isolation and growth.

General Characteristics

Organisms belonging to the genus *Francisella* are faintly staining, tiny, gram-negative coccobacilli that are oxidase- and urease-negative, weakly catalase-positive, nonmotile, non–spore forming, strict aerobes (*F. philomiragia* and *F. hispaniensis* are oxidase-positive). Current members of the species *F. tularensis* share greater than 99% identity based on 16S ribosomal ribonucleic acid (rRNA) sequence analysis. However, the range of deoxyribonucleic acid (DNA) relatedness in the remaining species varies from 39% to 97%. The most current taxonomy and clinical spectrum of disease is summarized in Table 37.1. For the most part, different subspecies are associated with different geographic regions.

Epidemiology and Pathogenesis

Francisellaceae is widely distributed throughout the environment. *F. tularensis* is the agent of human and animal tularemia. Tularemia is caused by two subspecies, *F. tularensis* subsp. *tularensis* (type A) and *F. tularensis* subsp. *holarctica* (type B). *Francisella novicida* and *F. philomiragia* are present in the environment and are opportunistic human pathogens, with infection occurring in either immunocompromised or patients with a recent history of dry drowning or near drowning. *F. hispaniensis* has been identified associated with a bacteremia in a small number of cases. Worldwide in distribution, *F. tularensis* is carried by many species of wild rodents, rabbits, beavers, and muskrats in North America. Humans become infected by handling the carcasses or skin of infected animals, by inhaling infective aerosols or ingesting contaminated freshwater, through insect vectors (primarily deerflies and ticks in the United States), and by being bitten by carnivores that have themselves eaten infected animals. Some francisellae persist in waterways, and transmission of *F. novicida* and *F. philomiragia* is associated with contact or inhalation of saltwater or brackish water, including near drowning victims. Rare cases of infection in immunocompromised patients with *F. hispaniensis* have been associated with exposure to brackish or saltwater.

Most cases in the United States are sporadic, occurring during the summer months in the states of South Dakota, Arkansas, Missouri, and Oklahoma.

The capsule of *F. tularensis* appears to be a necessary component for expression of full virulence, allowing the organism to avoid immediate destruction by polymorphonuclear neutrophils (PMNS). In addition to being extremely invasive, *F. tularensis* is an intracellular parasite that can survive in the cells of the reticuloendothelial system, where it resides after a bacteremic phase. Granulomatous lesions may develop in various organs. The genome of *F. tularensis* includes a pathogenicity island that encodes 18 genes involved in the virulence of the organism including an atypical type VI secretion system (T6SS) that is required for intracellular growth. The T6SS attaches to the outer membrane of cells and is anchored to the cell with a baseplate attached to the membrane complex. The T6SS then ejects effector molecules into the target cell, which allows the organism to enter the cell, escape the phagosome, and replicate in the cell. Fewer than 50 organisms are required to infect humans through either aerosol or cutaneous routes. *F. tularensis* subsp. *tularensis* is the most virulent for humans, with an infectious dose of less than 10 colony-forming units. *F. philomiragia* has been isolated from several patients, many of whom were immunocompromised or victims of near-drowning incidents. The organism is present in animals and ground water.

Spectrum of Disease

The disease associated with *F. tularensis,* **tularemia,** is recognized worldwide. In the United States the clinical

TABLE 37.1 Most Recent Taxonomy of the Genus *Francisella* and Key Characteristics

Organism	Primary Region	Disease in Humans	Requires Cystine/Cysteine
Francisella tularensis subsp. *tularensis* (type A)	North America (United States and Canada)	Most severe: Tularemia (all forms, see Table 37.2)	+
Francisella tularensis subsp. *holarctica* (type B)	Europe, former Soviet Union, Japan, North America	Moderate to severe: Tularemia (all forms)	+
Francisella novicida	North America, Thailand, and Australia	Mild illness; virulent in immunocompromised patients	–
Francisella philomiragia	North America, Turkey, Switzerland, and Australia	Rare, mild illness; virulent in immunocompromised individuals	–
Francisella hispaniensis	United States and Spain	Rare disease in humans	+

TABLE 37.2 Clinical Manifestations of *Francisella tularensis* Infection

Types of Infection	Clinical Manifestations and Description	Recommended Specimen Type Based on Clinical Manifestation
Ulceroglandular	Common; ulcer and lymphadenopathy; rarely fatal	Whole blood; serum; swabs from visible lesions; aspirates from lymph nodes or lesions
Glandular	Common; lymphadenopathy; rarely fatal	Whole blood; serum; aspirates from lymph nodes or lesions
Oculoglandular	Conjunctivitis, lymphadenopathy	Whole blood; serum; swabs from visible lesions; aspirates from lymph nodes or lesions
Oropharyngeal	Ulceration in the oropharynx	Whole blood; serum; pharyngeal swabs, bronchial/tracheal washes or aspirates, sputum, transthoracic lung aspirates, and pleural fluid
Systemic (typhoidal) tularemia	Acute illness with septicemia; 30%–60% mortality rate; no ulcer or lymphadenopathy	Whole blood; serum; pharyngeal swabs, bronchial/tracheal washes or aspirates, sputum, transthoracic lung aspirates, and pleural fluid
Pneumonic tularemia	Acquired by inhalation of infectious aerosols or by dissemination from the bloodstream; pneumonia; most serious form of tularemia	Whole blood; serum; pharyngeal swabs, bronchial/tracheal washes or aspirates, sputum, transthoracic lung aspirates, and pleural fluid

manifestations have been referred to as **rabbit fever, deer fly fever**, glandular type of tick fever, Ohara's or yatobyo disease, water rat trappers' disease, and **market men's disease.** The clinical manifestation depends on the mode of transmission, the virulence of the infecting organism, the immune status of the host, and the length of time from infection to diagnosis and treatment. The typical clinical presentation after inoculation of *F. tularensis* through abrasions in the skin or by arthropod bites includes the development of a lesion at the site and progresses to an ulcer; lymph nodes adjacent to the site of inoculation become enlarged and often necrotic. Once the organism enters the bloodstream, patients become systemically ill with high temperature, chills, headache, and generalized aching. Clinical manifestations of infection with *F. tularensis* range from mild and self-limiting to fatal; they include glandular, ulceroglandular, oculoglandular, oropharyngeal, systemic, and pneumonic forms. These clinical presentations are summarized in Table 37.2.

Laboratory Diagnosis

The United States classifies *F. tularensis* as a Tier 1 select agent. Any laboratory receiving or maintaining the organism must register with the Federal Select Agent program (http://www.selectagents.gov). Diagnostic laboratories are exempt from registration under the condition that the organism and all infectious materials are properly disposed of or transferred within 7 days of identification. *F. tularensis* is a Biosafety Level 2 pathogen, a designation that requires technologists to wear gloves and to work in a biologic safety cabinet (BSC) when handling clinical material that potentially harbors this agent. The organism is designated Biosafety Level 3 when the laboratorian is working with cultures; therefore, a mask is recommended for the handling of all clinical specimens and is very important for preventing aerosol acquisition of *F. tularensis.* Because tularemia is one of the most common laboratory-acquired infections, most microbiologists do not attempt to work with infectious material from suspected patients. Specimens should be analyzed in reference laboratories, state, or other public health laboratories that are equipped to handle *Francisella* spp.

Specimen Collection, Transport, and Processing

The most common specimens submitted to the laboratory are scrapings from infected ulcers, lymph node biopsies, and respiratory samples, including sputum, pharyngeal swabs, bronchial or tracheal washes or aspirates, and pleural fluid. Whole blood is an acceptable specimen for all types of tularemia; however, false-negative results may occur during early stages of disease. Serum is generally collected from all patients early in disease and during convalescence. The blood should be separated from the serum as soon as possible, preferably within 24 hours. The serum may be stored at 2°C to 8°C for up to 10 days. If long-term storage is required, the serum may be frozen. To minimize the loss of viable organisms, samples should be transported to the laboratory within 24 hours. If specimens are held longer than 24 hours, they should be refrigerated in Amie's transport medium. *F. tularensis* should remain viable for up to 7 days stored at ambient temperature in Amie's medium. Swab specimens should be placed in Amie's transport media containing charcoal. Specimens for molecular testing may be placed in guanidine isothiocyanate buffer for up to 1 month.

Specimen collection for the identification of *F. tularensis* is highly dependent on the type of clinical manifestation. A detailed description of the recommended type of specimen associated with the patient's clinical presentation is included in Table 37.3. In light of concerns about bioterrorism, laboratories must keep in mind that isolation of *F. tularensis* from blood cultures might be considered a potential bioterrorist attack; *F. tularensis* is considered one of the Select Biological Agents of Human Disease (Chapter 79).

TABLE 37.3 Characteristics of Organisms That Resemble *Francisella* sp.

	Acinetobacter spp.	*Bartonella* spp.	*Brucella* spp.[a]	*Francisella* spp.	*Haemophilus* spp.[b]	*Pasteurella multocida*	*Yersinia pestis*
Gram-stain morphology	Broad coccobacilli	Thin bacilli	Tiny coccobacilli	Very tiny coccobacilli	Small coccobacilli	Small coccobacilli	Small bacilli
Oxidase	–	–	+	–	V	+	–
Urease			+		V		

+, ≥90% positive; –, less than or equal to 10% positive; *V*, variable (11%–89% positive).

[a] Growth of some strains is enhanced by the presence of hemin (X factor).

[b] Requires hemin (X factor) and NAD (V factor) or NAD only for growth.

Modified from Caroll KC, Pfaller MA. *Manual of Clinical Microbiology*. 12th ed. Washington, DC: ASM Press; 2019.

Direct Detection Methods

Gram staining of clinical material is of little use with primary specimens unless the concentration of organisms is high, as in swabs from wounds or ulcers, tissues, and respiratory aspirates. The organisms tend to counterstain poorly with safranin. Replacing safranin with basic fuchsin may enhance identification. The organisms appear as tiny, single, and pleomorphic gram-negative rods. Gram staining may be of little diagnostic use. Fluorescent antibody stains and immunohistochemical stains are commercially available for direct detection of the organism in lesion smears and tissues and are typically available in reference laboratories.

Nucleic Acid Detection

Conventional and real-time polymerase chain reaction (PCR) assays have been developed to detect *F. tularensis* directly in clinical specimens. Of significance, several patients with clinically suspected tularemia with negative serology and culture had detectable DNA by PCR. PCR or the *tul4* gene, which is unique to *Francisella* spp., demonstrates a sensitivity of approximately 75%. Real-time PCR assays are available in the Laboratory Response Network (LRN) throughout the United States. These assays target multiple genes from the organisms, including the *tul4, iglC, fopA,* and *ISFtu2* elements. PCR assays are limited by the inability to discriminate between *F. tularensis* and *F. novicida.* Gene sequencing of 16s rRNA does not sufficiently differentiate the two species but does identify the organism to the genus level.

A high-throughput nucleic acid based test Biothreat Panel (BT) has been FDA cleared using the BioFire FilmArray system (BioFire Diagnostics, Salt Lake City, UT) for the detection of potential biothreat agents in environmental samples, but has not been approved for clinical diagnostic use. The BT panel tests for 16 pathogens and 26 targets, including two targets for *F. tularensis.*

Serodiagnosis

Because of the risk of infection to laboratory personnel and other inherent difficulties with culture, diagnosis of tularemia is usually accomplished serologically by whole-cell agglutination (febrile agglutinins or newer enzyme-linked immunosorbent assay techniques). Serum antibody detection is useful for all forms of tularemia. After the initial specimen, a convalescent sample should be collected at 14 days and preferably up to 3 to 4 weeks after the appearance of symptoms. A fourfold difference in titers in acute versus convalescent phase serum samples, in conjunction with one additional positive diagnostic test, such as culture or molecular tests, is considered a presumptive diagnosis for tularemia. However, clinical management or monitoring treatment is of little use in cases of tularemia. Patients who present with acute illness may produce all three major diagnostic antibodies—IgM, IgA, and IgG—simultaneously. In addition, antibodies may persist for 10 years.

Cultivation

Isolation of *F. tularensis* is difficult. The organism is strictly aerobic and is enhanced by enriched media containing sulfhydryl compounds (cysteine, cystine, thiosulfate, or IsoVitaleX) for primary isolation. Two commercial media for cultivation of the organism are available: glucose cystine agar (BBL; Microbiology Systems, Sparks, Maryland) and cystine-heart agar (Beckton Dickinson, Franklin Lakes, New Jersey, BBL); both require the addition of 5% sheep or rabbit blood. *F. tularensis* may grow on chocolate agar supplemented with IsoVitaleX, the nonselective buffered charcoal-yeast extract agar (BCYE) used for isolation of legionellae, or in modified Mueller-Hinton broth and tryptic soy broth supplemented with 1% to 2% IsoVitaleX. Growth is not enhanced by carbon dioxide. All species grow at 35°C to 37°C, with the exception of *F. noatunensis,* which has an optimal growth temperature of 22°C and demonstrates no growth at 37°C.

These slow-growing organisms require 2 to 4 days for maximal colony formation; they are weakly catalase-positive and oxidase-negative. Some strains may require up to 2 weeks to develop visible colonies. *F. philomiragia* is less fastidious than *F. tularensis.* Although *F. philomiragia* does not require cysteine or cystine for isolation, it is similar to *F. tularensis* in that it is a small, coccobacillary rod that grows poorly or not at all on MacConkey agar. This organism grows well on heart infusion agar with 5% rabbit blood or BCYE agar with or without cysteine. *F. tularensis* can be detected in commercial blood culture systems in 2 to 5 days. Because the organisms Gram stain poorly, an acridine orange stain may be required to visualize the organisms in a positive blood culture bottle.

Approach to Identification

Colonies are transparent, mucoid, and easily emulsified. Although carbohydrates are fermented, isolates should be identified serologically (by agglutination) or by a fluorescent antibody stain. Ideally, isolates should be sent to a reference laboratory for characterization.

F. philomiragia differs from *F. tularensis* biochemically; *F. philomiragia* is oxidase-positive by Kovac's modification, and most strains produce hydrogen sulfide in triple sugar iron agar medium, hydrolyze gelatin, and grow in 6% sodium chloride (no strains of *F. tularensis* share these characteristics).

Laboratory exposures have occurred in association with the management of *Francisella* species isolated from clinical specimens. Twelve microbiology employees were exposed to *F. tularensis* even though bioterrorism procedures were in place; the organism had been isolated from blood, respiratory, and autopsy specimens and grew on chocolate agar. In this situation, multiple cultures were handled on open benches without any additional personal protective equipment for a culture that appeared consistent with a *Haemophilus* species. As a result of this report, microbiologists

• BOX 37.1 Indications of a Possible *Francisella* Sp.

- Unusual Gram stain: small, poorly staining gram-negative rods seen mostly as single cells or amorphous gram-negative mass without distinct cell forms *(Francisella philomiragia)*
- Subcultures yield primarily pinpoint colonies on chocolate agar
- Oxidase-negative; weak or negative catalase test
- Negative satellite on X and V tests
- Small, gram-negative coccobacillus observed in a Gram-stained smear of a positive blood culture in which time to detection is longer than 24 hours
- Organism requires prolonged incubation on chocolate agar

must be aware of not only the key characteristics of this group of organisms (Box 37.1), but also the possible pitfalls in their identification (e.g., some strains grow well on sheep blood agar; identification kits may incorrectly suggest an identification of *Actinobacillus actinomycetemcomitans*). See Table 37.3 for differentiation of *F. tularensis* and similar gram-negative bacteria. If *F. tularensis* is suspect, all culture petri dishes should be taped from the top to the bottom in two places to keep them together for safety purposes.

Matrix-assisted laser desorption ionization time-of-flight mass spectrometry (MALDI-TOF MS) has been used to differentiate the species and subspecies of *Francisella*. However, identification of the different species may be limited due to the lack of availability of spectra within the commercial databases. Safety considerations should be considered prior to using MALDI-TOF MS. Use of the ethanol-formic acid tube extraction process inactivates *F. tularensis*, whereas the direct colony and formic acid extraction on the target plate is not as reliable.

Antimicrobial Susceptibility Testing and Therapy

The organism is susceptible to aminoglycosides, and streptomycin is the drug of choice. Gentamicin is a possible alternative; doxycycline and chloramphenicol may be used, although these two agents have been associated with a higher rate of relapse after treatment. Fluoroquinolones appear promising for treatment of even severe tularemia. Tularemia is an end-stage disease and is not transmitted person-to-person. Many species carry genomic or plasmid-borne copies of several beta-lactamases, despite the fact that introduction into humans is always from a natural reservoir where there should be minimal exposure to beta-lactams to maintain selective pressure. However, the development of resistance to the recommended antibiotics by *Francisella* is rare.

Antimicrobial susceptibility testing for *F. tularensis* is not generally performed in routine laboratories for safety considerations and the rare occurrence of the development of antibiotic resistance in the organism. Interpretative criteria and quality control limits for broth microdilution have been published by the Clinical and Laboratory Standards Institute (CLSI).

Prevention

The primary means of preventing tularemia is to reduce the possibility of exposure to the etiologic agent in nature, such as by wearing protective clothing to prevent insect bites and by refraining from handling dead animals. An investigative live-attenuated vaccine is available.

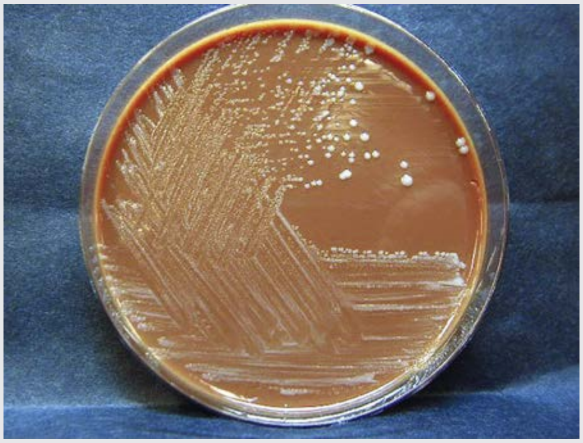
CASE STUDY 37.1

A 36-year-old male with human immunodeficiency virus (HIV) infection had been doing well on a prophylactic regimen. After camping in Yosemite National Park, he presents to his physician for a nonhealing, erythematous, 3-mm "cyst" on his neck. He was treated with ampicillin-sulbactam without resolution. A biopsy was performed. No organisms are seen on Gram staining, but the culture grows a tiny, gram-negative rod only on chocolate agar after 3 days of incubation (Fig. 37.1). The microbiologist finds the organism to be oxidase- and urease-negative but weakly catalase-positive. It does not satellite around a staphylococcal dot on blood agar. A beta-lactamase test result is positive. The patient is treated with a 4-week course of ciprofloxacin, and the lesion resolves.



• **Fig. 37.1** *Francisella tularensis* growing on chocolate agar after 72 hours of incubation. (Courtesy Mary K. York.)

Questions

1. The local health department identifies the isolate as *Francisella tularensis* by polymerase chain reaction (PCR) and by fluorescent stain. What do you think is the most commonly misidentified genus and species submitted as *F. tularensis*? What test differentiates these two organisms?
2. The isolate is oxidase- and urease-negative but weakly catalase-positive. After it is determined to be negative for satelliting around a staphylococcal dot on blood agar, what precautions should be taken when working with the culture?
3. Why is a beta-lactamase test performed?

Chapter Review

1. Which of the following media should be chosen for primary isolation of *F. tularensis*?
   - **a.** Blood
   - **b.** Cystine-heart
   - **c.** MacConkey
   - **d.** Chocolate

2. All of the following can cause humans to become infected with *F. tularensis except:*
   - **a.** Ticks
   - **b.** Inhalation
   - **c.** Deerflies
   - **d.** Person-to-person transmission

3. Which statement about *F. tularensis* is true?
   - **a.** Tularemia can be handled on an open bench.
   - **b.** Tularemia is sexually transmitted.
   - **c.** Tularemia causes vomiting and diarrhea-like symptoms.
   - **d.** Tularemia is one of the most common laboratory-acquired infections.

4. Optimal recovery of *F. tularensis* is acquired by:
   - **a.** Increased CO_2
   - **b.** Enriched media containing cysteine
   - **c.** 24-hour growth at room temperature
   - **d.** Anaerobic conditions

5. Which of the following may indicate the possibility of a *Francisella* species being identified?
   - **a.** Poorly staining gram-negative rod.
   - **b.** Oxidase-positive.
   - **c.** Organism grows on MacConkey agar at 24 hours.
   - **d.** Organism satellites on the X and V test.

6. The capsule of *F. tularensis* is necessary for the organism to:
   - **a.** Resist Gram staining
   - **b.** Avoid immediate destruction by polymorphonuclear neutrophils
   - **c.** Infect humans with an infection dose of less than five colony-forming units
   - **d.** Replicate in the lungs

7. The typical clinical presentation of *F. tularensis* includes:
   - **a.** A lesion that develops into an ulcer at the site of inoculation
   - **b.** High temperature, chills, headache, and aching
   - **c.** Enlargement and necrosis of lymph nodes
   - **d.** All of the above

8. *F. philomiragia* biochemically differs from *F. tularensis* by:
   - **a.** Nitrate and catalase reactions
   - **b.** Sodium hippurate and cephalothin reactions
   - **c.** Oxidase and gelatin hydrolysis reactions
   - **d.** Ornithine and indole reactions

9. **True or False**

______ Most cases of *F. tularensis* occur sporadically during the fall months.

______ Most *F. tularensis* cases occur in Wyoming, Montana, and Utah.

______ *F. novicida* and *F. philomiragia* are present in the environment.

______ *F. tularensis* infections can range from mild and self-limiting to fatal.

______ Serum antibody detection is useful for all forms of tularemia.

10. **Matching:** *Match each term with the correct description.*

______ cysteine
______ ulceroglandular
______ oculoglandular
______ pneumonic tularemia
______ systemic tularemia

a. most severe form of tularemia
b. ulcer at point of inoculation
c. requirement for *Francisella* growth
d. acute illness with septicemia
e. conjunctivitis

38

Streptobacillus spp. and *Spirillum minus*

OBJECTIVES

1. Describe the natural habitats of *Streptobacillus* spp. and *Spirillum minus.*
2. List the two ways in which *Streptobacillis* spp. are transmitted to humans.
3. Define Haverhill fever, rat-bite fever, and sodoku.
4. List the symptoms of rat-bite fever.
5. Describe the optimal conditions for culturing *S. moniliformis,* including media, supplements, atmospheric conditions, and length of incubation.
6. Describe the different appearances of *S. moniliformis* colonial morphology when grown on various media.
7. Describe how *S. minus* is detected in the laboratory.
8. Compare and contrast the microscopic appearance of *S. minus* and *S. moniliformis* in Gram-stained or other smears.

GENERA AND SPECIES TO BE CONSIDERED

Streptobacillus hongkongensis
Streptobacillus moniliformis
Streptobacillus notomysis
Spirillum minus

Streptobacillus are nonmotile, facultative anaerobic, filamentous gram-negative bacilli that require media containing blood, serum, or ascites fluid as well as incubation under carbon dioxide (CO_2) for isolation from clinical specimens. *S. moniliformis* and *S. notomysis* cause rat-bite fever or Haverhill fever in humans. *S. hongkongensis* has been isolated from patients with arthritis. *Spirillum minus* has never been grown in culture, but both are causative agents of rat-bite fever. Two additional species of *Streptobacillus* spp. have been identified in animals: *S. felis* was isolated from the lung of a cat and *S. ratti* from a black rat. Neither of these two species have been isolated from human infections.

Streptobacillus spp.

General Characteristics

The genus *Streptobacillus* is a member of the *Leptotrichiaceae* family. The *Streptobacillus* genus includes three species that have been isolated from human infections, *S. moniliformis, S. hongkongensis,* and *S. notomytis.* The organisms are facultative, nonmotile anaerobes that tend to be highly pleomorphic.

Epidemiology and Pathogenesis

The natural habitat of *Streptobacillus* spp. is the upper respiratory tract (nasopharynx, larynx, upper trachea, and middle ear) of wild and laboratory rats (mice, gerbils, squirrels, ferrets, weasels) and other rodents such as ferrets, gerbils, mice, and squirrels; in addition, this organism occasionally has been isolated from other animals, such as cats and dogs that have fed on rodents. *Streptobacillus* spp. are pathogenic for humans and are transmitted by two routes:

- A bite from any of the organisms previously listed, or possibly through direct contact with rat feces or saliva.
- Ingestion of contaminated food, such as unpasteurized milk or milk products and, less frequently, water.

The incidence of *Streptobacillus* spp. infections is unknown, but human infections appear to occur worldwide.

The pathogenic mechanisms associated with *Streptobacillus* spp. are unknown. The organism is known to spontaneously develop L forms (bacteria without cell walls), which may allow its persistence.

Spectrum of Disease

Despite the different modes of transmission, the clinical manifestations of *Streptobacillus* spp. infection are similar. When *S. moniliformis* is acquired by ingestion, the disease is called **Haverhill fever.**

Patients with rat-bite or Haverhill fever develop acute onset of chills, fever, headache, vomiting, and often severe joint pains. Symptoms usually occur within 3 to 10 days after exposure to an infected animal. Febrile episodes may persist for weeks or months. In the first few days of illness, patients develop a rash on the palms, soles of the feet, and other extremities. Complications can occur, including endocarditis, bacteremia, septicemia, septic arthritis, pneumonia, pericarditis, brain abscess, amnionitis, prostatitis, and pancreatitis. Blood culture negative endocarditis has been reported with *S. moniliformis.*

Laboratory Diagnosis

Specimen Collection, Transport, and Processing

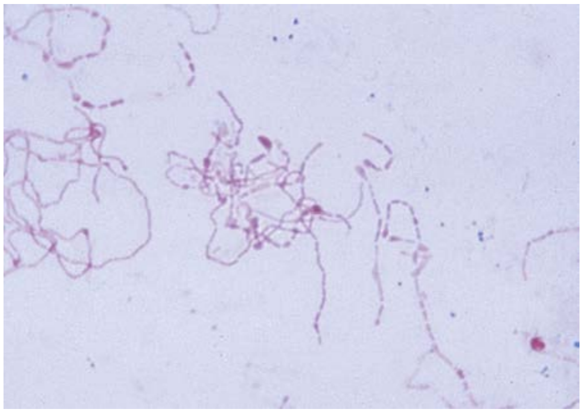
Unfortunately, the diagnosis of rat-bite fever caused by *Streptobacillus* spp. is often delayed because of lack of exposure history, an atypical clinical presentation, and the unusual microbiologic characteristics of the organism. Organisms may be cultured from blood or aspirates from infected joints, lymph nodes, or lesions. No special requirements have been established for the collection, transport, and processing of these specimens, except for blood. Because recovering *Streptobacillus* spp. from blood cultures are impeded by concentrations of sodium polyanethol sulfonate (SPS) used in blood culture bottles, an alternative to most commercially available bottles must be used. After collection by routine procedures (Chapter 67), blood and joint fluids are mixed with equal volumes of 2.5% citrate to prevent clotting and are then inoculated to brain-heart infusion cysteine broth supplemented with heated horse serum and yeast extract, commercially available fastidious anaerobe broth without SPS, or thiol broth.

Direct Detection Methods

Pus or exudates should be smeared, stained with Gram or Giemsa stain, and examined microscopically (Fig. 38.1). *Streptobacillus* spp. are pleomorphic, gram-negative rods. Cells may appear straight of variable size or as long, tangled chains and filaments with bulbar swellings. The cells may also appear spiral shaped and resemble a string of pearls. Direct detection of the 16S ribosomal ribonucleic acid (rRNA) gene sequence for *S. moniliformis* using polymerase chain reaction (PCR) analysis can be performed from the specimen or from the culture of the organism.

Cultivation

As previously mentioned, *S. moniliformis* requires the presence of blood, ascitic fluid, or serum for growth. Growth occurs on blood agar (15% sheep, horse, or rabbit); incubated in a very moist environment with 5% to 10% carbon dioxide (CO_2), usually after 48 hours of incubation at 37°C. Colonies are nonhemolytic. The addition of 10% to 30% ascitic fluid (available commercially from some media suppliers) or 20% horse serum should facilitate recovery of the organism. *S. hongkongensis* has been successfully recovered from clinical specimens using Columbia agar base enriched with sheep blood either anaerobically or increased (5%) CO_2. In broth cultures, the organism grows as “fluff balls” or “bread crumbs” near the bottom of the tube or on the surface of the red blood cell layer in blood culture media. Colonies grown on brain-heart infusion agar supplemented with 20% horse serum are small, smooth, glistening, colorless or grayish, and have irregular edges.



• **Fig. 38.1** Gram stain of *Streptobacillus moniliformis* from growth in thioglycollate broth with 20% serum. (Courtesy Robert E. Weaver, Centers for Disease Control and Prevention, Atlanta, GA.)

Colonies are embedded in the agar and may have a “fried egg” appearance, with a dark center and a flattened, lacy edge. These colonies are also referred to as **L-phase** colonies because they have undergone spontaneous transformation to the L form. Staining of L-form colonies yields coccobacillary or bipolar-staining coccoid forms (usually a special stain, such as the Dienes stain performed by pathologists, is required). Acridine orange stain also reveals the bacteria when Gram stain fails because of a lack of cell wall constituents.

As previously stated, Gram-stained organisms from standard colonies show extreme pleomorphism, with long, looped, filamentous forms, chains, and swollen cells. The club-shaped cells can be two to five times the diameter of the filament. Carbolfuchsin counterstain or Giemsa stain may be necessary for visualization (Fig. 38.1).

Approach to Identification

S. moniliformis does not produce indole and is catalase-, oxidase-, and nitrate-negative, in contrast to organisms with which the *Streptobacillus* sp. may be confused, such as *Actinobacillus* spp., *Aggregatibacter aphrophilus,* and *Cardiobacterium* spp. In addition, *S. moniliformis* is nonmotile and urea- and lysine decarboxylase–negative; hydrogen sulfide (H_2S) is not produced in triple sugar iron agar but can be detected using lead acetate paper. MALDI-TOF MS has been used to identify *S. moniliformis* from pure culture. In addition, nucleic acid amplification and 16S rRNA sequencing has been used to identify *Streptobacillus* spp. from culture and culture-negative clinical samples.

Serodiagnosis

Serologic diagnosis of rat-bite fever is also useful; most patients develop agglutinating titers to the causative organism. The specialized serologic tests are performed at national reference laboratories because the disease is extremely rare in the United States. A titer of 1:80 is considered diagnostic unless a fourfold rise in titer is demonstrated.

Antimicrobial Susceptibility Testing and Therapy

No standardized methods have been established for determining *S. moniliformis* susceptibility to various antimicrobials. Different *in vitro* techniques, such as agar dilution and disk diffusion, have had similar results. Although *S. moniliformis* is susceptible to a broad spectrum of antibiotics, penicillin is regarded as the drug of choice for human rat-bite fever. Combination therapy with penicillin and an aminoglycoside is recommended for systemic infections such as endocarditis to enhance the elimination of the cell wall-deficient L forms.

Prevention

There are no vaccines available to prevent rat-bite fever. Disease is best prevented by avoiding contact with animals known to harbor the organism. Individuals with frequent animal contact should wear gloves, practice regular handwashing, and avoid hand-to-mouth contact when handling rats or cleaning rat cages.

Spirillum minus

General Characteristics

Spirillum minus is a gram-negative, helical, strictly aerobic organism.

Epidemiology and Pathogenesis

Little information is available regarding the epidemiology or pathogenesis of *S. minus,* but it is supposed to be similar in some regard to that of *Streptobacillus* spp. The mode of transmission of infection is by a rat bite.

Spectrum of Disease

Spirillum minus also causes rat-bite fever but is primarily seen in Asia and is referred to as **sodoku** (*so,* rat; *doku,* poison). The clinical signs and symptoms are similar to those caused by *Streptobacillus,* except that arthritis is rarely seen in patients with sodoku, and swollen lymph nodes are prominent; febrile episodes are also more predictable in sodoku. The bite wound heals spontaneously, but 1 to 4 weeks later, it ulcerates to form a granulomatous lesion; at the same time, the patient develops symptoms of fever; headache; and a generalized, blotchy, purplish, maculopapular rash. Differentiation between rat-bite fever caused by *S. minus* and that caused by *Streptobacillus* is usually accomplished based on the clinical presentation of the two infections and isolation of the latter organism in culture. The incubation period for *S. minus* is much longer than that for streptobacillary rat-bite fever, which has occurred within 12 hours of the initial bite.

Laboratory Diagnosis

Specimen Collection, Transport, and Processing

Specimens commonly submitted for diagnosis of sodoku include blood, exudate, or lymph node tissues. There are no requirements for specimen collection, transport, or processing of the organisms discussed in this chapter. Refer to Table 5.1 for general information on this subject.

Direction Detection Methods

Because *S. minus* cannot be grown on synthetic media, diagnosis relies on direct visualization of characteristic spirochetes in clinical specimens using Giemsa or Wright stains or dark-field microscopy. *S. minus* appears as a thick, spiral, gram-negative organism with two or three coils and polytrichous polar flagella. Diagnosis is made by injection of lesion material or blood into experimental white mice or guinea pigs and subsequent recovery 1 to 3 weeks after inoculation.

Serodiagnosis

There is no specific serologic test available for *S. minus* infection.

Antimicrobial Susceptibility Testing and Therapy

Because this spirochete is nonculturable, routine antimicrobial susceptibility testing is not performed.

Prevention

No vaccines are available to prevent rat-bite fever. Disease is best prevented by avoiding contact with animals known to harbor the organism.

Visit the Evolve site for a complete list of procedures, review questions, and case studies.

CASE STUDY 38.1

An 8-year-old female presented with a 7-day history of worsening flulike illness with fever, cough, and arthralgias. By admission, the arthralgia was so severe that she refused to walk. A rash was noted on the dorsal surface of her hands and feet. The pediatrician suspected *Streptobacillus moniliformis* because the child had a pet rat that slept with her. The rat had never bitten her, but she did carry it around her neck. A routine blood culture was drawn. A second blood culture was collected in a tube and plated to blood and chocolate agars. A third culture was collected. Doxycycline was then started, and over the next few days the patient did well. The first and second cultures remained negative, but the third culture attempt was positive in less than 24 hours with a gram-negative rod. Subcultures of the bottle to blood, chocolate, *Brucella* (aerobic and anaerobic), and *Legionella* selective agars incubated in CO_2 were negative at 48 hours.

Questions

1. Why did the laboratory set up a culture with more blood than that recommended by the manufacturer?
2. Because *S. moniliformis* was suspected and there was no growth on any of the subcultures at 48 hours, what can the laboratory do to grow the organism on a plated medium to identify it?
3. How is the organism identified?

Chapter Review

1. When *S. moniliformis* is acquired by ingestion, the disease is called:
- **a.** Trench fever
- **b.** Haverhill fever
- **c.** Cat-scratch disease
- **d.** Lyme disease

2. Which of the following is *not* required for growth of *Streptobacillus*?
- **a.** Blood
- **b.** Ascitic fluid
- **c.** Cystine
- **d.** Serum

3. All of the following have been used to describe colonies of *S. moniliformis except:*
- **a.** Fluff balls
- **b.** Mercury drops
- **c.** Bread crumbs
- **d.** Fried egg

4. *S. minus* also causes rat-bite fever in humans and is referred to as:
- **a.** Haverhill fever
- **b.** Legionnaire's disease
- **c.** Hantavirus
- **d.** Sodoku

5. Definitive diagnosis of *S. minus* is made by:
- **a.** Mouse or guinea pig inoculation
- **b.** Serologic tests
- **c.** Culture of lymph node tissue
- **d.** Gram stain

6. The natural habitat of *Streptobacillus* is the upper respiratory tract of:
- **a.** African dwarf frogs
- **b.** Wild and laboratory rats
- **c.** Prairie rattlesnakes
- **d.** Black-footed ferrets

7. *S. moniliformis* and *S. minus* can be differentiated symptomatically by:
- **a.** Febrile episodes
- **b.** Rash
- **c.** Arthritis
- **d.** Headache

8. All of the following are necessary for the growth of *S. moniliformis except:*
- **a.** The presence of blood, ascitic fluid, or serum
- **b.** 48 hours of incubation at 37°C
- **c.** 5% to 10% CO_2 environment
- **d.** MacConkey agar in ambient air

9. On Giemsa staining, *S. minus* appears as:
- **a.** Club-shaped cells
- **b.** Extreme pleomorphism
- **c.** Spiral organisms with two or three coils of polytrichous polar flagella
- **d.** Bipolar-staining coccoid forms

SECTION 12 Gram-Negative Cocci

39

Neisseria and *Moraxella catarrhalis*

OBJECTIVES

1. Identify the clinical specimens or sources for the isolation of pathogenic *Neisseria* spp.
2. List the *Neisseria* species considered normal microbiota and the sites where they colonize the human body.
3. Explain the routes of transmission for the organisms discussed in this chapter; include the clinical relevance of asymptomatic carriers.
4. Define and describe the diseases associated with *Moraxella catarrhalis* and the pathogenic *Neisseria* spp., *Neisseria gonorrhoeae* and *Neisseria meningitidis* (i.e., pelvic inflammatory disease, disseminated gonococcal infection, ophthalmia neonatorum, pharyngitis, meningitis, and septicemia); include the signs and symptoms, treatments, and prognosis.
5. Describe the method of transport that yields optimal recovery of *N. gonorrhoeae,* including transport media, growth temperatures, and atmospheric conditions.
6. Describe the benefits of amplified testing for *N. gonorrhoeae* as it relates to diagnostic and clinical efficacy.
7. Identify the optimal growth conditions for the *Neisseria* species.
8. Name the appropriate biochemical tests for differentiating the *Neisseria* species, and explain the chemical principle for each test.
9. Biochemically differentiate the organisms in this chapter using carbohydrate use (cysteine trypticase agar [CTA]) and orthonitrophenyl galactoside (ONPG).
10. Describe the appropriate therapeutic agents for *N. gonorrhoeae.*
11. Compare and contrast the laboratory identification of *M. catarrhalis* and *Neisseria* spp.
12. Analyze laboratory data and disease signs and symptoms for correlation and identification of the etiologic agents discussed in this chapter.

GENERA AND SPECIES TO BE CONSIDERED

Current Name	Previous Name
Moraxella catarrhalis	*Branhamella catarrhalis, Neisseria catarrhalis*
Neisseria gonorrhoeae	
Neisseria meningitidis	
Other *Neisseria* spp.	
Neisseria cinerea	
Neisseria lactamica	
Neisseria polysaccharea	
Neisseria subflava	*Neisseria flava, Neisseria perflava*
Neisseria sicca	
Neisseria mucosa	
Neisseria flavescens	

General Characteristics

Species of the family *Neisseriaceae,* genus *Neisseria,* are discussed in this chapter, along with the family *Moraxellaceae,* species *Moraxella catarrhalis,* because of their biochemical and morphologic similarities. The organisms are all oxidase-positive, gram-negative diplococci that do not elongate when exposed to subinhibitory concentrations of penicillin. The rodlike *Neisseria* spp. and other *Moraxella* spp. are described in Chapter 27, and the genus *Acinetobacter,* an important clinical pathogen that is part of the family *Moraxellaceae,* is discussed in Chapter 20.

It is important to note that the implementation of next generation sequencing is beginning to identify inconsistencies in the differentiation of species among the current *Neisseria* taxonomy. Sequencing of the 16S rRNA gene generally provides sufficient interpretive criteria for identification within the genus *Neisseria.* However, lateral gene transfer can occur between species and as low as 1% diversity has been identified in the 16S rRNA sequence of *Neisseria* spp. Therefore, although the genus currently includes 30 described species, as additional target sequences are analyzed, species designations may change as more information becomes available.

Epidemiology

The *Neisseria* spp. are predominantly considered normal microbiota that reside on the mucous membranes of either humans or animals. Humans are the only natural host for

TABLE 39.1 **Epidemiology**

Organism	Habitat (Reservoir)	Mode of Transmission
Moraxella catarrhalis	Normal microbiota of upper respiratory tract; occasionally colonizes female genital tract.	Spread of patient's endogenous strain to normally sterile sites. Person-to-person nosocomial spread by respiratory droplets may occur.
Neisseria gonorrhoeae	Not part of normal microbiota. Only found on mucous membranes of genitalia, anorectal area, oropharynx, or conjunctiva at time of infection.	Person-to-person spread by sexual contact, including rectal intercourse and orogenital sex. May be spread from the infected mother to newborn during birth. Asymptomatic carriers are a significant reservoir for increased disease transmission.
Neisseria meningitidis	Colonizes oropharyngeal and nasopharyngeal mucous membranes of humans. Humans commonly carry the organism without symptoms.	Person-to-person spread by respiratory droplets, usually in settings of close contact (e.g., dormitories, prisons, shelters).
Other *Neisseria* spp.	Normal microbiota of the upper respiratory tract.	Spread of patient's endogenous strain to normally sterile sites. Person-to-person spread may also be possible, but these species are not common causes of human infections.

N. gonorrhoeae, a clinically significant pathogen found in the urogenital tract, which is never considered normal microbiota. Asymptomatic carriers of *N. gonorrhoeae* are the primary reservoir for dissemination within the human population. The actual prevalence of cases of infection with *N. gonorrhoeae* is likely significantly higher than what is reported by the US Centers for Disease Control and Prevention (CDC) because of the number of unrecognized and underreported cases.

The two major pathogenic species of *Neisseria, N. gonorrhoeae* and *N. meningitidis,* are transmitted person to person. *N. gonorrhoeae* is sexually transmitted, and *N. meningitidis* is spread via respiratory droplets. Infections caused by *M. catarrhalis* and the other *Neisseria* spp. usually involve a patient's endogenous strain. Except for *Neisseria gonorrhoeae* and *Neisseria animaloris,* the organisms considered in Table 39.1 are normal commensal organisms present in the upper respiratory tract of humans.

Pathogenesis and Spectrum of Disease

As noted in Table 39.2, infections caused by *M. catarrhalis* are usually localized to the respiratory tract and rarely disseminate. Among young children, cases of acute otitis media caused by *M. catarrhalis* have been widely recognized. *M. catarrhalis* can also infect older adults but tends to cause chronic upper respiratory infections in this population.

According to the CDC, *N. gonorrhoeae* is the second most commonly reported sexually transmitted infection (STI) in the United States. In 2017, there were a total of 555,608 reported cases of gonorrhea infection, up from 333,004 reported cases in 2013. This equates to a rate of 171.9 cases/100,000 population, a 75.2% increase since the low in 2009. Infections usually remain localized to the mucosal surfaces where the host is initially exposed to the organism (e.g., cervix, conjunctiva, oropharynx, anorectal area, or urethra of males). Localized infections may be asymptomatic or acute with a pronounced purulent response. The most common clinical presentation associated with *N. gonorrhoeae* is uncomplicated urethritis in men and genital infections in the endocervix in women. However, not all infections remain localized, and dissemination from the initial infection site can lead to severe disseminated disease (Table 39.2). Disseminated diseases with *N. gonorrhoeae* are uncommon but may result in serious morbidity and mortality, including gonococcal arthritis, endocarditis, and meningitis. Infants are at risk for acquiring infection in the eyes when passing through the birth canal. *N. gonorrhoeae* strains can also produce capsules, endotoxins, and adherence proteins to enhance protection from the host's immune responses (Table 39.2).

N. meningitidis, a leading cause of fatal bacterial meningitis in children and adults, exclusively infects humans and can be found colonizing the oropharynx and nasopharynx in approximately 10% of the population. Strains of *N. meningitidis* can be differentiated based on their distinct capsular polysaccharides. There are 12 serogroups, with eight commonly implicated in infections (A, B, C, X, Y, Z, W135, and L). The pathogenesis of the organism is related to nasopharyngeal colonization and the organism's virulence factors. The organism possesses pili that aid in organism attachment to the mucosal epithelium; opacity proteins that also play a role in host attachment; production of lipooligosaccharide, similar to lipopolysaccharide (endotoxin) of enteric gram-negative bacilli, which aids the organism in evading complement-mediated cell lysis; and the different capsular polysaccharides, which act as barriers to prevent phagocytosis.

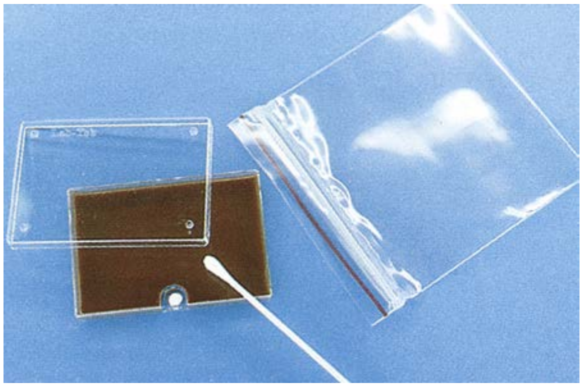
N. meningitidis also causes a severe disseminated infection commonly referred to as invasive meningococcal

TABLE 39.2 **Pathogenesis and Spectrum of Disease**

Organism	Virulence Factors	Spectrum of Disease and Infections
Moraxella catarrhalis	Uncertain; factors associated with cell envelope probably facilitate attachment to respiratory epithelial cells.	Most infections are localized to sites associated with the respiratory tract and include otitis media, sinusitis, and pneumonia. Lower respiratory tract infections often target elderly patients and those with chronic obstructive pulmonary disease. Rarely causes disseminated infections such as bacteremia, meningitis, and endocarditis. Carried frequently in children and older adults; not typically isolated from the oropharynx of healthy adults.
Neisseria gonorrhoeae	Several surface factors, such as pili (types T1 and T2 virulent and T3–T5 avirulent), mediate the exchange of genetic material between strains and attachment to human mucosal cell surface, invasion of host cells, and survival through the inhibition of phagocytosis in the presence neutrophils. Genetic-phase variation of pilus structure between types T1 and T5 allows the organism to vary its antigenic structure, preventing recognition by host immune cells. Capsule, lipooligosaccharide (endotoxin), and outer cell membrane proteins I–III are important in antigenic variation and for eliciting an inflammatory response. Protein II (Opa) facilitates adherence to phagocytic and epithelial cells. Protein II (RMP) blocks the bactericidal effect of host immunoglobulin G (IgG). Outer membrane porin (PorB) provides protection from the host's immune response, including serum complement–mediated cell death.	A leading cause of sexually transmitted infections. Genital infections include acute purulent urethritis, prostatitis, and epididymitis in males and acute cervicitis in females. These infections also may be asymptomatic in females. Other localized infections include pharyngitis, anorectal infections, and conjunctivitis (e.g., ophthalmia neonatorum of newborns acquired during birth from an infected mother). Disseminated infections result when the organism spreads from a local infection to cause pelvic inflammatory disease or disseminated gonococcal infection that includes bacteremia, arthritis, and metastatic infection at other body sites. Pelvic inflammatory disease (PID) may cause sterility, ectopic pregnancy, or perihepatitis, also referred to as Fitz-Hugh–Curtis syndrome.
Neisseria meningitidis	Surface structures, perhaps pili, facilitate attachment to mucosal epithelial cells and invasion to the submucosa. Once in the blood, survival is mediated by production of a polysaccharide capsule. Endotoxin release mediates many of the systemic manifestations of infection, such as shock. Cellular proteins are similar to those described for *N. gonorrhoeae*, including Por and Opa. Two porin proteins are produced (PorA and PorB). IgA protease degrades membrane-associated IgA, increasing the host's susceptibility to invasion.	Life-threatening, acute, purulent meningitis. Meningitis may be accompanied by appearance of petechiae (i.e., rash) that is associated with meningococcal bacteremia (i.e., meningococcemia). Bacteremia leads to thrombocytopenia, disseminated intravascular coagulation, and shock. Disseminated disease is often fatal. Less common infections include conjunctivitis, pneumonia, and sinusitis.
Other *Neisseria* spp.	Unknown; probably of low virulence.	Rarely involved in human infections. When infections occur, they can include bacteremia, endocarditis, and meningitis.

disease (IMD). The clinical presentation of IMD includes symptoms of meningitis and septicemia. It is believed that IMD is transmitted by individuals who present as carriers of *N. meningitidis.* Although there is no standard for assessing carriage rates of meningococcal specific serogroups, it appears that some specific serogroups are prevalent in different age groups and demonstrate a regional distribution. Identifying the primary serogroups within a population can be used in conjunction with epidemiologic data and can provide valuable information for the prevention of transmission and disease with the appropriate vaccine.

The other *Neisseria* spp. are not considered pathogens and are often referred to as saprophytic *Neisseria.* They are often viewed as normal microbiota in respiratory culture specimens and not fully identified. Some species (e.g., *N. sicca*, *N. lactamica, N. bacilliformis, N. elongate,* and *N. subflava*) have been occasionally identified as the causative agent of infectious endocarditis or bacteremia. Additional species, discussed in Chapter 27, may cause soft tissue infections following an animal bite.



• **Fig. 39.1** JEMBEC system. Plate contains modified Thayer-Martin medium. The CO_2-generating tablet is composed of sodium bicarbonate and citric acid. After inoculation, the tablet is placed in the well, and the plate is closed and placed in the zippered plastic pouch. The moisture in the agar activates the tablet, generating a CO_2 atmosphere in the pouch.

Laboratory Diagnosis

Specimen Collection and Transport

The pathogenic *Neisseria* spp. described in this chapter are sensitive to drying and temperature extremes. In addition to general information on specimen collection and transport provided in Table 5.1, there are some special requirements for isolation of *N. gonorrhoeae* and *N. meningitidis.*

Swabs, although not optimal, are acceptable for the collection of culture-based samples for *N. gonorrhoeae* and should be plated as soon as possible. Reduced recovery of the organism may result as soon as 30 minutes after collection. Dacron-, polyurethane-, rayon-, or nylon-tipped swabs may be used for culture-based collection. Swabs should be placed in a suitable transport media such as Amie's charcoal to prevent dehydration and inhibit toxic fatty acids that may be present in the fibers. Cotton-tipped swabs and those with wooden shafts should be avoided because they can be inhibitory or toxic to *N. gonorrhoeae*. Calcium alginate swabs, oil-based lubricants, and cotton buds should not be used because they have been found to be inhibitory to organism recovery. Refrigeration of samples transported in liquid Amie's media has demonstrated sufficient recovery of *N. gonorrhoeae* in culture after 24 hours. *N. gonorrhoeae* should be inoculated to growth media immediately after specimen collection for optimal organism recovery. The sample should then be placed in a container able to sustain an atmosphere of increased carbon dioxide (CO_2) during transport. Specially packaged media consisting of selective agar in plastic trays that contain a CO_2-generating system are commercially available (JEMBEC plates). The JEMBEC system (Fig. 39.1) consists of a modified Thayer-Martin plate, CO_2-generating pill, and plastic bag. After collection, the specimen should be inoculated as soon as possible by cross-streaking the agar surface in a "Z" formation to obtain isolated colonies, activating the CO_2-generating pill, and placing the agar in the plastic bag. This system is then transported to the laboratory at room temperature. Upon receipt in the laboratory, the plate should be incubated at 37°C in 3% to 5% CO_2. Alternatively, the specimen may be sent and streaked in the laboratory and then properly incubated. Additional commercial transport systems may be useful when the collection site is separate from the diagnostic laboratory.

Molecular assays for the identification of *N. gonorrhoeae* generally provide specific specimen collection and transport systems that can be used for either urine, vaginal, or urethral specimens. In the absence of a specific collection device, Dacron- or rayon-tipped swabs are recommended with the use of Amie's transport media. Calcium alginate swabs reportedly inhibit nucleic acid amplification.

Recovery of *N. gonorrhoeae* or *N. meningitidis* from normally sterile body fluids requires no special methods, except for blood cultures. Both organisms are sensitive to sodium polyanethol sulfonate (SPS), the preservative typically found in blood culture broths. If a blood culture broth is inoculated, the SPS content should not exceed 0.025%. In addition, if blood is first collected in Vacutainer tubes containing SPS (Becton Dickinson, Sparks, MD), the specimen must be transferred to the broth culture system within 1 hour of collection.

Nasopharyngeal swabs collected to detect *N. meningitidis* carriers should be plated immediately to the JEMBEC system, or they should be submitted on swabs placed in charcoal transport media and plated within 5 hours of collection.

Specimen Processing

The JEMBEC system should be incubated at 35°C to 37°C as soon as the plate is received in the laboratory.

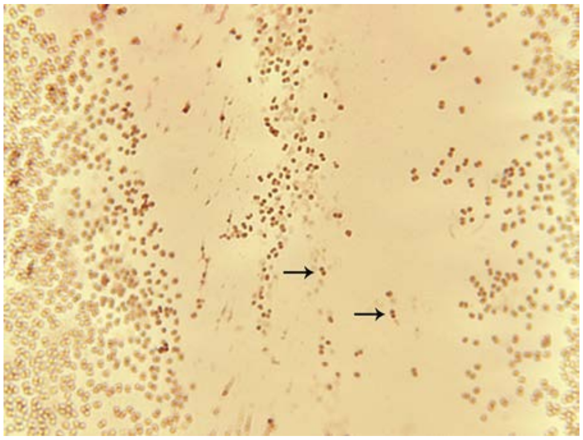
Any volume of clear fluid greater than 1 mL suspected of containing either of these pathogens should be centrifuged at room temperature at 1500 × *g* for 15 minutes. The supernatant fluid should then be removed and saved, and the sediment should be vortexed and inoculated onto the appropriate media (see Cultivation section).

Any specimens or cultures in which *N. meningitidis* is a consideration should be handled in a biologic safety cabinet to prevent laboratory-acquired infections.

Direct Detection Methods

Gram Stain

The majority of the members of the genus *Neisseria* and *M. catarrhalis* appear as gram-negative diplococci (Fig. 39.2) with adjacent sides flattened. The cells are described as "kidney- or coffee bean–shaped" diplococci; other *Neisseria* spp. appear as gram-negative rods or elongated coccoid forms. Direct Gram staining of urethral discharge from symptomatic males with urethritis is an important test for gonococcal disease. The appearance of gram-negative diplococci inside polymorphonuclear leukocytes (PMNs) is diagnostic in this situation. However, because the normal vaginal and rectal microbiota are composed of gram-negative coccobacilli,



• **Fig. 39.2** Gram stain of *Neisseria gonorrhoeae* showing gram-negative diplococci *(arrows)*.

which can resemble *Neisseria* spp., direct examination of endocervical secretions in symptomatic females or rectal specimens is presumptive evidence of gonococcal infection, and the diagnosis must be confirmed by additional testing. In addition, avirulent strains may be present in specimens as extracellular diplococci; these are not pathogenic. Pharyngeal specimens should not be Gram stained, because nonpathogenic, commensal *Neisseria* spp. may be present, and the presence of these organisms is not diagnostic of infection.

The direct Gram stain of body fluids for either *N. gonorrhoeae* or *N. meningitidis* is best accomplished using a cytocentrifuge to concentrate small numbers of organisms 100-fold.

Nucleic Acid Detection

Nucleic acid–based methods have replaced old enzyme-linked immunosorbent assay systems for rapid diagnosis of *N. gonorrhoeae.* The US Food and Drug Administration (FDA) has approved a number of amplified tests for the *in vitro* detection of *N. gonorrhoeae* from clinical specimens. (For a discussion of nucleic acid–based methods, see Chapter 8.)

Amplified assays are commercially available from a variety of manufacturers. Nucleic acid amplification tests are superior to culture. The sensitivity, specificity, and positive predictive value (PPV) of the molecular assays for *N. gonorrhoeae* vary between manufacturers due to the use of different genomic target regions in the assays. A few of these tests are cartridge-based, point-of-care assays that require minimal training and rapid turnaround. Additional test systems are suitable for large-scale screening programs and can be fully integrated into automated molecular testing systems. However, the results obtained from the automated molecular test systems are not admissible as evidence in medicolegal cases or cleared for oropharyngeal, rectal, ocular, or pediatric specimens. An advantage of many of the FDA-approved nucleic acid–based tests for *N. gonorrhoeae* is the ability to detect *Chlamydia trachomatis* from the same specimen, because coinfections are common. For additional information regarding *C. trachomatis,* refer to Chapter 43. *N. gonorrhoeae* DNA can be found in a specimen for up to 3 weeks after a successful treatment regimen; therefore, amplified nucleic acid–based methods should not be used to assess rates of cure.

Nucleic acid–based methods are also available for the detection of *N. meningitidis.* Sequence-based typing methods combined with serologic typing are currently recommended. Real-time assays are advantageous because they can quantify the amount of amplifiable template (DNA) in the sample. Molecular targets for identification include polymerase chain reaction (PCR) and sequencing of a variety of genes, including *porA, porB, fetA* (associated with *porA*), global housekeeping genes, *penA* (penicillin susceptibility), and factor H binding protein. The two genes recommended for species-specific identification by the CDC include the *ctrA* gene that is exclusive to *N. meningitidis* and is responsible for forming part of the capsule biosynthesis locus, and the copper-zinc superoxide dismutase gene, *sodC,* which has only been described in strains of *N. meningitidis.* The *sodC* gene is advantageous as a target for use in qPCR (quantitative PCR) assays because it can be used to detect nongroupable strains of *N. meningitidis* that do not contain *ctrA.* The polysialyltransferase genes *csb, csc, csw*, and *csy* can be used for serogrouping of B, C, W, and Y. At the time of this writing, the bioMerieux FilmArray meningitis/encephalitis panel is the only FDA-approved molecular assay available for the detection of *N. meningitidis*, along with 13 other viral and bacterial pathogens.

It is important to follow the manufacturer's recommendations when evaluating nucleic acid–based diagnostic tests for the identification of *Neisseria* spp. Some of the assays have limitations with regard to the type of specimen that may be used, cross reactivity with nonpathogenic species, and assay inhibition and false-negative results caused by substances present in patient samples.

Cultivation

Media of Choice

N. meningitidis, M. catarrhalis, and saprophytic *Neisseria* spp. grow well on trypticase soy agar with 5% sheep blood and enriched media, such as chocolate agar. *N. gonorrhoeae* is more fastidious and typically does not grow on blood agar but will grow on chocolate agar. Because gonococci and sometimes meningococci must be isolated from sites that contain large numbers of normal microbiota (e.g., genital tract or upper respiratory tract), selective media have been developed to facilitate their recovery. The first of these was Thayer-Martin medium, a chocolate agar with an enrichment supplement (IsoVitaleX), and the antimicrobials colistin (to inhibit gram-negative bacilli), nystatin (to inhibit yeast), and vancomycin (to inhibit gram-positive bacteria). This original medium was subsequently modified to include trimethoprim (to inhibit the swarming observed with *Proteus* spp.), and its name was changed to modified Thayer-Martin medium (MTM). Martin-Lewis (ML) medium is similar to MTM except that anisomycin, an antifungal agent, is substituted for nystatin and the concentration of vancomycin is increased. GC-LECT agar is a selective medium that contains additional antimicrobials to inhibit bacteria found in oropharyngeal specimens; it includes vancomycin and lincomycin (to inhibit gram-positive bacteria), colistin (to inhibit gram-negative bacteria), amphotericin B (to inhibit yeast), and trimethoprim (to inhibit swarming *Proteus* spp. and *Capnocytophaga* spp.).

New York City (NYC) medium, a transparent clear-to-yellow medium containing lysed horse blood, horse plasma, yeast dialysate, and the same antimicrobials as MTM, also has been used. The advantage of NYC medium is that genital mycoplasmas (*Mycoplasma hominis* and *Ureaplasma urealyticum;* refer to Chapter 44) also grow on this medium. Some strains of *N. gonorrhoeae* are inhibited by the concentration of vancomycin in the selective media. The addition of nonselective chocolate agar is recommended, especially in suspect cases that are culture-negative or for sterile specimens (e.g., joint fluid).

Unlike the pathogenic species, some of the saprophytic *Neisseria* spp. may grow on MacConkey agar, although poorly. *N. gonorrhoeae* and *N. meningitidis* will grow in most broth blood culture media but grow poorly in common nutrient broths such as thioglycollate and brain-heart infusion. *M. catarrhalis* and the other *Neisseria* spp. grow well in almost any broth medium.

Incubation Conditions and Duration

Agar plates should be incubated at 35°C to 37°C for 72 hours in a CO_2-enriched, humid atmosphere. *N. gonorrhoeae, N. meningitidis,* and *M. catarrhalis* grow best under conditions of increased CO_2 (3% to 7%). This atmosphere can be achieved using a candle jar, CO_2-generating pouch, atmospheric vacuum system, or CO_2 incubator. If incubating using a candle jar, only white, unscented candles should be used because other types may be toxic to *N. gonorrhoeae* and *N. meningitidis.*

Humidity can be provided by placing a pan with water in the bottom of a CO_2 incubator or by placing a sterile gauze pad soaked with sterile water in the bottom of a candle or vacuum jar.

All cultures should be held for 72 hours prior to resulting a negative culture for *N. gonorrhoeae* and *N. meningitidis.*

Colonial Appearance

Table 39.3 describes the colonial appearance and other distinguishing characteristics (e.g., pigment) of *M. catarrhalis* and the *Neisseria* spp. on chocolate agar.

TABLE 39.3 Colonial Appearance and Other Characteristics on Chocolate Agar[a]

Organism	Appearance
Moraxella catarrhalis	Large, pinkish to brown, opaque, smooth; friable "hockey puck" consistency: colony may be moved intact over the surface of the agar.
Neisseria gonorrhoeae	Small, grayish white, convex, translucent, shiny colonies with either smooth or irregular margins; may be up to five different colony types on primary plates.
Neisseria meningitidis	Medium, smooth, round, moist, gray to white; encapsulated strains are mucoid; may be greenish cast in agar underneath colonies.
Neisseria cinerea	Small, grayish white; translucent; slightly granular.
Neisseria elongata	Small, grayish white; translucent
Neisseria flavescens	Medium, yellow, opaque, smooth.
Neisseria lactamica	Small, nonpigmented or yellowish, smooth, transparent.
Neisseria mucosa	Large, grayish white to light yellow, translucent; mucoid because of capsule.
Neisseria polysaccharea	Small, grayish white to light yellow, translucent, raised.
Neisseria sicca	Large, nonpigmented, wrinkled, coarse and dry, adherent.
Neisseria subflava	Medium, greenish yellow to yellow, smooth, entire edge.

[a] Appearance on blood agar is the same as on chocolate agar except for pigmentation; colonies are less opaque on blood agar. Note: *N. gonorrhoeae* does not grow on classic sheep blood agars.

Approach to Identification

Various commercial systems are available for the rapid identification of the coccoid *Neisseria* spp. and *M. catarrhalis.* These systems use biochemical or enzymatic substrates and work very well for the pathogenic species (*N. gonorrhoeae, N. meningitidis,* and *M. catarrhalis*). A heavy inoculum of the organism is required, but because these systems detect the activity of preformed enzymes, viability of the organisms in the inoculum is not essential. Manufacturers' instructions should be followed exactly; several systems have been developed for strains isolated on selective media and should not be used to test other gram-negative diplococci.

Biochemical Identification

Table 39.4 presents some conventional biochemical tests that traditionally have been used to identify these organisms. The extent to which identification of isolates is carried out depends on the source of the specimen and the suspected species of the organism involved.

An isolate from a child or a person involved in a case of sexual abuse must be identified unequivocally because of the medicolegal ramifications of the results. It is recommended that these organisms be identified using at least two different types of tests (i.e., biochemical, immunologic, enzymatic,

TABLE 39.4 Biochemical and Physiologic Characteristics of *Moraxella catarrhalis* and Coccoid *Neisseria* spp.

Organism	Growth On:			Rapid Fermentation Sugars								
	Modified Thayer-Martin[a]	Nutrient Agar at 35°C	Blood or Chocolate Agar at 25°C	Glucose	Maltose	Lactose	Sucrose	Fructose	Nitrate Reduction	Gas from Nitrate Reduction	0.1% Nitrite Reduction	Superoxol (30% H_2O_2)

Neisseria subflava[i]	–	+	+	V	+	–	–	–	–	–	+	2+

[a] Growth defined as >10 colonies.

[b] Butyrate and DNase positive.

[c] *N. cinerea* may be differentiated from *N. flavescens* by a positive reaction with the amylosucrase test.

[d] Some strains of *N. cinerea* may appear glucose-positive in some rapid systems and be mistaken for *N. gonorrhoeae*. However, *N. cinerea* grows on nutrient agar at 35°C and reduces nitrite, unlike *N. gonorrhoeae.*

[e] *N. elongata* subsp. *glycolytica* is positive for acid production from glucose.

[f] *N. subflava* biovar *flava* is positive for acid production from fructose and *N. subflava* biovar *perflava* is positive for acid production from sucrose and fructose.

[g] Only 2 of 10 strains were tested.

[h] *Kingella denitrificans* may grow on modified Thayer-Martin agar and be mistaken for *N. gonorrhoeae* on microscopic examination. However, *K. denitrificans* can reduce nitrate and is catalase negative, unlike *N. gonorrhoeae*.

[i] *Neisseria subflava* produces a yellow pigment on Loeffler agar; *N. sicca* does not.

+, >90% of strains positive; (+), >90% of strains positive but reaction may be delayed (i.e., 2–7 days); –, >90% of strains negative; *V*, variable.

Data compiled from Centers for Disease and Control; Carroll KC, Pfaller MA, Landry ML, et al. *Manual of Clinical Microbiology*. 12th ed. Washington, DC: ASM; 2019; and Weyant RS, Moss CW, Weaver RE, et al, editors. *Identification of Unusual Pathogenic Gram-negative Aerobic and Facultatively Anaerobic Bacteria*. 2nd ed. Baltimore: Williams & Wilkins; 1996.

amplified nucleic acid–based testing or by matrix-assisted laser desorption ionization time-of-flight mass spectroscopy (MALDI-TOF MS). Isolates from normally sterile body fluids should also be completely identified. However, isolates from genital sites in adults at risk of STI can be identified presumptively (i.e., oxidase-positive, gram-negative diplococci that grow on gonococcal selective agar). Likewise, an oxidase-positive, gram-negative diplococcus that hydrolyzes tributyrin using the enzyme butyrate esterase from an eye or ear culture can be identified as *M. catarrhalis* (Fig. 12.7).

Matrix-Assisted Laser Desorption Ionization Time-of-Flight Mass Spectrometry

MALDI-TOF MS is an automated mass spectrometry system that can identify organisms based on their protein structure (Chapter 7). Two major mass spectrometry systems are available for and have demonstrated the ability to identify *Neisseria* and *Moraxella* species. There have been reports of misidentification of commensal *Neisseria* species as *N. meningitidis*. Only organisms that are FDA-cleared for the specific MALDI-TOF MS system may be reported; however, other species may be validated by the individual laboratory.

Comments About Specific Organisms

Determination of carbohydrate utilization patterns historically has been performed in cysteine trypticase soy agar (CTA) with 1% glucose (dextrose), maltose, lactose, and sucrose (Evolve Procedure 39.1). This medium is no longer widely used because it does not work well for oxidative *Neisseria* spp., specifically *N. gonorrhoeae* and *N. meningitidis.* Carbohydrate utilization patterns are currently determined by inoculating an extremely heavy suspension of the organism to be tested in a small volume of buffered, low-peptone substrate with the appropriate carbohydrate. These methods do not require subculture or growth, and results are available in approximately 4 hours. Other rapid identification kits that are commercially available include the *Neisseria* Preformed Enzyme Test (PET) (BioConnections, Knypersley, United Kingdom), the RapID NH (ThermoFisher Scientific, Waltham, MA), or the API NH (bioMérieux, Marcy-l'Étoile, France). Each of these different kits has varying levels of sensitivity for correctly identifying *N. gonorrhoeae,* especially if the strain is proline iminopeptidase (Pip) negative.

Saprophytic *Neisseria* spp. are not routinely identified in the clinical laboratory. *Neisseria cinerea* may be misidentified as *N. gonorrhoeae* if the isolate produces a weak positive glucose (dextrose) reaction. However, it grows on nutrient agar at 35°C, whereas the gonococcus does not. Moreover, *N. cinerea* is inhibited by colistin, whereas *N. gonorrhoeae* is not.

M. catarrhalis can be differentiated from the gonococci and meningococci based on its growth on blood agar at 22°C and on nutrient agar at 35°C, the reduction of nitrate to nitrite, its inability to use carbohydrates, and its production of DNase. Severe *M. catarrhalis* is the only member of this group of organisms that hydrolyzes DNA.

Chromogenic substrate enzyme tests for beta-galactosidase, gamma-glutamyl aminopeptidase, and prolyl-hydroxyl prolyl aminopeptidase are available for the differentiation of *N. gonorrhoeae, N. meningitidis, N. lactamica,* and *M. catarrhalis. M. catarrhalis* lacks all three of these enzymes. The presence of prolyl-hydroxyl prolyl aminopeptidase alone identifies an organism as *N. gonorrhoeae.* The presence of beta-galactosidase and gamma-glutamyl aminopeptidase indicates *N. meningitidis.* Two commercial chromogenic substrate kits are the Gonocheck II (EY Laboratories, San Mateo, CA) and BactiCard *Neisseria* (Remel Laboratories, Lenexa, KS). A limitation of these methods is misidentification of various nonpathogenic strains of *Neisseria* spp. In addition, isolate colonies on selective media should be used to prevent misidentification of contaminants as a *Neisseria* spp. Modified chromogenic substrate kits, such as the BactiCard *Neisseria,* can be used to identify and speciate *Neisseria* and *Haemophilus* organisms from selective and nonselective media. These modified tests use a combination of enzyme substrate tests and additional biochemical tests.

N. lactamica may grow on selective media and may be confused with *N. meningitidis.* The ONPG test (Procedure 12.32) is used to determine an organism's ability to produce beta-galactosidase, which is an indicator of lactose utilization. *N. lactamica* is ONPG positive, and *N. meningitidis* is ONPG negative.

The eugonic fermenter *N. animaloris* propagates well on routine laboratory media and ferments glucose (dextrose); this distinguishes it from dysgonic fermenters that grow poorly on blood and chocolate agars (Chapter 27). *N. animaloris* ferments no carbohydrates other than glucose and is indole negative and arginine dihydrolase positive.

Immunoserologic Identification

A single particle agglutination method is available for immunoserologic identification of *N. gonorrhoeae* in the United States. The GonoGen II test (Becton Dickinson, Sparks, MD) can be performed from colonies growing on primary plates in which isolates are typed with specific monoclonal antibodies. The GonoGen II is a colorimetric test that uses antibodies adsorbed to metal sol particles. False-positives have occurred with *N. lactamica* and *N. meningitidis,* as well as false-negatives with other isolates. Extended protein extraction methods can be used to improve the sensitivity and specificity of the test.

Serotyping

Twelve different serogroups are distinguishable for *N. meningitidis.* Antisera are commercially available for identifying *N. meningitidis* serogroups A, B, C, H, I, K, L, W135, X, Y, and Z. Some manufacturers produce polyvalent antisera containing combinations of serogroups for identification. Serologic identification is usually performed by slide agglutination. A, B, C, W135, and Y are the serotypes that most commonly cause systemic disease in the United States. Serotyping is an important tool that reference or public health laboratories should possess to help aid in the identification of clusters of cases that may be related during outbreak investigations.

Nucleic acid amplification methods referred to as genogrouping are more reliable for the identification of commensal strains of *Neisseria* species. Whole genome sequencing is expected to replace serotyping.

Antimicrobial Susceptibility Testing and Therapy

Although beta-lactamase production is common among *M. catarrhalis* isolates, many beta-lactam antimicrobials maintain activity against these isolates. Because several other agents are also effective, susceptibility testing to guide therapy is not routinely required.

Standard methods have been established for performing *in vitro* susceptibility testing with *N. gonorrhoeae* and *N. meningitidis* (Chapter 11). The Clinical and Laboratory Standards Institute (CLSI) recommends the use of agar dilution for minimum inhibitory concentration (MIC) measurements and GC agar containing 1% growth supplement for *N. gonorrhoeae* disk diffusion methods.

In addition, various agents can be considered for testing and therapeutic use. Historically, fluoroquinolones were widely used to treat gonorrhea; however, resistance to these agents has emerged (i.e., fluoroquinolone-resistant *N. gonorrhoeae* [FRNG]), and they are no longer recommended for treatment of gonococcal infections.

The Gonococcal Isolate Surveillance Project (GISP) is a national collaborative surveillance project in the United States. The program was established in 1986 to analyze and monitor antimicrobial resistance trends among *N. gonorrhoeae*. Participating regional labs test isolates for resistance to antimicrobials that were commonly prescribed to treat gonococcal urethritis, including azithromycin, cefixime, ceftriaxone, ciprofloxacin, gentamicin, penicillin, and tetracycline.

Because of increasing resistance of fluoroquinolones reported in 2007, the CDC stopped recommending these agents (e.g., ciprofloxacin, levofloxacin) for treatment of gonococcal urethritis. This left cephalosporins as the only treatment option. In 2010, the CDC recommended dual therapy of a cephalosporin with azithromycin or tetracycline. Between 2006 and 2011, MICs to the oral cephalosporin cefixime have increased, and more treatment failures were reported throughout the world. As a result, in 2015 the CDC issued an update to their treatment guidelines that suggests a single-dose intramuscular injection of 250 mg of ceftriaxone taken along with either a 1-g oral dose of azithromycin or 100 mg oral doxycycline twice daily for 7 days. However, because many patients may be co-infected with *C. trachomatis*, dual therapy with azithromycin is recommended for eliminating both infections, as *C. trachomatis* is susceptible to a 1-g oral dose of azithromycin. Patients with severe penicillin immunoglobulin E (IgE)-mediated allergies may warrant treatment with an alternative regimen; however, there are limited data on their utility. Alternative therapy includes a single-dose of 320 mg oral gemifloxacin with 2 g of oral azithromycin, or a single-dose intramuscular injection with 240 mg gentamicin and 2 g oral dose of azithromycin.

Although beta-lactamase production in *N. meningitidis* is rare, decreased susceptibility to penicillin, mediated by altered penicillin-binding proteins, is emerging. Resistance to sulfonamides is also quite common. The CLSI recommends that susceptibility testing be performed by disk diffusion on Mueller-Hinton agar or using cation-adjusted Mueller-Hinton broth in microdilution. All testing should occur within a biologic safety cabinet to minimize laboratory-acquired infections.

Prevention

The CDC recommends vaccination against *N. meningitidis* to prevent meningitis in adolescents and young adults. Currently, 11- to 12-year-olds should be vaccinated with a quadrivalent meningococcal conjugate vaccine. The two quadrivalent vaccines in the United States protect against serogroups A, C, W, and Y. The CDC recommends that a booster vaccine be given around age 16. If the initial vaccine is given to an adolescent between 13 and 15 years of age, the booster should be administered at age 18, when the patient enters a period of increased risk. Children with weakened immune systems (human immunodeficiency virus [HIV] positive, asplenia, complement deficiency, or some immunosuppressive drugs) should be given the quadrivalent vaccines earlier; depending on the age and disease, this may start as early as 8 weeks old and is given in multiple doses. There is also a vaccine available for serogroup B *N. meningitidis.* Historically, this vaccine was recommended only for people 10 years of age and older who had been identified as being at increased risk for exposure to serogroup B (e.g., community outbreak). However, the Advisory Committee on Immunization Practices has revised their position and allows individual clinical decision-making regarding the use of the serogroup B meningococcal vaccine. This is a multistep vaccination, and for each dose, the same manufacturer should be used because they are not interchangeable.

Ophthalmia neonatorum occurs when *N. gonorrhoeae* from an infected mother is transmitted to the newborn during vaginal delivery. Previously, this was a leading cause of neonatal blindness. Prophylactic administration of antimicrobials after birth has dramatically reduced the development of gonococcal conjunctivitis. The CDC recommends a single dose of 0.5% erythromycin ophthalmic ointment into each eye at birth. Silver nitrate is no longer manufactured in the United States, and povidone-iodine has not been adequately studied and is therefore not recommended.

CASE STUDY 39.1

An elderly male with a history of chronic obstructive pulmonary disease (COPD) after 20 years of heavy smoking presents to the emergency department with shortness of breath; severe cough; and profuse, yellow sputum production. Crackles and wheezing can be heard on chest examination. A sputum culture is positive for many intracellular gram-positive, lancet-shaped diplococci. Gram-negative diplococci were observed in the smear. The patient was placed on amoxicillin/clavulanic acid, and other supportive measures.

Questions

1. List the pathogenic agents most often found to be involved in acute infections of patients with COPD.
2. List the tests required to identify *Moraxella catarrhalis* definitively and rapidly.
3. The culture from this patient grew *Streptococcus pneumoniae* and *M. catarrhalis*. What antibiotics could be used to treat both infections? Is susceptibility testing necessary with this isolate or can empiric therapy be used?

PROCEDURE 39.1

Carbohydrate Utilization Method—Cysteine Trypticase Soy Agar

Purpose

The carbohydrate utilization method is the traditional method used to identify *Neisseria* spp. based on carbohydrate utilization in cysteine trypticase soy agar (CTA) with the addition of 1% of a specific carbohydrate (glucose [dextrose], maltose, lactose, or sucrose) and phenol red as a pH indicator.

Method

1. Using an inoculating loop, prepare a heavy inoculum in saline of a pure isolate from a subculture no more than 24 hours old obtained on nonselective media.
2. Using an inoculating needle, transfer the sample from the prepared tube and stab the top half of the CTA carbohydrate tube. Inoculate one of each of the CTA media: glucose, maltose, lactose, and sucrose.
3. Tightly cap the tubes and incubate at 35°C–37°C in ambient air. Incubate an uninoculated control tube simultaneously.
4. After incubation, examine the tubes within 24–72 hours for a yellow color at the top of the media; this indicates acid production and a positive result for the carbohydrate utilization test.

Expected Results and Quality Control

Positive: Yellow color at the top of the tube only, indicating carbohydrate use.
Negative: No color change compared with the control, an uninoculated tube.

Organism	Glucose	Maltose	Lactose	Sucrose	Fructose
Neisseria cinerea	Neg	Neg	Neg	Neg	Neg
Neisseria elongata	Neg	Neg	Neg	Neg	Neg
Neisseria flavescens	Neg	Neg	Neg	Neg	Neg
Neisseria lactamica	Pos	Pos	Pos	Neg	Neg
Neisseria gonorrhoeae	Pos	Neg	Neg	Neg	Neg
Neisseria meningitidis	Pos	Pos	Neg	Neg	Neg
Neisseria mucosa	Pos	Pos	Neg	Pos	Pos
N. subflava biovar *flava*	Pos	Pos	Neg	Neg	Pos
N. subflava biovar *perflava*	Pos	Pos	Neg	Pos	Pos
Neisseria subflava biovar *subflava*	Pos	Pos	Neg	Pos	Pos
Moraxella catarrhalis	Neg	Neg	Neg	Neg	Neg

Limitations

Avoid incubation in carbon dioxide (CO_2), which may alter the pH of the media, resulting in a color change to yellow throughout the entire tube and a false-positive reaction. A yellow color change throughout the tube also may indicate the presence of contaminating organisms. Caution should be used in interpreting the test result, and other confirmatory tests should be performed.

Chapter Review

1. Which organism is *not* a normal inhabitant of the respiratory tract?
- **a.** *M. catarrhalis*
- **b.** *N. meningitidis*
- **c.** *N. mucosa*
- **d.** *N. gonorrhoeae*

2. For which of the following are quadrivalent vaccines available?
- **a.** *B. pertussis*
- **b.** *M. catarrhalis*
- **c.** *N. meningitidis*
- **d.** *N. gonorrhoeae*

3. Which of the following is a leading sexually transmitted infection?
- **a.** *N. gonorrhoeae*
- **b.** *N. lactamica*
- **c.** *N. sicca*
- **d.** *N. mucosa*

4. Identification of *N. gonorrhoeae* can be accomplished by all of the following *except*:
- **a.** Particle agglutination
- **b.** Gram stain
- **c.** MALDI-TOF MS
- **d.** Amplified assays

5. Which of the following media is *not* acceptable for primary growth of *N. gonorrhoeae*?
- **a.** Chocolate
- **b.** Thayer-Martin
- **c.** Blood
- **d.** Martin-Lewis

6. *M. catarrhalis* grows best under which conditions?
- **a.** Anaerobic atmosphere
- **b.** 42°C
- **c.** Increased CO_2
- **d.** 25°C

7. *N. gonorrhoeae* can be differentiated from *N. meningitidis* by:
- **a.** Dextrose fermentation
- **b.** Maltose fermentation
- **c.** Lactose fermentation
- **d.** Nitrate reduction

8. All of the following statements about *N. gonorrhoeae* are true *except:*
- **a.** Particle agglutination methods are available for identification.
- **b.** The sample should be incubated at 36°C for 72 hours in a CO_2-enriched environment.
- **c.** The sample may be refrigerated if plating is delayed.
- **d.** The organism may appear to have up to five different colony types.

9. An organism grows on blood agar at room temperature and nutrient agar at 37°C. The organism has the ability to use carbohydrates and is nitrate positive, DNase positive, and ONPG negative. This organism is:
- **a.** *N. gonorrhoeae*
- **b.** *N. meningitidis*
- **c.** *N. lactamica*
- **d.** *M. catarrhalis*

10. All of the following are advantages of using amplified testing over culturing *except:*
- **a.** It is more sensitive.
- **b.** It is suitable for large screening programs.
- **c.** It is admissible in medicolegal cases.
- **d.** It allows testing for *C. trachomatis* at the same time.

11. **True or False**

_____ Men who have sex with men (MSM) are the primary reservoirs for the dissemination of *N. gonorrhoeae* in the human population.

_____ CTA sugars do not require subculture for growth and can be read in 4 hours.

_____ Infection with *M. catarrhalis* may lead to severe disseminated disease.

_____ Genital isolates of *Neisseria* spp. in adults with high-risk behavior must be completely identified.

_____ The presence of prolyl-hydroxyl prolyl aminopeptidase alone identifies an organism as *N. meningitidis.*

12. **Matching:** *Match the correct term with the appropriate description.*

_____ *N. gonorrhoeae*
_____ *N. meningitidis*
_____ Thayer-Martin
_____ Saprophytic
_____ JEMBEC
_____ A, B, C, Y, and W135
_____ A, C, Y, and W135

a. nonpathogenic
b. CO_2-generating culture system
c. *N. meningitidis* groups seen in the United States
d. Antigens in a *N. meningitidis* vaccine
e. Leading cause of STIs
f. Selective agar for culturing *Neisseria* spp.
g. Cause of fatal bacterial meningitis

13. **Short Answer**

A synovial fluid sample is submitted for culture during the night shift at approximately 2 a.m. The laboratory is short-staffed and busy testing and supplying blood products after a local nightclub shooting. The synovial fluid sample is placed in the refrigerator until sufficient time is available to plate the sample to the appropriate media. At approximately 6 a.m., the day shift personnel find the specimen in the refrigerator. If the physician suspects an isolate of the organisms discussed in this chapter, how should the laboratory staff proceed? Should the specimen be processed, or should a repeat sample be submitted? Explain your reasoning.

40

Overview and General Laboratory Considerations

OBJECTIVES

This chapter provides an overview of the methods used to identify anaerobic microorganisms. The detailed technical procedures discussed are designed for use in conjunction with specifics provided in Chapter 41 to develop a clear understanding of the full process, from specimen collection to identification. However, readers should consider the following general objectives for the information and methods provided.

1. State the specific diagnostic purpose for the test methodology.
2. Briefly describe the test principle associated with the test methodology.
3. Outline limitations and describe a process for troubleshooting or reporting results if a test result is equivocal or indistinguishable.
4. State the appropriate quality-control organisms and results used with each testing procedure.
5. Define and differentiate obligate (strict), moderate, facultative, and aerotolerant anaerobes.
6. List suitable specimens for isolation of anaerobic bacteria and characteristics of these specimens that might suggest the presence of an anaerobic infection.
7. Explain the proper techniques for collecting, transporting, and processing clinical specimens for anaerobic bacteriology.
8. Explain the use of antigen detection methodologies in the diagnosis of anaerobic infections.
9. List the media used for cultivation of anaerobic bacteria.
10. Describe the appropriate incubation conditions for cultivation of anaerobic bacteria.
11. Describe the procedures for the identification of and antibiotic susceptibility testing for anaerobic bacteria.

General Characteristics

The organisms described in this chapter and in Chapter 41 are common etiological agents of a variety of clinical conditions. The organisms included in this chapter are predominant in the human microbiome and are often opportunistic pathogens. These organisms do not grow in the presence of oxygen (O_2); they are **obligate** or **strict anaerobes** (0% O_2). Obligate anaerobes are killed upon brief exposure (less than a few minutes) to atmospheric oxygen. Obligate anaerobes include *Prevotella* spp., *Fusobacterium* spp., and *Bacteroides* spp., which are included in these chapters. These chapters also include some **aerotolerant organisms** (5% O_2), such as *Actinomyces* spp., *Bifidobacterium* spp., and *Clostridium* spp., which are capable of growth in the presence of either reduced or atmospheric oxygen (microaerobic) but grow best under anaerobic conditions. Finally, **facultative anaerobes** do not require atmospheric oxygen but are capable of growth in oxygen and anaerobic environments.

Anaerobic organisms lack superoxide dismutase and catalase, the enzymes required to break down reactive oxygen species produced during respiration or aerobic metabolism. In addition, oxygen has a high affinity for organic compounds containing nitrogen, hydrogen, carbon, and sulfur, which interfere with normal biologic activity. Because they are unable to protect themselves against the action of oxygen, anaerobes require an environment free of oxygen to survive and grow.

Specimen Collection and Transport

The importance of proper collection and transport of specimens for anaerobic culture cannot be overemphasized. Because indigenous anaerobes are often present in large numbers as normal microbiota on mucosal surfaces, even minimal contamination of a specimen can produce misleading results. Box 40.1 shows the specimens acceptable for anaerobic culture; Box 40.2 presents specimens that are likely to be contaminated and therefore are unacceptable for anaerobic culture. In general, material for anaerobic culture is best collected by tissue biopsy or by aspiration using a needle and syringe to prevent contamination with normal microbiota. After collection, the air must be expelled from the device to prevent the reduction or loss of viable anaerobes in the sample. Because of the potential for contamination with normal microbiota, swabs are generally not recommended for the collection of anaerobes.

• BOX 40.1 Clinical Specimens Suitable for Anaerobic Culture

Bile
Biopsy of endometrial tissue obtained with an endometrial suction curette (Pipelle; Unimar, Wilton, CT)
Blood
Bone marrow
Bronchial washings obtained with a double-lumen plugged catheter
Cerebrospinal fluid
Culdocentesis aspirate
Decubitus ulcer (if obtained from base of the lesion after thorough debridement of the ulcer's surface)
Fluid from normally sterile site (e.g., joint)
Material aspirated from abscesses (the best specimens are from loculated or walled-off lesions)
Percutaneous (direct) lung aspirate or biopsy
Peritoneal (ascitic) fluid
Sulfur granules from a draining fistula
Suprapubic bladder aspirate
Thoracentesis (pleural) fluid
Tissue obtained at biopsy or autopsy
Transtracheal aspirate
Uterine contents (if collected using a protected swab)

• BOX 40.2 Clinical Specimens Unsuitable for Anaerobic Culture

Bronchial washing or brush (unless collected with a double-lumen plugged catheter)
Coughed (expectorated) sputum
Feces (except for *Clostridioides difficile*)
Gastric or small-bowel contents (except in blind loop syndrome)
Ileostomy or colostomy drainage
Nasopharyngeal swab
Rectal swab
Secretions obtained by nasotracheal or orotracheal suction
Swab of superficial (open) skin lesion
Throat swab
Urethral swab
Vaginal or cervical swab
Voided or catheterized urine

However, as previously described in Chapter 5, flocked swabs commercially available from numerous manufacturers have an improved design that enhances the recovery of both aerobes and anaerobes but are still prone to contamination and can be used when no other specimen type may be collected.

A crucial factor in obtaining valid results with anaerobic cultures is the transport of the specimen; the lethal effect of atmospheric oxygen must be nullified until the specimen can be processed in the laboratory. Recapping a syringe and transporting the needle and syringe to the laboratory is no longer acceptable because of safety concerns involving needle stick injuries. Even aspirates must be injected into an oxygen-free transport tube or vial. A large variety of transport devices that contain prereduced anaerobic media for the preservation of microorganisms are available commercially.

Macroscopic Examination of Specimens

Upon receipt in the laboratory, specimens should be inspected for characteristics that strongly indicate the presence of anaerobes: (1) foul odor; (2) sulfur granules (associated with *Actinomyces* spp., *Propionibacterium* spp., or *Eubacterium* sp.); and (3) brick red fluorescence under long wavelength ultraviolet (UV) light (associated with pigmented *Prevotella* or *Porphyromonas* spp.).

Direct Detection Methods

Gram Staining

The Gram stain is an important rapid tool for anaerobic bacteriology. Gram stain morphology from direct specimens should be carefully noted if an anaerobic infection is suspected, because organisms may no longer be viable and additional testing, such as anaerobic cultures, may demonstrate no growth. Not only does a properly performed Gram stain reveal the types and relative numbers of microorganisms and host cells present, it also serves as a quality control measure for the adequacy of anaerobic techniques. The absence of leukocytes does not rule out the presence of a serious anaerobic infection, however, because certain organisms, such as clostridia, produce necrotizing toxins that destroy white blood cells. A positive Gram stain with a negative culture may indicate (1) poor transport methods, (2) excessive exposure to air during specimen processing, (3) failure of the system (jar, pouch, or chamber) to achieve an anaerobic atmosphere, (4) inadequate types of media or old media, or (5) killing of microorganisms by antimicrobial therapy.

Standard Gram stain procedures and reagents are used, except that the safranin counterstain is left on for 3 to 5 minutes. Gram-negative anaerobes often stain poorly with safranin, resulting in failure to visualize pathogenic organisms. As an alternative, 0.5% aqueous basic fuchsin can be used as the counterstain to improve identification of gram-negative anaerobes. In addition, some gram-positive anaerobes (e.g., *Clostridium* spp.) stain pink. Enhanced Gram stain reagents are available that contain different concentrations in the reagents, in addition to a Gram enhancer, which is applied after decolorization to suppress the red color in the background, aiding the differentiation of gram-negative anaerobes.

Table 40.1 presents the cellular morphology seen with Gram staining of common anaerobes.

TABLE 40.1 Minimal Criteria Grouping Gram Stain Morphology, Aerotolerance, and Clinical Significance of Anaerobic Bacteria

Organism	Gram Stain[a]	Clinical Significance
Actinobaculum spp.	Gram-positive slightly curved rods; some species may branch	Urinary tract infections
Actinomyces spp.	Gram-positive, branching, beaded or banded, thin, filamentous rods	Actinomycosis; orocervicofacial, thoracic, and abdominopelvic forms
Actinotignum spp.	Gram-positive straight or slightly curved rods	Urinary tract infections
Alloscardovia spp.	Gram-positive short irregular shaped rods	Urinary tract infections
Alistipes spp.	Gram-negative rods	Appendicitis, intraabdominal fluids, abscesses, and urine
Anaerococcus spp.	Gram-positive cocci arranged in short chains or tetrads	Wound infections
Anaeroglobus sp.	Gram-negative cocci with cells approximately 0.5–1.1 μm in diameter	Postoperative wounds
Atopobium spp.	Elongated gram-positive cocci or coccobacilli; occur singly, in pairs, or in short chains	Bacterial vaginosis
Bacteroides spp.	Gram-negative, straight rods with rounded ends; occur singly or in pairs; cells may be described as resembling a safety pin (Fig. 41.4)	Bacteremia, ulcers, abscesses, bronchial secretions, bone, intraabdominal infections; body fluids
Bifidobacterium spp.	Gram-positive diphtheroid; coccoid or thin, pointed shape; or larger, highly irregular, curved rods with branching; rods terminate in clubs or thick, bifurcated (forked) ends ("dog bones")	Predominantly bacterium but may be isolated from a variety of sources
Bilophila wadsworthia	Gram-negative, pale-staining, delicate rods	Intraabdominal infections, abscesses, and bacteremia
Bulleidia spp.	Gram-positive short, straight, or slightly curved; singly or in pairs	Periodontitis and abscesses
Catabacter spp.	Gram-positive coccobacilli or short rods	Bacteremia
Clostridioides difficile	Gram-positive straight rods; may produce chains of up to six cells aligned end to end; spores oval and subterminal	Antibiotic associated disease, diarrhea, and colitis
Clostridium botulinum	Gram-positive, straight rods; occur singly or in pairs; spores usually subterminal and resemble a tennis racket	Food poisoning, botulism; wound botulism and infant botulism, a life-threatening neuromuscular disorder
Clostridium clostridioforme	Gram-positive rod that stains gram negative; long, thin rods; spores usually not seen; elongated football shape with cells often in pairs	Variety of human infections that may be serious and invasive
Clostridium histolyticum		Bacteremia; trauma associated gas gangrene; skin and other soft tissue infections
Clostridium novyi	Gram-positive rods with subterminal spores	Skin and other soft tissue infections; cutaneous gas gangrene
Clostridium perfringens	Gram-variable straight rods with blunt ends; occur singly or in pairs; spores seldom seen but if present are large and central to subterminal, oval, and swell cell; large boxcar shapes	Bacteremia; trauma-associated gas gangrene, skin and other soft tissue infections; enteric foodborne disease (food poisoning); enteritis necroticans and necrotizing enterocolitis; anaerobic cellulitis
Clostridium ramosum	Gram-variable straight or curved rods; spores rarely seen but are round and terminal; more slender and longer than *C. perfringens*	Abscesses, peritonitis, bacteremia, and chronic otitis media in children; bacteremia in adults

Continued

TABLE 40.1 **Minimal Criteria Grouping Gram Stain Morphology, Aerotolerance, and Clinical Significance of Anaerobic Bacteria—cont'd**

Organism	Gram Stain[a]	Clinical Significance
Clostridium septicum	Gam positive in young cultures but becomes gram negative with age; stains unevenly; straight or curved rods; occur singly or in pairs; spores subterminal, oval, and swell cells	Bacteremia; trauma-associated gas gangrene; skin and other soft tissue infections; spontaneous nontraumatic gas gangrene
Clostridium sordellii	Gram-positive rods; subterminal spores	Skin and other soft tissue infections; cutaneous gas gangrene; gynecological infections; anaerobic cellulitis
Clostridium tertium	Gram-variable rods; terminal spores	Neutropenic enterocolitis and meningitis in immunocompromised patients
Clostridium tetani	Gram positive, becoming gram negative after 24-h incubation; occur singly or in pairs; spores oval and terminal or subterminal with drumstick or tennis racket appearance	Tetanus associated with puncture wounds
Cryptobacterium spp.	Gram-positive short rods in chains	Oral infections
Curtobacterium spp.	Pleomorphic gram-positive rods, may be branching	Associated with prosthetic infections such as joints and heart valves
Eggerthella spp.	Gram-positive, small, straight rod with rounded ends	Bacteremia
Eggerthii spp.	Gram-positive irregular rods in short chains	Dental abscess with bacteremia; empyema
Eisenbergiella spp.	Gram-positive medium to long, wavy filamentous rods with tapered ends	Bacteremia
Eubacterium spp.	Gram-positive pleomorphic rods or coccobacilli; occur in pairs or short chains; *Eubacterium alactolyticum* has a seagull-wing shape similar to *Campylobacter* spp.; *Eubacterium nodatum* is similar to *Actinomyces* spp. with beading, filaments, and branching	Oral and other various infections; abscesses, bacteremia, sinusitis, tonsillitis
Filifactor spp.	Gram-positive short, regular bacilli	Oral infections
Finegoldia magna	Gram-positive cocci with cells >0.6 μm in diameter; in pairs and clusters; resemble staphylococci	Infections in various body sites including endocarditis, meningitis, pneumonia, skin, and soft tissue; bone and joint infections, chronic wounds and ulcers, septic arthritis, upper respiratory infections; bacteremia
Fusobacterium spp.	Gram-negative, pale-staining, irregularly stained, highly pleomorphic rods with swollen areas, filaments, and large, bizarre, round bodies	Oral and other various infections; abscesses, bacteremia, sinusitis, tonsillitis
Lactobacillus spp.	Gram-variable pleomorphic rods or coccobacilli; straight, uniform rods have rounded ends; short coccobacilli resemble streptococci	Bacteremia, endocarditis, intraabdominal abscesses; various other infections
Leptotrichia spp.	Gram-negative, large, fusiform rods with one pointed end and one blunt end	Bacteremia in immunocompromised patients; lesions in the oral and gastrointestinal mucosa; endocarditis; bacterial vaginosis
Mobiluncus spp.	Gram-variable, small, thin, curved rods; the two species can be divided based on cell length	Vaginal tract; bacterial vaginosis
Mogibacterium spp.	Gram-positive short rods	Oral infections
Moryella spp.	Gram-positive elongated rods with pointed ends	Abscesses
Olsenella spp.	Short, elliptical gram-positive rods; occur singly, in pairs, or short chains	Dental caries

TABLE 40.1 **Minimal Criteria Grouping Gram Stain Morphology, Aerotolerance, and Clinical Significance of Anaerobic Bacteria—cont'd**

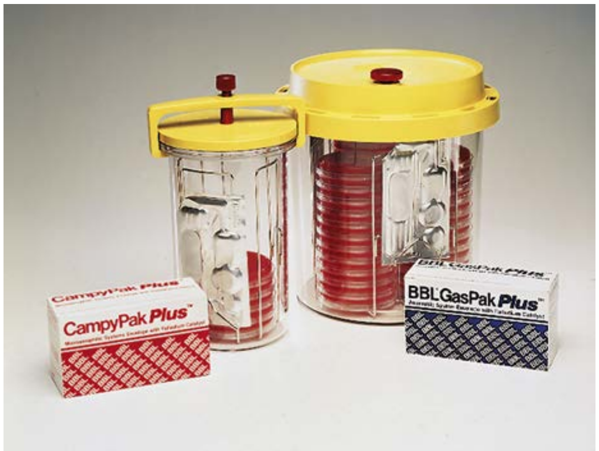
Organism	Gram Stain[a]	Clinical Significance
Parabacteroides spp.	Gram-negative rods	Intraabdominal infections, bacteremia
Paraeggerthella sp.	Gram-positive, coccobacilli in chains	Bacteremia
Parvimonas micros	Gram-positive cocci with cells <0.7 μm in diameter; occur in packets and short chains	Oral pathogen, periodontal infections, skin and wound infections, intraabdominal infections, septicemia, gynecological infections, otitis media, and sinus infection
Peptoniphilus spp.		Pressure ulcers and rhinosinusitis
Peptostreptococcus spp.	Gram-positive, large coccobacillus; often in chains	Polymicrobial infections in a variety of body sites; acute and chronic wound infections
Porphyromonas spp.	Gram-negative coccobacilli	Periodontal disease, necrotizing ulcerative gingivitis, abscesses, intraabdominal, bacterial vaginosis, synovial fluid (arthritis)
Prevotella spp.	Gram-negative rods or coccobacilli; occur in pairs or short chains	Oral infections, necrotizing ulcerative gingivitis, pericoronitis, abscesses; associated with respiratory infections in cystic fibrosis patients, ventilator-associated pneumonia
Propionibacterium spp.	Gram-positive, pleomorphic, diphtheroid-like rod; club-shaped to palisade arrangements; called *anaerobic diphtheroids*	Acne and superficial skin infections
Propionimicrobium spp.	Gram-positive diphtheroid or club-shaped rods	Urinary tract infections
Pseudoramibacter spp.	Gram-positive pleomorphic rods that occur in pairs	Oral infections
Scardovia spp.	Gram-positive small, coccoid rods	Dental caries
Slackia spp.	Gram-positive cocci, coccobacilli, rods; singly or in clumps	Oral infections or abscesses
Solobacterium spp.	Gram-positive short, straight, or slightly curved rods that occur in pairs or short chains	Bacteremia; various infections
Tannerella spp.	Gram-negative rods	Periodontal disease, bacterial vaginosis, synovial fluid (arthritis)
Veillonella spp.	Gram-negative, tiny diplococci in clusters, pairs, and short chains	Polymicrobial infections of various body sites; meningitis, osteomyelitis, prosthetic joint infections, pleuropulmonary infection, bacteremia, and endocarditis
Varibaculum spp.	Gram-positive short, straight, or curved rods, diphtheroid	IUD infections

Specimen Processing

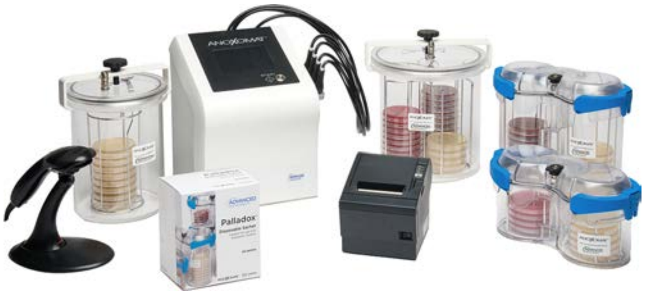
Specimens for anaerobic culture may be processed in the biologic safety cabinet, after which they are incubated in anaerobic jars or pouches or in an anaerobic chamber.

Anaerobe Jars or Pouches

The most commonly used system for creating an anaerobic atmosphere is the **anaerobe jar.** Anaerobe jars are available commercially from several companies. For example, the GasPak (Fig. 40.1) is made by Becton Dickinson (Sparks, MD); other companies that produce these devices include EM Diagnostic Systems (Gibbstown, NJ) and Oxoid USA (Columbus, MD). All of these systems use a clear, heavy plastic jar with a lid clamped down to make it airtight. Anaerobic conditions can be set up by two methods. The first method uses a commercially available envelope containing a hydrogen and CO_2 generator activated either by adding water (GasPak) or by the moisture on the agar plates (EM Diagnostic Systems and Oxoid USA). The production of heat within a few minutes (detected by touching the top



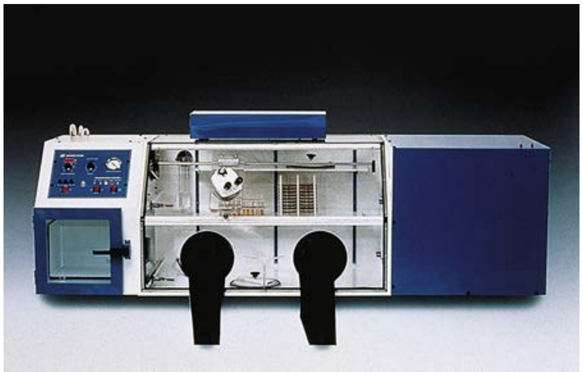
• **Fig. 40.1** GasPak anaerobe jar (BD Diagnostic Systems, Sparks, MD). Inside the jar are inoculated plates, an activated gas-generating envelope, and an indicator strip. A wire-mesh basket attached to the lid of the jar contains palladium-coated alumina pellets that catalyze the reaction to remove oxygen. Newer models of the GasPak jar use reagent packs that simply require the addition of water to catalyze a reaction (see text). (From Mahon CR. *Textbook of Diagnostic Microbiology.* 5th ed. St. Louis: Elsevier; 2015.)



• **Fig. 40.2** Advanced Anoxomat System for the cultivation of anaerobic, microaerophilic, and capnophilic organisms. (Photos courtesy Advanced Instruments, Inc., Norwood, MA.)

of the jar) and subsequent development of moisture on the walls of the jar are indications that the catalyst and generator envelope are functioning properly. Reduced conditions are achieved in 1 to 2 hours, although the methylene blue or resazurin indicators take longer to decolorize.

Alternatively, the **evacuation-replacement** method can be used to create a specific environment in a short period. Air is removed from the sealed jar by drawing a vacuum and replaced with a combination of three different gases. The final fill of the jar is made with a gas mixture containing 80% to 90% nitrogen, 5% to 10% hydrogen, and 5% to 10% CO_2. Many anaerobes require CO_2 for maximal growth. The Anoxomat (Advanced Instruments, Inc., Norwood, MA; Fig. 40.2) is a complete system for the culturing of anaerobes, capnophiles, and microaerophilic organisms. The system provides the flexibility of creating optimal conditions in separate jars and may be adapted to the laboratory's needs. The atmosphere in the jars is monitored using an indicator to check anaerobiosis. The disadvantage is that plates must be removed from the jars to view bacterial growth on the plates.



• **Fig. 40.3** Gloveless anaerobe chamber. Anaerobic chambers were developed more than 40 years ago, and a variety of new models are being used in cutting-edge research. (Courtesy Anaerobe Systems, Morgan Hill, CA.)

Anaerobe bags or **pouches** are useful for laboratories processing small numbers of anaerobic specimens. A widely used anaerobic pouch is the BD Biobag Type A (Becton Dickinson and Company, Franklin Lakes, NJ). Besides specimen transport, the pouch can be used to incubate one or two agar plates. If moisture or condensation has not accumulated on the inside of the bag or pouch, it is possible to view the plates without removing them from the bag.

Holding Jars

If anaerobic jars or pouches are used for incubation, holding jars should be used during specimen processing and examination of cultures. Holding jars are anaerobic jars with loosely fitted lids attached by rubber tubing to nitrogen gas. Uninoculated plates are kept in holding jars pending use for culture setup, and inoculated plates are kept in holding jars pending incubation or examination; this minimizes exposure to oxygen.

Anaerobe Chamber

Anaerobic chambers, or **glove boxes,** are made of molded or flexible clear plastic. The flexible clear plastic chambers are the most widely used type. Specimens and other materials are placed in the chamber through an air lock. The technologist uses gloves (Forma Scientific, Marietta, OH) or sleeves (Sheldon Manufacturing, Cornelius, OR) to form airtight seals around the arms (Fig. 40.3). Media stored in the chamber are kept oxygen-free, and all work on a specimen, from inoculation through workup, is performed under anaerobic conditions. A gas mixture of 5% CO_2, 10% hydrogen, and 85% nitrogen, plus a **palladium catalyst** (reacts with water to produce hydrogen and carbon dioxide), maintain the anaerobic environment inside the chamber.

Anaerobic Media

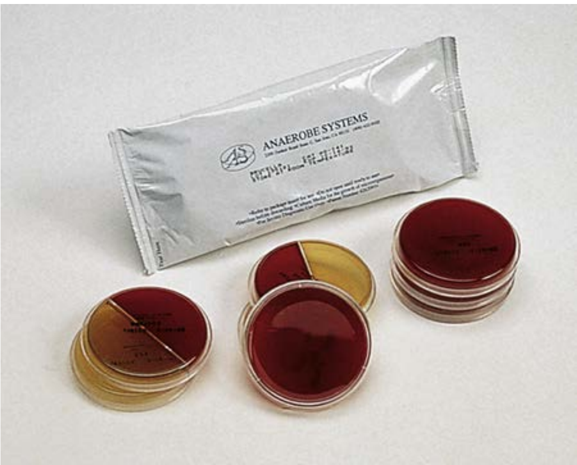
Initial processing of anaerobic specimens involves inoculation of appropriate media. Table 40.2 lists commonly used anaerobic media. Primary plates should be freshly prepared or used within 2 weeks of preparation. Plates stored for longer

TABLE 40.2 Common Anaerobic Media

Medium	Components/Comments	Primary Purpose
Anaerobic blood agar (Ana BA)	May be prepared with Columbia, Schaedler, CDC, *Brucella,* or brain-heart infusion base supplemented with 5% sheep blood, 0.5% yeast extract, hemin, L-cystine, and vitamin K_1.	Nonselective medium for isolation of anaerobes and facultative anaerobes
Bacteroides bile esculin agar (BBE)	Trypticase soy agar base with ferric ammonium citrate and hemin; bile salts and gentamicin act as inhibitors.	Selective and differential for *Bacteroides fragilis* group; good for presumptive identification
Laked kanamycin-vancomycin (LKV)	*Brucella* agar base with kanamycin (75 μg/ mL), vancomycin (7.5 μg/mL), vitamin K_1 (10 μg/mL), and 5% laked blood.	Selective for isolation of *Prevotella* and *Bacteroides* spp.
Anaerobic phenylethyl alcohol agar (PEA)	Nutrient agar base, 5% blood, phenylethyl alcohol.	Selective for inhibition of enteric gram-negative rods and swarming by some clostridia
Egg yolk agar (EYA)	Egg yolk base.	Nonselective for determination of lecithinase and lipase production by clostridia and fusobacteria
Cycloserine cefoxitin fructose agar (CCFA)	Egg yolk base with fructose, cycloserine (500 mg/L), and cefoxitin (16 mg/L); neutral red indicator.	Selective for *Clostridioides difficile*
Cooked meat (also called chopped meat) broth	Solid meat particles initiate growth of bacteria; reducing substances lower oxidation-reduction potential (Eh).	Nonselective for cultivation of anaerobic organisms; with addition of glucose, can be used for gas-liquid chromatography
Peptone–yeast extract–glucose broth (PYG)	Peptone base, yeast extract, glucose, cysteine (reducing agent), resazurin (oxygen tension indicator), salts.	Nonselective for cultivation of anaerobic bacteria for gas-liquid chromatography
Thioglycollate broth	Pancreatic digest of casein, soy broth, and glucose to enrich growth of most bacteria. Thioglycollate and agar reduce Eh. May be supplemented with hemin and vitamin K_1.	Nonselective for cultivation of anaerobes, facultative anaerobes, and aerobes

periods accumulate peroxides and become dehydrated; this results in growth inhibition. Reduction of media in an anaerobic environment eliminates dissolved oxygen but has no effect on the peroxides. Prereduced, anaerobically sterilized (PRAS) media are produced, packaged, shipped, and stored under anaerobic conditions. They are commercially available from a variety of manufacturers (Fig. 40.4) and have an extended shelf life of up to 6 months.

In general, anaerobic media should include a nonselective anaerobic blood agar (BA) (containing horse or sheep blood, additional hemin, and vitamin K) and all of the following selective media: ***Bacteroides* bile esculin agar (BBE), laked kanamycin-vancomycin BA (LKV), anaerobic phenylethyl alcohol agar (PEA), and an anaerobic broth.** In addition, aerobic 5% sheep BA, chocolate agar, and MacConkey agar are set up because most anaerobic infections are polymicrobic and may include aerobic or facultative anaerobic bacteria. A backup broth, usually thioglycollate, is inoculated to enrich small numbers of anaerobes in tissues and other sterile specimens and in some cases should be held for up to 14 days. Most anaerobes grow well on any of these media.



• **Fig. 40.4** Prereduced, anaerobically sterilized (PRAS) plated media. (Courtesy Anaerobe Systems, Morgan Hill, CA.)

Cultures for *Clostridioides difficile* are plated on a special selective medium, **cycloserine cefoxitin fructose agar (CCFA)** or **egg yolk agar (EYA).** There are also selective media for groups of anaerobes, such as *Actinomyces* spp., although they are rarely used in the clinical laboratory.

Special anaerobic blood culture systems containing various media, including thioglycollate broth, thiol broth, and Schaedler broth, are commercially available. Although many anaerobes will grow in the aerobic blood culture bottle, it is better to use an unvented anaerobic broth when attempting to isolate these organisms from blood or bone marrow.

Incubation Conditions and Duration

Inoculated plates should be immediately incubated under anaerobic conditions at 35°C to 37°C for 48 hours. In general, cultures should not be exposed to oxygen until after 48 hours' incubation, because anaerobes are most sensitive to oxygen during their log phase of growth. Plates may be removed from the anaerobic environment at 24 hours, briefly evaluated, and returned to the anaerobic environment. Plates incubated in an anaerobe chamber or bag can be examined at 24 hours without oxygen exposure for typical colonies of *B. fragilis* group or *Clostridium perfringens.* Plates that show no growth at 48 hours should be incubated for at least 5 days before being discarded. Thioglycollate broth can be incubated anaerobically with the cap loose or anaerobically with the cap tight. Broths should be inspected daily for 7 days.

In addition to the anaerobic media, a chocolate agar plate (CHOC) should be inoculated to determine whether the anaerobe is a facultative or strict obligate anaerobe. The CHOC should be placed in the CO_2 incubator. A 5% sheep BA plate is inoculated and placed in an anaerobic environment. The plates should be incubated at 35°C to 37°C for 48 hours. This test is referred to as an **aerotolerance test.** If an organism is a true strict anaerobe, there should be no visible growth on the chocolate plate after incubation. However, some anaerobes are aerotolerant and will be visible on the sheep BA plate, including *Propionibacterium* spp., *Clostridium* spp., *Lactobacillus* spp., *Actinomyces* spp., and other genera.

Approach to Identification

The direct Gram stain is essential in the identification of a potential anaerobic infection and may be the only procedure available in some laboratories. Table 40.1 provides an overview of many anaerobic bacteria including the expected Gram stain results and clinical significance. The complete identification of anaerobes can be costly, often requiring various biochemical tests. Most clinical laboratories no longer perform complete identification of anaerobes because presumptive identification is just as useful in assisting the physician in determining appropriate therapy. Therefore, the approach to identification taken in this chapter emphasizes simple, rapid methods to identify commonly isolated anaerobic bacteria. Identification should proceed in a stepwise fashion, beginning with examination of the primary plates.

Examination of Primary Plates

Anaerobes are usually present in mixed culture with other anaerobes and facultative bacteria. The combination of selective and differential agar plates yields information that suggests the presence and perhaps the types of one or more anaerobes. Primary anaerobic plates should be examined with a hand lens (8×) or, preferably, a stereoscopic microscope. Colonies should be described from the various media and semi-quantitated.

All colony morphotypes from the nonselective anaerobic BA should be characterized and subcultured to purity plates, because facultative and obligate anaerobic bacteria commonly have similar colonial appearances. Colonies on PEA are processed further if they are different from colonies growing on the anaerobic BA or if colonies on the anaerobic BA are impossible to subculture because of overgrowth by swarming clostridia, *Proteus,* or other organisms.

The backup broth (e.g., thioglycollate) should be Gram stained; if cellular types are seen that were not present on the primary plates, the broth should be subcultured. In addition, if no growth is seen on the primary plates, the backup broth should be subcultured to the battery of anaerobic media included in the primary plating setup. The broth should be subcultured even if it appears clear to ensure no anaerobic organisms are present.

Subculture of Isolates

A single colony of each distinct morphotype is examined microscopically using a Gram stain and is subcultured for aerotolerance testing. Fig. 40.5 presents a basic algorithm for processing isolated colonies. A sterile wooden stick or platinum loop should be used to subculture colonies to:

- A CHOC to be incubated in carbon dioxide (CO_2) for aerotolerance
- An anaerobic BA plate and a chocolate plate to be incubated anaerobically (purity plate)

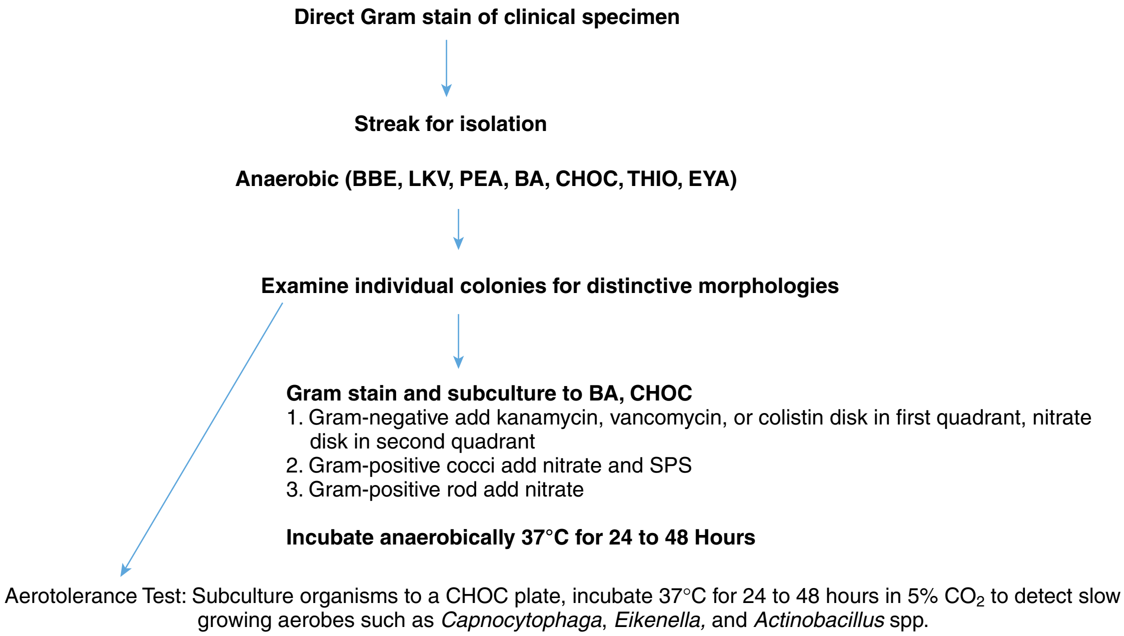
The CHOC should be inoculated first, so that if only the anaerobic BA plate grows, there is no question of not having enough organisms to initiate growth. The following antibiotic identification disks are placed on the first quadrant of the purity plate (Evolve Procedure 40.1):

- Kanamycin, 1 mg
- Colistin, 10 µg
- Vancomycin, 5 µg

These disks aid preliminary grouping of anaerobes and verify the Gram stain results, but they do not imply susceptibility of an organism for antibiotic therapy.

Three other disks may be added to the anaerobic BA plate at this time. A nitrate disk may be placed on the second quadrant for subsequent determination of nitrate reduction; a sodium polyanethol sulfonate (SPS) disk can be placed near the colistin disk for rapid presumptive identification of *Peptostreptococcus anaerobius* if gram-positive cocci are seen on Gram staining; and a bile disk may be added to the second quadrant to detect bile inhibition if gram-negative rods are seen on Gram staining.

If processing is performed on the open bench, all plates should promptly be incubated anaerobically, because some



Direct Gram stain of clinical specimen
Streak for isolation
Anaerobic (BBE, LKV, PEA, BA, CHOC, THIO, EYA)
Examine individual colonies for distinctive morphologies
Gram stain and subculture to BA, CHOC
1. Gram-negative add kanamycin, vancomycin, or colistin disk in first quadrant, nitrate disk in second quadrant
2. Gram-positive cocci add nitrate and SPS
3. Gram-positive rod add nitrate
Incubate anaerobically 37°C for 24 to 48 Hours
Aerotolerance Test: Subculture organisms to a CHOC plate, incubate 37°C for 24 to 48 hours in 5% CO_2 to detect slow growing aerobes such as *Capnocytophaga*, *Eikenella,* and *Actinobacillus* spp.

• **Fig. 40.5** Algorithm for isolation and identification of anaerobic bacteria. *BA*, Sheep blood agar; *BBE, Bacteroides* bile esculin agar; *CHOC*, chocolate agar; *EYA*, egg yolk agar (for suspected *Clostridium* spp.); *LKV*, laked kanamycin-vancomycin agar; *PEA*, phenylethyl agar; *SPS*, sodium polyanethol sulfonate; *THIO*, thioglycollate enrichment broth (should be examined daily and incubated for up to 7 days if no growth is identified on primary media; subculture to anaerobic media if growth is detected in broth culture).

clinical isolates (e.g., *Fusobacterium necrophorum* subsp. *necrophorum* and some *Prevotella* spp.) may die after relatively short exposure to oxygen. The primary plates are reincubated, along with the purity plates, for an additional 48 to 72 hours and are again inspected for slowly growing or pigmenting strains.

Presumptive Identification of Isolates

Information from the primary plates in conjunction with the atmospheric requirements, Gram stain results, and colony morphology of a pure isolate provides preliminary differentiation of many anaerobic organisms. Considering the specimen source and expected organisms from the site can be a useful aid in this process. Phenotypic characteristics for the identification of commonly isolated groups of anaerobic bacteria are included in Chapter 41.

Definitive Biochemical Identification

Various techniques can be used for definitive identification of anaerobic bacteria. Such methods may include the following:

- PRAS biochemicals
- Miniaturized biochemical systems (e.g., API 20A [bioMérieux, St. Louis, MO])
- Rapid, preformed enzyme detection panels (e.g., RapID-ANA II [Remel, Lenexa, KS]; BBL Brand Crystal Anaerobe ID [Becton Dickinson]; Rapid Anaerobe Identification Panel [MicroScan, Beckman Coulter, Brea, CA]; Vitek ANI card [bioMérieux]).

For commonly isolated anaerobic bacteria, the commercial identification systems and biochemical kits reliably identify the anaerobic bacteria. However, caution must be used in interpretation, and the results must be correlated with other clinical information, including the site of infection, Gram staining results, and colonial morphology. The high cost of some methods alone does not justify their use in most clinical laboratories.

Rapid Identification Methods

Nucleic acid–based testing has been used to identify anaerobic organisms. These methods include polymerase chain reaction (PCR), multiplex PCR, and oligonucleotide microarrays.

Matrix-assisted laser desorption ionization time-of-flight mass spectrometry (MALDI-TOF MS) has been used to identify anaerobes from clinical specimens (Chapter 7). MALDI-TOF MS is less expensive than traditional culture-based biochemical testing and nucleic acid–based testing. MALDI-TOF MS has also been used to detect the hydrolysate of meropenem and ertapenem identifying carbapenemase-producing anaerobic bacteria.

Antimicrobial Susceptibility Testing and Therapy

When mixed infections are encountered, definitive information about the identification of each species present usually does not affect therapeutic management. Because most clinically

TABLE 40.3 Summary of Antimicrobial Susceptibility Testing Methods for Anaerobic Bacteria

	Test Methods		
Test Conditions	**Agar Dilution**	**Broth Microdilution**	**E-Test**
Medium	*Brucella* agar supplemented with hemin (5 µg/mL), vitamin K (1 µg/mL), and 5% (V/V) laked sheep blood	*Brucella* broth supplemented with hemin (5 µg/mL), vitamin K (1 µg/mL), and lysed horse blood (5%)	*Brucella* blood agar

relevant anaerobes are susceptible to first-line antimicrobials, knowledge of their presence and Gram stain morphologies in mixed cultures is usually sufficient for guiding therapy. Therefore, definitive identification methods that follow the schemes outlined should be judiciously applied to clinical situations in which an anaerobic organism is isolated in pure culture from a normally sterile site (e.g., clostridial myonecrosis).

The therapeutic options for each of the major groups of anaerobic bacteria change rapidly; therefore, therapeutic use of the antimicrobial agents listed generally requires the performance of antimicrobial susceptibility testing with anaerobic isolates (Table 40.3). Although standard susceptibility testing methods have been established for testing anaerobic bacteria against various antimicrobial agents, the fastidious nature of many species and the labor intensity involved in using these methods indicate that testing should be done only under recommended circumstances (Box 40.3).

Although certain commercial methods (e.g., E-test, Spiral Gradient; Chapter 11) may facilitate anaerobic susceptibility testing in some way, the difficulty of assigning clinical significance to many anaerobic isolates and the availability of several highly effective empiric therapeutic choices significantly challenge a laboratory policy of routinely performing susceptibility testing with these organisms. Because of the difficulty associated with the growth, identification, and susceptibility testing of anaerobes, inclusion of these organisms in nucleic acid direct detection systems such as the Biofire blood culture identification system is important to initiate effective therapy in systemic disseminated infections.

• BOX 40.3 Indications for Performing Antimicrobial Susceptibility Testing With Anaerobic Bacteria

- To establish patterns of susceptibility of anaerobes to new antimicrobial agents
- To periodically monitor susceptibility patterns of anaerobic bacteria collected in and among specific geographic areas or particular health care institutions
- To assist in the therapeutic management of patients, when such information may be critical because of the following:
  - Known resistance of a particular species to commonly used agents
  - Therapeutic failures and/or persistence of an organism at a site of infection
  - Lack of a precedence for therapeutic management of a particular infection
  - Severity of an infection (e.g., brain abscess, osteomyelitis, infections of prosthetic devices, and refractory or recurrent bacteremia)

PROCEDURE 40.1

Antibiotic Identification Disks

Principle

Most anaerobes have a characteristic susceptibility pattern to colistin (10 µg), vancomycin (5 µg), and kanamycin (1 mg) disks. The pattern generated usually confirms a dubious Gram stain reaction (with few exceptions, gram-positive anaerobes are susceptible to vancomycin). The patterns also help subcategorize the anaerobic gram-negative bacilli into groups.

Method

1. Allow the three cartridges of disks to equilibrate to room temperature.
2. Transfer a portion of one colony to an anaerobic blood agar plate. Streak the first quadrant several times to produce a heavy lawn of growth; then streak the other quadrants for isolation.
3. Place the colistin, kanamycin, and vancomycin disks in the first quadrant, well separated from each other.
4. Incubate the plates anaerobically for 48 hours at 35°C.

Expected Results

Observe for a zone of inhibition of growth. A zone of 10 mm or less indicates resistance, and a zone greater than 10 mm indicates susceptibility.

Quality Control

1. Colistin
   Positive: *Fusobacterium necrophorum* subsp. *necrophorum*
   Negative: *Bacteroides fragilis*
2. Kanamycin
   Positive: *Clostridium perfringens*
   Negative: *B. fragilis*
3. Vancomycin
   Positive: *C. perfringens*
   Negative: *B. fragilis*

PROCEDURE 40.2

Nagler Test

Purpose

This test is performed to differentiate *Clostridium perfringens* from other *Clostridium* spp. based on the neutralization of lecithinase C activity by the presence of antitoxin.

Principle

Bacterial lecithinase breaks down lecithin in egg yolk, producing an insoluble complex of diglycerides. The production of diglycerides in egg yolk agar results in an opaque halo around the lecithinase-positive colony. In addition, organisms that produce lipase produce an opalescence or pearly layer on egg yolk agar.

Method

1. Inoculate one half of the egg yolk agar with 60 µL of *C. perfringens* antitoxin. Spread evenly with a flat spreader or a loop.
2. Allow the antitoxin to absorb into the agar medium before proceeding.
3. Streak the test organism in a straight line across the antitoxin-treated media through the nontreated media.
4. Inoculate the positive and negative control across the antitoxin-treated media through the nontreated media.
5. Incubate the plate anaerobically at 35°C–37°C for up to 48 h.

Expected Results

The plate should be examined for an opalescent halo around the inoculum and inhibition of the antitoxin.

A positive result is indicated by the disappearance of or a reduction in the opacity on the antitoxin side of the streak; this indicates neutralization of the lecithinase activity.

A negative result is indicated by the presence of opacity on the antitoxin half of the plate.

Limitations

Interpretation may be difficult because of diffusion of lecithinase into the media. Comparing the sample with an uninoculated plate may aid interpretation.

A heavy inoculum of *Clostridium baratii* and *Clostridium absonum* may produce a partial cross reaction.

Clostridium sordellii and *Clostridium bifermentans* produce an enzyme related to lecithinase C, which may result in a cross reaction.

Quality Control

Positive: *C. perfringens*
Negative: *Clostridioides difficile*

From the National Standard Methods Working Group for Clinical Bacteriology, Department for Evaluations, Standards and Training, Center for Infections, Health Protection Agency, London, UK.

Chapter Review

1. All of the following specimens are acceptable for anaerobic culture *except:*
  a. Bile
  b. Joint fluid
  c. Skin swab
  d. Aspirate

2. After preliminary plating, all isolated colonies should be subcultured and incubated on:
  a. BA in 2% O_2
  b. CHOC in 5% CO_2
  c. CHOC in 0% O_2
  d. BA in 0% O_2 and 5% CO_2

3. Specimen characteristics of an anaerobic infection include:
  a. Foul odor, presence of sulfur granules, and green fluorescence
  b. Foul odor, presence of metachromatic granules, and green fluorescence
  c. Foul odor, sulfur smell, and red fluorescence
  d. Foul odor, presence of sulfur granules, and red fluorescence

4. Which primary plating medium consists of a *Brucella* agar base containing kanamycin and vancomycin?
  a. BBE
  b. PEA
  c. EYA
  d. LKV

5. A wound specimen is collected on a swab and placed in transport media. The swab is placed in the refrigerator for approximately 30 minutes before transport to the laboratory. The laboratory technologist immediately plates the swab to BBE, LKV, PEA, CHOC, and BA and inoculates a THIO tube. All plates and the tube are incubated anaerobically for 7 days without growth. Which of the following is the likely reason that no anaerobic bacteria were cultivated?
  a. Poor transport method
  b. Excessive exposure to air during processing
  c. Inadequate media
  d. None of the above

6. A gram-negative rod is isolated from a clinical specimen collected from a female patient with a genital swab. The organism is characterized as kanamycin-sensitive, colistin-sensitive, vancomycin-resistant, bile hydrolysis–negative, and positive for urea hydrolysis and nitrate reduction. This organism is most likely:
  a. *Fusobacterium* spp.
  b. *B. ureolyticus*
  c. *Veillonella* spp.
  d. *C. difficile*

7. **Matching:** *Match each term with the associated term.*

______ *Mobiluncus* spp.
______ *Actinomyces*
______ *Bifidobacterium*
______ *C. perfringens*
______ *Bacteroides* spp.
______ *C. difficile*
______ *C. septicum*
______ *Eubacterium*
______ *C. tetani*
______ *B. thetaiotaomicron*
______ *F. varium*

a. pseudomembrane
b. gas gangrene
c. molar tooth
d. lock jaw
e. bacterial vaginosis
f. dog bones
g. fried egg
h. seagull wing
i. esculin hydrolysis
j. Medusa head
k. punctiform

8. **Short Answer**

Anaerobic cultures are incubated in a GasPak chamber. Upon opening and examining the culture plates, the microbiologist notes that, according to the indicator result, the anaerobic jar did not operate properly. What may have caused the indicator to fail to function properly? What is the next step in the laboratory with regard to the incubated cultures and isolates?

41

Overview of Anaerobic Organisms

OBJECTIVES

1. For each group of organisms listed, provide the general characteristics, including Gram stain reactions, colonial morphology, growth requirements (media, oxygen requirement, and temperature), laboratory identification, and clinical significance.
2. Differentiate normal anaerobic bacteria from pathogenic bacteria isolated from clinical specimens.
3. Describe the pathogenesis and virulence factors associated with the *Clostridium* species *Clostridium perfringens, Clostridium botulinum, Clostridioides difficile, Clostridium septicum,* and *Clostridium tetani.*
4. Define and discuss the pathogenesis for anaerobic cellulitis, gas gangrene, clostridial gastroenteritis, pseudomembranous enterocolitis, botulism, actinomycosis, bacterial vaginosis, and enteritis necroticans.
5. Differentiate the four forms of botulism (food poisoning, wound botulism, infant botulism, and botulism resulting from intestinal colonization).
6. Compare paralysis associated with botulism with tetanus.
7. Explain the procedure for spore isolation and growth using the ethyl alcohol shock procedure.
8. List the appropriate specimen collection, transport, and storage conditions for the recovery of anaerobic organisms.
9. Explain aerotolerance testing, including how to perform the test, what media are used, and the reason or reasons the media is important.
10. Identify the special potency antibiotics and explain the typical resistance patterns used to identify the various anaerobic groups (e.g., gram-positive cocci, gram-negative cocci).
11. Correlate disease signs and symptoms with laboratory data to identify the etiologic agent of infection.

As previously described in Chapter 40, the organisms in this chapter predominantly do not grow in the presence of oxygen.

Epidemiology

Most of the anaerobic bacteria that cause infections in humans are also part of our normal microbiota. The ecology of these organisms is such that various species and genera exhibit preferences for the body sites they inhabit (**endogenous anaerobes**). The gram-positive cocci account for approximately one-third of the anaerobic organisms isolated from clinical samples. Other pathogenic anaerobes (e.g., *Clostridium botulinum* and *Clostridium tetani*) are soil and environmental inhabitants (**exogenous anaerobes**) and not considered part of the normal human microbiota.

The ways in which anaerobic infections are acquired are summarized in Table 41.1. Person-to-person, health care–associated transmission of *Clostridioides difficile* among hospitalized patients presents an enormous clinical and infection control dilemma. Most anaerobic infections occur when a patient's normal microbiota gains access to a sterile site as a result of disruption of some anatomic barrier.

Pathogenesis and Spectrum of Disease

The types of infections and diseases in humans caused by anaerobic bacteria span a wide spectrum. Certain species, such as *C. botulinum* and *C. tetani,* produce some of the most potent toxins known. In contrast, specific virulence factors for the organisms commonly encountered in infections (e.g., *Bacteroides fragilis* group, *C. difficile*) are not well understood (Table 41.2).

Most anaerobic infections involve a mixture of anaerobic and facultative anaerobic organisms (e.g., Enterobacterales), which creates problems in identification and diagnosis to establish the extent to which a particular anaerobic species contributes to infection. In addition, as ubiquitous members of the normal microbiota, anaerobic organisms commonly contaminate clinical materials. For these reasons, assigning clinical significance to anaerobic bacteria isolated in the laboratory is important, although often difficult.

Gram-Positive, Spore-Forming Bacilli

The clostridia are endospore forming, obligate anaerobic (or aerotolerant), catalase-negative, gram-positive bacilli (Fig. 41.1). Using chemotaxonomic and polyphasic characterization, *Clostridium difficile* has now been placed into a new genus, *Clostridioides.* The genus *Clostridium* contains more than 240 species and subspecies. *Clostridioides* and C*lostridium* will be included together throughout this chapter as clostridia. The clostridia microscopic morphology appear long, short, straight, or curved pleomorphic rods arranged in pairs or short chains. If spores are not present on Gram stain, the ethanol shock spore or heat shock spore test can separate this group from the non–spore-forming

TABLE 41.1 Acquisition of Anaerobic Infections and Diseases

Mode of Acquisition	Examples
Endogenous strains of normal microbiota gain access to normally sterile sites, usually as a result of one or more predisposing factors that compromise normal anatomic barriers (e.g., surgery or accidental trauma) or alter other host defense mechanisms (e.g., malignancy, diabetes, burns, immunosuppressive therapy, aspiration)	Wide variety of infections involving several anatomic locations, including bacteremia, head and neck infections, dental and orofacial infections, pneumonia and other infections of the thoracic cavity, intraabdominal and obstetric and gynecologic infections, bite wound and other soft tissue infections, and gangrene (i.e., clostridial myonecrosis). Organisms most commonly encountered in these infections include *Bacteroides fragilis* group, *Prevotella* spp., *Porphyromonas* spp., *Fusobacterium nucleatum, Peptostreptococcus* spp., and *Clostridium perfringens*.
Contamination of existing wound or puncture by objects contaminated with toxigenic *Clostridium* spp.	Tetanus (*Clostridium tetani*), gas gangrene (*Clostridium perfringens*, and, less commonly, *Clostridium septicum, Clostridium novyi*, and others).
Associated with medically induced abortions, normal vaginal delivery, and cesarean section delivery	*Clostridium sordellii* infections in young healthy women resulting in fatal postpartum infections.
Ingestion of preformed toxins in vegetable- or meat-based foods	Botulism (*Clostridium botulinum*) and other clostridial food poisonings (*C. perfringens*).
Colonization of gastrointestinal tract with a potent toxin-producing organism	Infant botulism (*C. botulinum, Clostridium butyricum*, and *Clostridium baratii*).
Person-to-person spread	Health care–associated spread of *Clostridioides difficile*–induced diarrhea and pseudomembranous colitis; bite wound infections caused by a variety of anaerobic species.

TABLE 41.2 Pathogenesis and Spectrum of Disease for Anaerobic Bacteria

Organism	Virulence Factors	Spectrum of Disease and Infections
Gram-Positive Bacilli, Spore-Forming		
Clostridium perfringens	Produces several exotoxins; alpha-toxin, the most important, mediates destruction of host cell membranes; enterotoxin inserts and disrupts membranes of mucosal cells; beta-toxin is a cytotoxin.	Gas gangrene (myonecrosis) and necrotizing fasciitis: Life-threatening, toxin-mediated destruction of muscle and other tissues after traumatic introduction of the organism. Food poisoning: Caused by release of the toxin after ingestion of large numbers of the organism. Usually self-limiting and benign; manifested by abdominal cramps, diarrhea, and vomiting. Enteritis necroticans (necrotizing enteritis; NEC): Life-threatening infection that causes ischemic necrosis of the jejunum. Often associated with immunocompromised patients (e.g., those with diabetes, alcohol-induced liver disease, or neutropenia). NEC, a gastrointestinal disease that causes bowel necrosis and inflammation, affects low-birth-weight, premature infants.
Clostridium sordellii	Produces a variety of bacterial proteases and phospholipases. Produces up to seven exotoxins, including lethal toxin (LT), hemorrhagic toxin (HT), and enterotoxins A, B, and C.	Gas gangrene of the uterus following abortion, normal delivery, or cesarean section. Patient presents with little or no fever, lack of purulent discharge, hypotension, peripheral edema, and an increased white blood cell (WBC) count. Infection is typically fatal, and death is rapid.
Clostridium tetani	Produces tetanospasmin (TeNT), a neurotoxic exotoxin that disrupts nerve impulses to muscles.	Tetanus (commonly known as lockjaw). Organism establishes a wound infection and elaborates TeNT, a potent toxin that mediates generalized muscle spasms. If the disease goes untreated, spasms continue to be triggered by even minor stimuli, leading to exhaustion and, eventually, respiratory failure.

Continued

TABLE 41.2 **Pathogenesis and Spectrum of Disease for Anaerobic Bacteria—cont'd**

Organism	Virulence Factors	Spectrum of Disease and Infections
Clostridium botulinum	Produces an extremely potent neurotoxin (BoNT).	Foodborne botulism: Results from ingestion of preformed toxin in nonacidic vegetable or mushroom foodstuffs. Absorption of the toxin leads to nearly complete flaccid (rag doll) paralysis of respiratory and other essential muscle groups. Infant botulism: Occurs when the organism elaborates the toxin after it has colonized the gastrointestinal tract of infants (i.e., infant botulism). Wound botulism: Occurs when *C. botulinum* produces the toxin from an infected wound site. Intestinal botulism: Intestinal colonization has been associated with surgery and administration of antibiotics. Occurs in children and adults.
Clostridioides difficile	Produces toxin A (TcdA), an enterotoxin, and toxin B (TcdB), a cytotoxin. Both toxin A and toxin B are classified as large clostridial cytotoxins. The toxins glycosylate guanosine triphosphate (GTP) signaling proteins, leading to a breakdown of the cellular cytotoxin and cell death.	Organism requires diminution of normal gut microbiota by the activity of various antimicrobial agents to become established in the gut of hospitalized patients. Once established, elaboration of one or more toxins results in antibiotic-associated diarrhea or potentially life-threatening inflammation of the colon. When the surface of the inflamed bowel is overlaid with a "pseudomembrane" composed of necrotic debris, white blood cells, and fibrin, the disease is referred to as pseudomembranous colitis. Only strains producing toxin A or toxin B (or both) cause infections.
Gram-Positive Bacilli, Non–Spore-Forming		
Actinobaculum spp.	Unknown	Associated with urinary tract infections. Identified in a variety of severe infections including urosepsis, bacteremia, cellulitis, spondylodiscitis, and endocarditis.
Actinotignum schaalii	Unknown; often associated as a predominant member in polymicrobial biofilms in urinary tract infections.	Most commonly associated with urinary tract infections; has been isolated in endocarditis, abscesses, cellulitis, and bacteremia. There is an approximately 15% mortality rate in cases of bacteremia and severe sepsis.
Actinomyces spp.	No well-characterized virulence factors. Infections usually require disruption of the protective mucosal surface of the oral cavity, respiratory tract, gastrointestinal tract, and/or female genitourinary tract.	Usually involved in mixed oral or cervicofacial, thoracic, pelvic, and abdominal infections caused by the patient's endogenous strains. Also involved in periodontal disease and dental caries. Identified in a variety of soft tissue infections, including perianal, groin, ancillary, breast, and other abscesses.
Atopobium spp.	Atopobium vaginae is a predominant organism isolated concurrently as a constituent of *Gardnerella vaginalis* biofilm associated with bacterial vaginosis.	Identified in association with dental and respiratory infections and bacteremia. Isolated from various infections in the genital tract, including bacterial vaginosis.
Bifidobacterium spp.	Unknown, no differences have been identified in invasive versus noninvasive strains using whole genome sequencing (Esaiassen, 2017).	Commonly associated with dental infections, periodontal disease, peritonitis, pneumonia, abdominal abscesses, and bacteremia.
Cryptobacterium curtum	Overproduction of citrulline during bacterial metabolism in periodontal infections has been linked to the development of rheumatoid arthritis.	Associated with chronic periodontitis, endodontic infections, and dental abscesses. Translocation to other areas of the body have implicated the organism in the development of pelvic abscesses, gynecologic infections, and wounds.

TABLE 41.2 **Pathogenesis and Spectrum of Disease for Anaerobic Bacteria—cont'd**

Organism	Virulence Factors	Spectrum of Disease and Infections
Cutibacterium spp.	Different species produce factors that may be associated with virulence; *C. avidum* produces an extracellular polysaccharide-like structure that may be associated with biofilm formation and avoiding phagocytosis produces neuraminidase that may also be involved in pathogenicity; *C. granulosum* produces pililike structures involved in adherence; *C. acnes*' ability to produce biofilm and increase adherence is well documented: lipase is produced by most species resulting in the hydrolysis of triglycerides and sebum contributing to cutaneous skin lesions; all three species listed here produce hyaluronidase that may be involved in tissue damage.	Associated with inflammatory process in acne. Identified in systemic opportunistic infections, including endocarditis, central nervous system (CNS) infections, osteomyelitis, and arthritis. As part of normal skin flora, the organism is considered the most common anaerobic contaminant of blood cultures and is often ignored.
Eggerthella spp.	Some species are able to oxidase bile acids in the gastrointestinal tract. It is unknown if this is associated to the pathogenicity of the organism.	Recovered from a variety of infections including intraabdominal and periabdominal infections. Associated with meningitis, necrotizing pneumonia, osteomyelitis, and other disseminated infections. Mortality ranges from 20% to 40% in cases of human infections.
Eubacterium spp.	Unknown	Usually associated with mixed infections of the oral cavity, abdomen, pelvis, or genitourinary tract.
Lactobacillus spp.	Pili and adhesion proteins that make the organisms useful in probiotics, also enhances the organism's ability to cause infection in other areas of the body.	Associated with advanced dental caries. Organism has been identified in endocarditis, meningitis, intraabdominal infections, liver abscesses, septicemia, and bacteremia. Several species are commonly used in probiotics to maintain and restore normal intestinal bacterial microbiota. Severe infections do occur when these organisms translocate out of their normal environment, often in patients with underlying comorbidities.
Olsenella spp.	Unknown	Predominantly associated with dental infections and periodontitis, and bacteremia.
Propionimicrobium lymphophilum	Unknown	Predominantly associated with urinary tract infections.
Pseudopropionibacterium propionicum	Unknown	Known to cause actinomycosis as well as oral and eye infections.
Pseudoramibacter alactolyticus	Unknown	Primarily associated with dental infections including periodontitis, endodontic infections, dental caries, and oral abscesses.
Slackia spp.	Unknown	Predominantly associated with chronic periodontitis, polymicrobial abscesses in various body sites, and bacteremia.
Varibaculum spp.	Unknown	Associated with IUD, cerebral, post-auricular, submandibular, breast abscesses and other soft-tissue infections. Has been isolated from urine, sinus, and vaginal tract specimens.

Continued

TABLE 41.2 **Pathogenesis and Spectrum of Disease for Anaerobic Bacteria—cont'd**

Organism	Virulence Factors	Spectrum of Disease and Infections
Other miscellaneous genera: *Anaerostipes, Bulleidia, Catonella, Eggerthia, Lachnoanaerobaculum, Moryella, Oribacterium, Robinsoniella, Filifactor*	*Filifactor alocis* is known to induce proinflammatory cytokine secretion in gingival epithelial cells inducing apoptosis contributing to tissue damage in periodontal disease.	Many of these genera are associated with similar infections as the other non–spore-forming gram-positive bacilli including dental infections, genitourinary, vaginal, abscesses, soft-tissue infections, and bacteremia.
Mobiluncus spp. (considered gram-variable)	Unknown	Organisms are found in the vagina and have been associated with bacterial vaginosis, but their precise role in gynecologic infections is unclear. Eighty-two percent of neovaginal samples from transgender patients are positive for *M. curtisii*. Organisms have been isolated from breast, hepatic, and intraabdominal abscesses, and bacteremia.
Gram-Negative Bacilli		
Bacteroides fragilis group, other *Bacteroides* spp., *Prevotella* spp., *Porphyromonas* spp. *Fusobacterium nucleatum* and other *Fusobacterium* spp.	Anaerobic, gram-negative bacilli that produce capsules, endotoxin, and succinic acid, which inhibit phagocytosis, and produce various enzymes that mediate tissue damage.	Most infections still require some breach of mucosal integrity that allows the organisms to gain access to deeper tissues. Organisms most commonly encountered in anaerobic infections. Infections are often mixed (polymicrobial) with infections caused by other anaerobic and facultative anaerobic organisms. Infections occur throughout the body, usually as localized or enclosed abscesses, and may involve the cranium, periodontium, thorax, peritoneum, liver, and female genital tract. May also cause bacteremia, aspiration pneumonia, septic arthritis, chronic sinusitis, decubitus ulcers, and other soft tissue infections. The hallmark of most but not all infections is the production of a foul odor. In general, infections caused by *B. fragilis* group occur below the diaphragm; pigmented *Prevotella* spp., *Porphyromonas* spp., and *F. nucleatum* generally are involved in head and neck and pleuropulmonary infections.
Bilophila wadsworthia	Unknown	Significant pathogen commonly isolated in intraabdominal polymicrobial abscesses.
Leptotrichia spp.	Unknown	Increasingly isolated from immunocompromised patients associated with oral or gastrointestinal lesions and bacteremia. Some isolates have been identified in infective endocarditis in immunocompetent patients.
Sutterella wadsworthensis	Unknown	Commonly isolated from a variety of infections including appendicitis, peritonitis, rectal, or perirectal abscesses.
Gram-Positive Cocci		
Anaerococcus lactolyticus	No definitive virulence factors known.	Diabetic and pressure ulcers.

TABLE 41.2 **Pathogenesis and Spectrum of Disease for Anaerobic Bacteria—cont'd**

Organism	Virulence Factors	Spectrum of Disease and Infections
Anaerococcus prevotii	No definitive virulence factors known.	Predominantly isolated from vaginal discharges and ovarian, peritoneal, sacral, and lung abscesses; has been identified in blood cultures.
Anaerococcus vaginalis	No definitive virulence factors known.	Diabetic and pressure ulcers; has been identified in blood cultures.
Finegoldia magna	Demonstrated ability to form biofilm as well as several virulence factors including adhesion factors and extracellular transpeptidases that promote colonization.	Most often found in infections associated with skin and soft tissue, bone, and joint infections; chronic wounds such as diabetic and pressure ulcers. The organism has also been isolated from disseminated infections such as endocarditis, meningitis, pneumoniae, septic arthritis, and upper respiratory infections.
Murdochiella asaccharolyticus	No definitive virulence factors known.	Isolated from abdominal and sacral abscesses and polymicrobial bacterial vaginosis.
Parvimonas micra	*P. micra* has been shown to produce a variety of enzymes capable of tissue destruction, including collagenase, hemolysin, and elastase; induces production of **gingipain** (extracellular proteases) in polymicrobial infections with *Porphyromonas gingivalis,* causing biofilm formation and down regulation of inflammatory cytokines.	Normal oral microbiota; however often associated with periodontal, endodontic, and peritonsillar infections. It is also isolated in polymicrobial infections in various body sites including cutaneous, wound, otitis media, sinus, pleural empyema and septic-pulmonary embolism, intraabdominal, anorectal abscess, septicemia, gynecological, vertebral osteomyelitis, and prosthetic joint infections.
Peptoniphilus spp.	No definitive virulence factors known.	Most often associated with pressure ulcers and chronic rhinosinusitis; has been isolated from bone, joint, and bloodstream infections.
Peptostreptococcus anaerobius	No definitive virulence factors known.	Most often isolated from polymicrobic infections, including abscesses of the brain, ear, jaw, oral and pleural cavities, pelvis, urogenital tract, wound infections, and abdominal cavity.
Peptostreptococcus stomatis		Has been isolated in polymicrobial abscesses associated with colorectal cancer.
Gram-negative cocci		
Veillonella spp.	No definitive virulence factors known.	May be involved in mixed infections. Organisms have been isolated in increasingly serious infections, including meningitis, osteomyelitis, endocarditis, bacteremia, pleuropulmonary, and prosthetic infections.

anaerobic bacilli (Evolve Procedure 41.1). Some strains of *Clostridium perfringens, Clostridium ramosum,* and *Clostridium clostridioforme* may not produce spores or survive a spore test, so it is important to recognize these organisms using other characteristics. Some clostridia typically stain gram negative, although they are susceptible to vancomycin on the disk test. Several species of clostridia grow aerobically (*Clostridium tertium, Clostridium carnis, Clostridium histolyticum,* and occasional strains of *C. perfringens*), but they produce spores only under anaerobic conditions. *C. perfringens* may appear weakly catalase-positive.

Clostridia are widespread in nature because of their ability to form spores, referred to as endospores, in the mother cell (Table 41.3). In addition, they are present in large numbers as normal microbiota in the gastrointestinal tract of humans and animals, the female genital tract, and the oral mucosa.

C. botulinum is listed by the Centers for Disease Control and Prevention (CDC) as a potential agent of bioterrorism (Chapter 79). Spores of *C. botulinum* are widely distributed in soil and aquatic environments. Botulism is diagnosed by the demonstration of **botulinum neurotoxin (BoNT)** in serum, feces, gastric contents, vomitus, or a suspect food (food poisoning) or environmental specimen (potential bioterrorism incident). Aerosolized botulinum toxin is highly unstable, and the more likely route would be intentional food intoxication. This means that most hospital laboratories must know how to package and ship such a specimen to the state health department or CDC. *C. botulinum*

PROCEDURE 41.1

Ethanol Shock Spore Isolation

Purpose

Clostridium species can be recovered from mixed populations of organisms and identified using the ethanol shock spore technique. Although heat-resistant spore techniques are commonly used to select for spores, heat resistance varies with species and strains within a species.

Principle

Ethyl alcohol has little to no effect on bacterial spores; however, it is toxic to vegetative microorganisms. The ethyl alcohol denatures the cell membrane of gram-negative organisms and is capable of interfering with metabolism in both gram-negative and gram-positive organisms.

Method

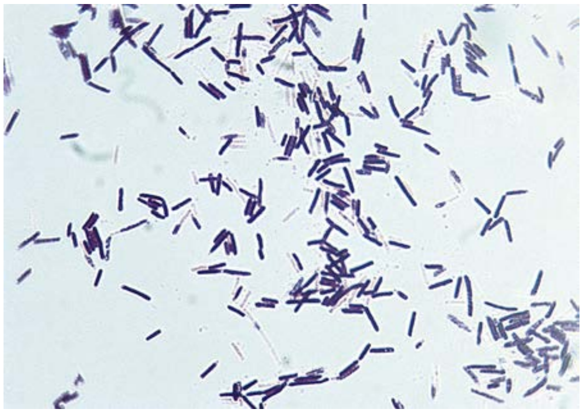
1. The specimen should be cultured in thioglycolate broth and incubated for 72 hours at 30°C.
2. Equal volumes of the enrichment culture are mixed with absolute ethanol (ethyl alcohol) and allowed to stand for 1 hour at room temperature (22°C to 25°C).
3. After the previous incubation, inoculate anaerobic blood agar plates with aliquots of the ethanol-culture mixture. This procedure should result in the isolation of individual colonies.
4. Place the plates in an anaerobic chamber or Bio-Bag and incubate at 35°C to 37°C for 48 hours.

Expected Results

Ethanol treatment of samples should result in the killing of all vegetative microorganisms. However, clostridial endospores may be resistant to ethanol, and after ethyl alcohol treatment, the spores will germinate upon inoculation and proper incubation on anaerobic blood agar in anaerobic conditions.

Limitations

The resistance or susceptibility of clostridial endospores to ethyl alcohol treatment varies within species and within strains of a single species. The lack of growth after ethyl alcohol shock treatment does not rule out the presence of a clostridial organism.



• Fig. 41.1 Gram stain of *Clostridium perfringens*.

is rarely isolated in the clinical microbiology laboratory. In addition to *C. botulinum,* BoNT can be produced by *Clostridium butyricum, Clostridium baratii*, and *Clostridium argentinense.* Table 41.2 describes the pathogenesis of the commonly encountered *Clostridium* spp.

Laboratory Diagnosis and Specimen Collection

As stated in Chapter 40, the proper collection and transport of specimens for anaerobic culture cannot be overemphasized. General considerations are included in the discussion in Chapter 40. However, special collection instructions must be followed for some clostridial illnesses, specifically suspected gas gangrene or necrotizing fasciitis (*C. perfringens* and *C. ramosum*), foodborne *C. perfringens* and *C. botulinum, C. difficile* pseudomembranous enterocolitis, *Clostridium septicum* neutropenic enterocolitis (NEC), and enteritis necrotans (*C. perfringens*). Food and freshly passed fecal specimens must be sent to a public health laboratory for confirmation of *C. perfringens* food poisoning; these should be transported at 4°C. The specimens should be processed within 24 hours of collection. The clinical diagnosis of botulism is confirmed by demonstration of botulinum toxin in serum, feces, vomitus, or gastric contents, as well as by recovery of the organism from the stool of patients (Fig. 41.1). Several methods are available, including cell culture assays, enzyme-linked immunosorbent assay (ELISA), and reverse passive latex agglutination.

C. perfringens–associated enteritis necroticans infection requires the collection of three blood cultures from three different venipuncture sites, stool (25 g or 25 mL of liquid) and bowel contents, or bowel tissue. Specimens should be Gram stained, cultured, and isolated. Follow-up tests to identify the organism are determined by the interpretation of the initial Gram stain. The isolate should be serologically typed. If gas gangrene or necrotizing fasciitis is suspect, multiple tissue samples are collected from the site of infection, because organisms may not be uniformly distributed throughout the infection. As with enteritis necroticans, samples should be Gram stained for early presumptive diagnosis. It is important to note any gram-positive rods because sporulation is not always noted in tissue for *C. perfringens* and *C. ramosum.* If spores are noted, the location (terminal, subterminal, or central) and the shape (spherical or oval) should be noted. In addition, polymerase chain reaction (PCR) testing is available for *C. perfringens.*

Suspected *C. difficile* infection (CDI) requires the collection of a freshly passed stool specimen (10 to 20 mL preferred; minimum 5 mL or 5 g) for culture, nucleic acid amplification, and toxin assays for both toxin A and toxin B. Nontoxigenic strains can colonize patients. Assays that detect the organism alone should be combined with an assay to determine toxin status. Only liquid or unformed stools should be processed for CDI to prevent unnecessary treatment of patients colonized with the bacterium. Formed stools or rectal swabs are adequate to detect carriers by culture or nucleic acid–based tests but are inadequate for toxin assays. Specimens should be cultured within 2 hours after collection. Figs. 41.2 and 41.3 demonstrate the isolation of *C. difficile* on **cycloserine cefoxitin fructose agar (CCFA)** and anaerobic blood agar. Specimens may be stored in anaerobic transport bags at 4°C for up to 48 hours; however, this reduces the recovery rate of viable organisms in culture. Specimens for toxin assays may be stored at 4°C for 72 hours or frozen at −70°C if a longer delay is expected.

Varieties of immunoassays are commercially available for the identification of *C. difficile* enterotoxin. In addition, a variety of nucleic acid–based platforms and assays have been developed for the amplification of the toxin A *(tcdA),* toxin B *(tcdB),* toxin C *(tcdC),* and binary toxin *(cdt)* genes. Stool samples may be submitted for nucleic acid–based testing. The assays include amplification of the glutamate dehydrogenase (GDH) gene or 16S ribosomal ribonucleic acid (rRNA) as internal control housekeeping genes. Detection of the GDH and 16S rRNA genes without the presence of a toxin gene would indicate a nonpathogenic strain or carrier state. Some studies indicate that nucleic acid–based testing without a confirmatory test leads to overdiagnosis of CDI, cannot differentiate a disease state from a carrier state, and should be limited to patients who present with diarrhea. Cell culture cultivation or toxin assays are still recommended.

The CDC maintains a 24-hours-a-day, 365-days-per-year hotline to provide emergency assistance in cases of botulism. Botulinum toxin is a potential bioweapon. Acceptable specimens for the diagnosis of *C. botulinum* or *C. tetani* infection include serum, feces, enema fluid, gastric aspirates, vomitus, tissue, exudates, or postmortem specimens. Specimens for infant botulism should include serum and stool; those for wound botulism should include serum, stool, and tissue biopsy. Serum specimens should be collected immediately after the onset of symptoms. All specimens should be stored and shipped at 4°C. Detection of the toxin BoNT is diagnostic for *C. botulinum* infection. The mouse bioassay remains the recommended method of analysis for the identification of BoNT. The bioassay requires splitting the specimen into two samples. One sample is boiled at 80°C for 10 minutes, inactivating the toxins. The two samples are independently injected intraperitoneal into two separate mice. One mouse serves as the negative control (inactivated specimen), and the other serves as the "test" sample. The

mice are observed for neurologic symptoms. The presence of toxin is presumptively indicated with the development of symptoms and death in the test animal but not the control animal. The toxins associated with *C. botulinum, C. tetani,* and *C. perfringens* (BoNT, **tetanus neurotoxin [TeNT],** and **iota toxin**) are considered extremely dangerous. The CDC recommends the use of Biosafety Level 3 practices and precautions, including immunization for the toxins; however, the vaccine is no longer available from the CDC.

The specimens of choice for *C. septicum* NEC include three different blood cultures from three different venipuncture sites, stool, and lumen contents or tissue from the involved ileocecal area; a muscle biopsy or aspirate of fluid from the sample should also be collected if myonecrosis (death of muscle tissue) is suspected. Table 41.4 provides an identification scheme for representative anaerobic organisms.

Nucleic Acid Detection and MALDI-TOF MS (Gram-Positive)

Nucleic acid detection using 16s rRNA gene sequencing may be useful for the identification of asaccharolytic species of clostridia. *C. tetani* can be directly detected by PCR. BoNT toxin and *C. difficile* toxin genes can be detected using real-time PCR assays; however, as previously indicated, toxin activity should be determined using an alternate method. Nontoxigenic strains may harbor the genes but do not produce the BoNT. Matrix-assisted laser desorption ionization time-of-flight mass spectrometry (MALDI-TOF MS) can be used to identify clostridia species more effectively than biochemical methods. Some clostridia may require pretreatment with formic acid for optimal extraction in MALDI-TOF MS.

Gram-Positive, Non–Spore-Forming Bacilli

Many genera of gram-positive, non–spore-forming bacilli are infrequently isolated as opportunistic infections. Some of the more commonly isolated genera include *Actinobaculum, Actinomyces, Actinotignum, Atopobium, Bifidobacterium, Eubacterium, Eggerthella, Collinsella, Cryptobacterium, Cutibacterium,* anaerobic *Lactobacillus, Mobiluncus, Olsenella, Paraeggerthella, Atopobium, Propionimicrobium,* and *Varibaculum*. These organisms are typically normal microbiota on the mucosal surfaces of the human digestive tract and urogenital tract and on the skin. Many of the organisms are identified in polymicrobic infections of the mucosal surface, such as the oral or vaginal cavity or the urogenital tract.

The genera *Actinomyces* (anaerobic and aerotolerant) and *Mobiluncus* (strictly anaerobic) include species that show non–acid-fast, gram-positive, pleomorphic branching rods or coccobacilli. Direct examination and the macroscopic presence in purulent exudate of "sulfur granules," which reveal gram-positive filaments when crushed, is diagnostic for an infection with *Actinomyces* spp. *Mobiluncus* spp., a cause of bacterial vaginosis, usually is diagnosed on Gram staining of vaginal secretions by observation of gram-variable, curved rods with tapered ends. It is rarely isolated in the clinical laboratory because vaginal secretions are not acceptable specimens for anaerobic culture. *Actinobaculum* spp. are typically rod-shaped facultative anaerobes that are normal microbiota of the human genitourinary tract. *Propionibacterium* spp. are anaerobic and aerotolerant, pleomorphic, gram-positive rods. The bacterium produces propionic acid from glucose. *Bifidobacterium* spp. are strictly anaerobic or microaerophilic, gram-positive, pleomorphic rods that appear as rods or are branched or club-shaped. *Lactobacillus* spp. contain microaerophilic, catalase-negative, gram-positive rods capable of producing lactic acid from glucose fermentation. The genus *Eubacterium* remains poorly characterized, although its species are commonly isolated from oral infections. *Eggerthella* and *Paraeggerthella* are associated with intraabdominal and periabdominal infections, as well as bloodstream infections, which have a high mortality. The pathogenic mechanisms and the spectrum of diseases associated with these organisms are included in Table 41.2.

Laboratory Diagnosis

Differentiation of the gram-positive, non–spore-forming anaerobes can be determined using the characteristics that include hemolysis, fluorescence under long-wave UV illumination, and colony and Gram stain morphology. Follow-up tests to identify the organism is determined by the

interpretation of the initial Gram stain results. Additional tests include an aerotolerance test (Evolve Procedure 41.2) or growth in 5% CO_2, followed by routine screening of special-potency antibiotic susceptibility patterns. The gram-positive organisms typically are resistant to colistin (10 µg), susceptible to vancomycin (5 µg), and have variable sensitivity to kanamycin (1 mg). Additional rapid testing includes a 15% catalase test, production of indole, nitrate reduction, and motility. Many of these organisms are relatively biochemically inert, rendering phenotypic biochemical identification unreliable.

Nucleic Acid Detection and MALDI-TOF MS (Gram-Negative)

No rapid molecular amplification tests are available in the clinical laboratory at the time of this writing. Sequencing of the 16S rRNA is considered the gold standard for organism identification; however, not all organisms in this group can be characterized using this gene. Additional sequencing of housekeeping genes is required for some organisms. Whole genome sequencing (WGS) has the potential to replace 16S rRNA methods; however, sufficient WGS databases are not currently available. MALDI-TOF MS has been successfully used to identify commonly isolated anaerobes; however, formic acid extraction is required to achieve optimal spectra and identification of the anaerobic gram-positive rods. In addition, due to the lack of information in available FDA-cleared databases, identification has relied on the research use only (RUO) databases in addition to other available testing methods. MALDI-TOF MS identification is expected to improve as the databases become optimized and approved for the detection of these organisms in the clinical laboratory. Table 41.4 provides an identification scheme for representative anaerobic organisms.

Gram-Negative Rods

Bacteroides fragilis Group

The anaerobic gram-negative rods typically are isolated from the mucosal surfaces of the human oral cavity and gastrointestinal tract (Fig. 41.4). (Table 41.2 presents an overview of the pathogenesis and infections associated with these organisms.) The *Bacteroidaceae* family consists of the saccharolytic, bile-resistant, nonpigmented *B. fragilis* group. The genus consists of approximately 50 species, more than

PROCEDURE 41.2

Aerotolerance Test

Purpose

The aerotolerance test is an essential confirmatory test for the isolation of a suspected anaerobic microorganism.

Principle

Strictly anaerobic organisms are sensitive to oxygen. After primary isolation of a suspected isolate on anaerobic sheep blood agar, the organism is subcultured to a chocolate plate and incubated in carbon dioxide (CO_2). Because some anaerobes are fastidious, chocolate agar is used to support the nutritional needs of the organisms.

Method

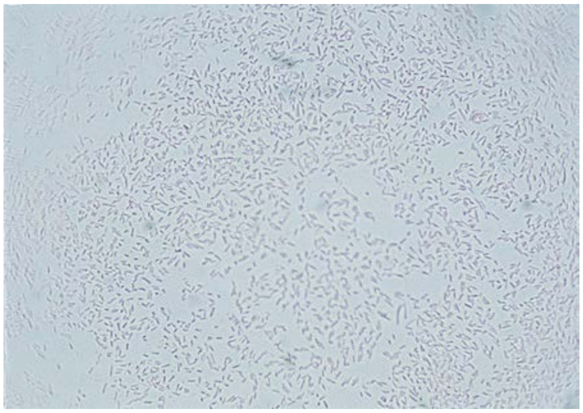
1. After isolation of the primary organism, streak the organism to a chocolate agar plate and incubate the plate at 35°C to 37°C in 5% CO_2 for 24 hours.
2. After incubation, examine the chocolate agar plate for growth. If no growth is seen, incubate an additional 24 hours and recheck for growth to ensure that the organism is anaerobic.

Expected Results

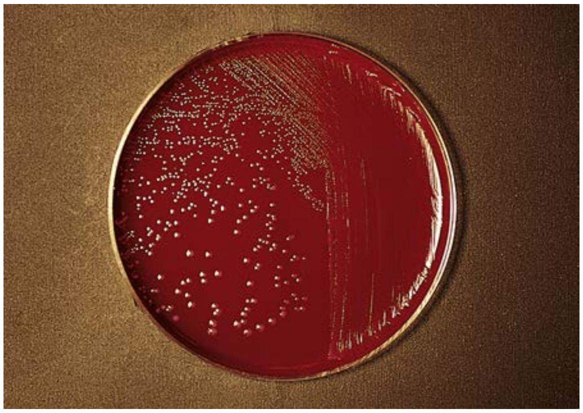
Growth on the chocolate agar plate indicates that the organism is not an anaerobe.

Limitations

Strictly anaerobic organisms are very sensitive to exposure to oxygen, which necessitates minimal exposure. If no growth occurs on primary isolation media or on chocolate agar, the organism may no longer be viable, and a negative result should not be reported.



• **Fig. 41.4** Gram stain of *Bacteroides fragilis*.



• **Fig. 41.5** *Bacteroides fragilis* on anaerobic blood agar.

25 of which have been isolated from human infection. *B. fragilis* is the most common organism isolated from clinical specimens, followed by *Bacteroides thetaiotaomicron* and *Bacteroides ovatus.* These organisms have been associated with a variety of infections.

The gram-negative *B. fragilis* group grows in 20% bile. These organisms are almost always resistant to all three special-potency antibiotic disks (Figs. 41.5 and 41.6). Rare strains of *B. fragilis* are susceptible to colistin.

Nonpigmented *Prevotella* spp.

Prevotella spp. are ubiquitous in the oral cavity and are an important component of dental biofilms. *Prevotella* organisms have been identified in the esophagus and stomach and isolated from human feces. Most are bile-sensitive, kanamycin-resistant, gram-negative rods. Colistin susceptibility is variable, and almost all strains are catalase- and indole-negative.

Pigmented *Porphyromonas* and *Prevotella* spp.

The *Porphyromonadaceae* family comprises seven genera, including *Butyricimonas*, *Coprobacter, Parabacteroides, Porphyromonas, Tannerella, Odoribacter,* and *Barnesiella. Porphyromonas* generally is considered the major pathogen in the *Porphyromonadaceae* family. There are approximately 19 species of *Porphyromonas* spp., 10 of which are commonly isolated from humans (*P. asaccharolytica, P. bennonis, P. bronchialis, P. catoniae, P. endodontalis, P. gingivalis, P. pasteri, P. pogonae, P. somerae,* and *P. uenonis*). Most *Porphyromonas* spp. are asaccharolytic and pigmented. The *Prevotellaceae* includes saccharolytic organisms that have been isolated from a variety of body sites, including the oral cavity and feces. Colonies that fluoresce brick red or produce brown to black pigment are included in the pigmented *Prevotella* (Fig. 41.7) and *Porphyromonas* spp. (Fig. 41.8). Some species appear coccobacillary on Gram staining.

• **Fig. 41.7** *Prevotella disiens* on laked kanamycin-vancomycin blood agar. Note the black pigment (*arrow*).

Fusobacteriaceae

The *Fusobacteriaceae* family includes the genera *Fusobacterium, Leptotrichia,* and *Sneathia.* These organisms are nonmotile, pleomorphic rods and typically are isolated from the oral cavity as integral components of dental biofilms or from the female genital tract (Fig. 41.9). The gram-negative *Fusobacterium* spp. (Fig. 41.10) are sensitive to kanamycin, and most strains fluoresce chartreuse. Different species have characteristic cell and colony morphologies.

The genus *Leptotrichia* includes seven validly described species. *Leptotrichia* spp. are saccharolytic, very large, fusiform rods with one pointed end and one blunt end that typically produce lactic acid. Colonies are large, gray, and

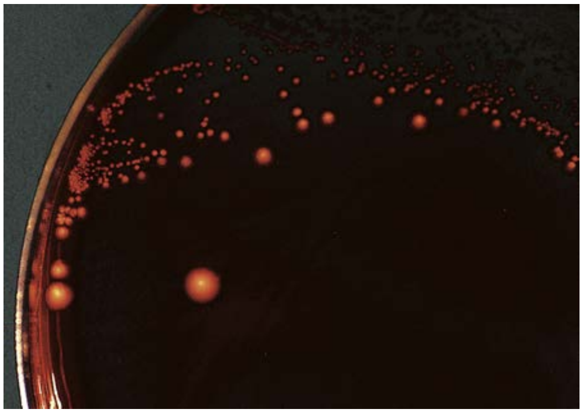
convoluted. They are most often isolated from the oral cavity or urogenital tract.

Proteobacteria

The phylum Proteobacteria contains a variety of clinically significant organisms, including *Bilophila wadsworthia, Desulfovibrio, Desulfomicrobium,* and *Sutterella wadsworthensis. B. wadsworthia* is an anaerobic, asaccharolytic, bile-resistant, gram-negative rod. *S. wadsworthensis* is an asaccharolytic, bile-resistant, short, gram-negative rod. *B. wadsworthia* phenotypically resembles *Campylobacter ureolyticus* (Chapter 33) but is resistant to bile and is strongly catalase-positive. *Desulfomicrobium* spp. are motile, spiral-shaped organisms capable of reducing sulfate. *Desulfomicrobium orale* has been associated with periodontal disease. There are more than 70 species of *Desulfovibrio*. These organisms are rarely associated with human infections.



• **Fig. 41.11** *Peptostreptococcus anaerobius* on anaerobic blood agar.

Anaerobic Gram-Positive and Gram-Negative Cocci

As stated earlier in this chapter and in Chapter 40, the proper collection and transport of specimens for anaerobic culture cannot be overemphasized. General considerations are included in the discussion in Chapter 40. The gram-positive anaerobic cocci typically are part of the normal microbiota of the oral cavity, upper respiratory tract, gastrointestinal tract, female genitourinary tract, and skin. The anaerobic cocci are non–spore forming and may appear slightly elongated. The cells vary in size and may be arranged in tetrads, chains, clusters, pairs, or clumps. Carbohydrate utilization varies among the genera. In addition, organisms typically classified as aerobic, such as *Staphylococcus epidermidis,* include strictly anaerobic strains. *Staphylococcus saccharolyticus* and *Staphylococcus aureus* subsp. *anaerobius* grow under anaerobic conditions, although after subculture they may develop aerotolerance. If a gram-positive coccus demonstrates resistance to metronidazole (5 µg) after 48 hours of incubation, it is likely a *Streptococcus* species. Among anaerobic gram-positive cocci, the genera of clinical importance are *Peptostreptococcus* (Fig. 41.11), *Finegoldia, Gallicola, Parvimonas, Peptoniphilus, Murdochiella, Peptococcus, Ezakiella, Staphylococcus,* and *Anaerococcus.*

The gram-negative anaerobic cocci are part of the normal microbiota of the oral cavity and the gastrointestinal, genitourinary, and respiratory tracts of humans. The category of anaerobic gram-negative cocci is based on Gram stain morphology. This category includes the genera *Veillonella, Megasphaera, Anaeroglobus, Negativicoccus,* and *Acidaminococcus.*

The genus *Veillonella* is ubiquitous as part of the normal microbiota of the human oral cavity and the genitourinary, respiratory, and gastrointestinal tracts. Human microbiome studies have begun to look at the balance of various anaerobic gram-negative cocci in normal and diseased tissue. In some instances, there are increased numbers of gram-negative cocci associated with abnormal clinical presentations such as *Megasphaera* in high-risk human papilloma viral infections and *Negativicoccus* in ground glass nodules associated with lung adenocarcinoma. When isolated from a clinical specimen, *Veillonella* are typically part of a mixed or polymicrobial culture.

Laboratory Diagnosis

Direct examination of clinical specimens reveals gram-positive or gram-negative cocci in chains, pairs, or singly. Some gram-positive cocci, in particular *Peptoniphilus asaccharolyticus*, are easily over-decolorized and can be misidentified as gram-negative. Follow-up tests to identify the organism are determined by the initial Gram stain. Organisms typically are isolated on anaerobic blood agar and can be differentiated using the special-potency antibiotic disks previously described in this chapter. Gram-positive cocci are sensitive to vancomycin and resistant to colistin. Gram-negative cocci typically are resistant to vancomycin. *Peptostreptococcus anaerobius* (≥12 mm) and *Parvimonas micra* (<12 mm) demonstrate sensitivity to sodium polyanethol sulfonate (SPS). *P. micra* also produces a milky halo around the colonies on blood agar. Interpretation and identification of either gram-positive or gram-negative cocci from a clinical specimen should be reported with caution and should correlate with the patient's signs and symptoms. Table 41.4 provides an identification scheme for representative anaerobic organisms.

Nucleic Acid Detection and MALDI-TOF MS

Nucleic acid–based methods have been developed to identify both anaerobic gram-positive and gram-negative cocci in the clinical laboratory. These methods include 16S rRNA sequencing, PCR, and oligonucleotide array assays. However, these methods are not without limitations. *Veillonella* demonstrates very low 16s rRNA variation making this method insufficient for species identification. Additional anaerobic cocci genera and species identifications are limited due to the lack of available reference sequence information in the databases. MALDI-TOF MS has been successfully used to identify many of the commonly isolated anaerobic gram-positive cocci. This method is also based on the spectra of 16s ribosomal proteins and housekeeping genes and may pose similar limitations on the identification of *Veillonella* spp. that are seen in nucleic acid–based methods.

Result Reporting

It is of primary importance to determine whether the clinical sample was properly collected when considering the isolation and identification of an anaerobic organism. Interpretations should be carefully interpreted because of the potential for contamination of specimens with the patient's normal microbiota. In addition, recent or current antimicrobial therapy should be reviewed.

Isolation of anaerobes from normally sterile sites is considered clinically significant, and should be identified and reported to the clinician.

Prevention

A multiple-dose vaccine is available for the prevention of tetanus. The immunogen, which is adsorbed **tetanus toxoid** (inactivated toxin), is administered with diphtheria toxoid and pertussis vaccine as a triple antigen called Tdap. Single boosters of diphtheria and tetanus (Td or Tdap) or tetanus alone are recommended every 10 years. These vaccines can be used to catch up individuals who did not complete their full childhood vaccinations of DTap.

Immunoprophylaxis in wound management depends on the type of wound. Completely immunized individuals with minor or uncontaminated wounds do not require specific treatment. However, completely immunized individuals with major or contaminated wounds should get a booster of tetanus toxoid if they have not had one in the previous 5 years. Finally, a partially immunized individual or one who has never been immunized should receive a dose of tetanus toxoid immediately. In addition, passive immunization with human **tetanus immune globulin (TIG)** should be given if an individual has a major wound or a wound contaminated with soil that contains animal feces.

Individuals who have eaten food suspected of containing botulinum toxin should be purged with **cathartics** (laxatives), have their stomach pumped, and be given high enemas.

Chapter Review

1. A rectal swab is submitted for anaerobic culture. The laboratory scientist should:
   a. Set up the swab on the routine laboratory media for anaerobic culture
   b. Set up the swab on routine stool and anaerobic media
   c. Reject the specimen
   d. Use the swab for toxin testing to identify *C. difficile*
2. Sulfur granules in a clinical specimen indicate the presence of:
   a. *Clostridium* spp.
   b. *Fusobacterium* spp.
   c. *Actinomyces* spp.
   d. *Peptostreptococcus* spp.
3. The ethanol shock procedure is used to differentiate:
   a. *Actinomyces* and *Bifidobacterium* spp.
   b. *Prevotella* and *Porphyromonas* spp.
   c. *Clostridium* and *Bacteroides* spp.
   d. *Bacteroides* and *Actinomyces* spp.
4. The physician suspects a case of *C. perfringens*–associated enteritis necroticans. The specimen(s) required for diagnosis is/are:
   a. Three blood cultures and a stool specimen
   b. A stool specimen
   c. A colonic tissue biopsy
   d. Stool and a colonic tissue biopsy
5. In the diagnosis of *C. difficile* infection (CDI), all of the following are true *except:*
   a. Specimens may be stored for up to 3 days before processing.
   b. Specimen collection requires a fresh stool for culture and toxicity testing.
   c. Liquid stool is used primarily to provide material for ease of toxicity testing.
   d. Liquid or partially formed stool is required to prevent false diagnosis of a carrier state.
6. A suprapubic urine aspirate is collected and submitted for anaerobic culture. After 72 hours of incubation and biochemical testing, the organism is identified as a gram-positive, aerotolerant, catalase-negative rod. The organism is most likely:
   a. *Lactobacillus* sp.
   b. *Bifidobacterium* sp.
   c. *Eubacterium* sp.
   d. *C. septicum*
7. Transmission of anaerobic infections is predominantly a result of:
   a. Medical device inoculation
   b. Nosocomial spread
   c. Contaminated food and water
   d. Normal microbiota
8. A patient presented to the emergency department complaining of a foul-smelling, purulent wound on his hand. The patient states that he injured his hand 3 days earlier while working in the yard. Microbiology cultures are ordered, and after 72 hours, the following results are obtained: gram-negative rod, growth on anaerobic blood agar, positive aerotolerance, weakly catalase-positive, colistin-resistant, kanamycin-resistant, and vancomycin-sensitive. The organism is most likely:
   a. *B. fragilis*
   b. *C. perfringens*
   c. *F. nucleatum*
   d. *B. thetaiotaomicron*
9. **Matching:** *Match each term with the best description.*

_____ *Mobiluncus* spp.
_____ *C. botulinum*
_____ *C. difficile*
_____ *Propionibacterium* spp.
_____ *P. micra*
_____ *Actinomyces*
_____ *Prevotella* spp.
_____ *Leptotrichia* spp.
_____ *C. perfringens*
_____ honey
_____ bioassay
_____ *Bacteroides* spp.

a. sulfur granules
b. propionic acid
c. brick red fluorescence
d. pseudomembranous colitis
e. pointed- and blunt-ended cell morphology
f. infant botulism
g. flaccid paralysis
h. bacterial vaginosis
i. bile resistant
j. neutropenic enterocolitis
k. BoNT
l. SPS sensitive

10. **Short Answer**
    (1) Why is it necessary to Gram stain the clinical specimen upon receipt in the laboratory when an anaerobic culture is ordered?
    (2) An organism is identified that is resistant to all three special potency disks (RRR) and demonstrates bile resistance. What is the likely identity of the organism?
    (3) After testing with the special potency disks, you identify an organism as gram-positive cocci. The Gram stain indicates that the organism is gram negative. What is the reason (or reasons) for the discrepancy? What would be the next step in laboratory diagnosis?

42

Mycobacteria

OBJECTIVES

1. Describe the general characteristics of the *Mycobacterium* spp., including oxygen requirements, staining patterns and cellular morphology, artificial media required for cultivation and growth, and macroscopic colonial pigmentation.
2. Explain the chemical composition of the bacterial cell wall.
3. Explain the microscopic staining characteristics of *Mycobacterium* spp. using the Gram stain and acid-fast staining methods.
4. List the most common of the pathogenic *Mycobacterium* spp. and state for each the natural habitat, mode of transmission, and reservoir.
5. Differentiate *Mycobacterium tuberculosis* clinical infections based on the signs and symptoms of the following: primary infection, latent infection, disseminated infection, and reactivation.
6. Compare the current safety and containment methods recommended for handling mycobacterial infectious materials and routine bacteriology in a diagnostic laboratory.
7. Describe the purified protein derivative (PPD) test, also referred to as the tuberculin skin test. What is the significance of a positive result?
8. List the clinical specimens acceptable for recovery of mycobacteria and describe the limitations of recovery from each type of specimen.
9. Justify the use of deoxyribonucleic acid (DNA) probes and molecular sequencing or amplification methods and matrix-assisted laser desorption ionization time-of-flight mass spectrometry (MALDI-TOF MS) to identify *Mycobacterium* spp.
10. Evaluate the effectiveness of the staining procedures—Kinyoun, Ziehl-Neelsen, and fluorescent staining (auramine-rhodamine or acridine orange)—for identifying mycobacteria.
11. Describe the requirements for using digestion and decontamination procedures to improve the recovery of *Mycobacterium* spp.
12. Explain the limitations of digestion and decontamination procedures.
13. Explain the methods commonly used for the biochemical identification of *Mycobacterium* spp. (i.e., niacin, nitrate, urease, modified catalase, Tween 80, tellurite, arylsulfatase, thiophene-2-carboxylic acid hydrazide [TCH], and 5% NaCl tests), including the purpose, principle, and control organisms used for each.
14. Describe the basic process and safety requirements associated with the extraction and processing of *Mycobacterium* spp. for MALDI-TOF MS TOF.
15. Describe the role of the human immunodeficiency virus (HIV) and acquired immunodeficiency syndrome (AIDS) in the dissemination and/or pathogenesis of infections with *Mycobacterium* spp.
16. Explain the recommended susceptibility testing methods and state when susceptibility testing is required or recommended for *Mycobacterium* spp.

MAJOR GENERA AND SPECIES TO BE CONSIDERED

Mycobacterium tuberculosis Complex

M. tuberculosis
M. bovis
M. bovis bacillus Calmette-Guérin (BCG)
M. africanum
M. caprae
M. canettii
M. microti
M. mungi
M. orygis
M. pinnipedii

Nontuberculous Mycobacteria

Slow-Growing Pathogens

M. avium complex (10 species, not listed here)
M. gordonae
M. haemophilum
M. kansasii
M. malmoense
M. marinum
M. ulcerans
M. xenopi

Rapid-Growing Opportunistic Pathogens

M. fortuitum group (10 species)
M. chelonae/abscessus group (6 species and 3 subspecies)
M. mucogenicum group (3 species)
M. smegmatis group (2 species)

Early Pigmented Rapid-Growing Opportunistic Pathogens

M. bacteremicum
M. canariasense
M. cosmeticum
M. mageritense/M. wolinskyi group (2 species)
M. monacense
M. neoaurum

Nonculturable Nontuberculosis Mycobacteria

M. leprae

Traditionally, *Mycobacterium* spp. have been classified according to phenotypic characteristics. However, since the late 1980s, molecular diagnostics have been used to shift the characterization of these organisms to genotypic studies. This chapter discusses both the phenotypic characterization and the new taxonomy based on molecular genetic data.

The organisms that belong to the genus *Mycobacterium* are aerobic (although *M. tuberculosis, M. bovis* BCG, and *M. avium* subsp. *paratuberculosis* demonstrate growth in reduced oxygen concentrations), non–spore-forming (except for *Mycobacterium marinum* and *M. avium* subsp. *paratuberculosis*), nonmotile, very thin, slightly curved or straight rods (0.2–0.6 × 1–10 μm). Some species may display a branching morphology. *Mycobacterium* is the only genus in the *Mycobacteriaceae* family (order Actinomycetales, class Actinomycetes). Genera that are closely related to *Mycobacterium* include *Corynebacterium, Nocardia, Rhodococcus, Segniliparus, Tsukamurella,* and *Gordonia.*

Mycobacterium spp. have an unusual cell wall; it contains N-glycolylmuramic acid instead of N-acetylmuramic acid and has a very high lipid content, which creates a hydrophobic permeability barrier. Because of this structure, mycobacteria are difficult to stain with commonly used basic aniline dyes such as those used in Gram staining. Although these organisms cannot be readily Gram stained, they are generally considered gram positive. However, they resist decolorization with acidified alcohol (3% hydrochloric acid) after prolonged application of a basic fuchsin dye or with heating of this dye after its application. This important property of mycobacteria, which derives from their cell wall structure, is referred to as **acid fastness;** this characteristic distinguishes mycobacteria from other genera. **Rapid-growing mycobacteria (RGM),** in which growth is apparent sooner than 7 days after subculture to Lowenstein-Jensen medium, may partially or completely lose this characteristic as a result of their growth characteristics.

Another important feature of many species is that they grow more slowly than most other human pathogenic bacteria because of their hydrophobic cell surface. Because of this hydrophobicity, organisms tend to clump, so that nutrients are not easily allowed into the cell. A single cell's generation time (the time required for a cell to divide into two independent cells) may range from approximately 20 to 36 hours for *Mycobacterium ulcerans.* **Slow-growing mycobacteria,** by definition, require more than 7 days to produce colonies on solid media. The variation in generation times among the mycobacteria results in the formation of visible colonies in 2 to 60 days at optimum temperature.

The genus *Mycobacterium* includes several highly pathogenic species included in the *M. tuberculosis* complex—*M. uclerans* and the nonculturable *M. leprae*. There are also more than 180 species of nonculturable **nontuberculosis mycobacteria (NTM),** many of which are increasingly found in opportunistic pathogens that are found throughout the environment.

The NTM slow-growing mycobacteria comprise more than 90 species, several of which are clinically significant. These organisms produce a spectrum of infections in humans and animals ranging from localized lesions to disseminated disease. Some species cause only human infections and others have been isolated from a wide variety of animals. Many species are also found in water and soil.

For the most part, mycobacteria can be divided into two major groups based on fundamental differences in epidemiology and association with disease: those belonging to the *M. tuberculosis* complex and the others to the NTM group.

Mycobacterium tuberculosis Complex

Tuberculosis was endemic in animals in the Paleolithic period, long before it ever affected humans. This disease (also called **consumption**) has been recognized in all ages and climates. For example, tuberculosis was the subject of a hymn in a sacred text from India dating from 2500 BC, and deoxyribonucleic acid (DNA) unique to *M. tuberculosis* was identified in lesions from the lung of 1000-year-old human remains found in Peru.

General Characteristics

In the clinical microbiology laboratory, the term **complex** is commonly used to describe two or more species for which distinction is complicated and has little or no medical importance. The mycobacterial species that occur in humans and belong to the *M. tuberculosis* complex include *M. tuberculosis, Mycobacterium bovis, M. bovis* BCG, *Mycobacterium africanum, Mycobacterium caprae, Mycobacterium microti, Mycobacterium canettii, Mycobacterium mungi, Mycobacterium orygis,* and *Mycobacterium pinnipedii.* All these species are capable of causing tuberculosis. It should be noted that species identification might be required for epidemiologic and public health reasons. The organisms that belong to the *M. tuberculosis* complex are considered slow growers and their colonies are nonpigmented.

Epidemiology and Pathogenesis

Epidemiology

M. tuberculosis is the cause of most cases of human tuberculosis, particularly in developed countries. *M. tuberculosis* complex organisms are not able to replicate in the environment and are therefore isolated to growth in tissues of humans and other warm-blooded animals. An estimated 2.4 billion people, or one-third of the world's population, are infected with *M. tuberculosis.* This reservoir of infected individuals results in approximately 10 million new cases of tuberculosis and 2.9 million deaths annually. Tuberculosis continues to be a public health problem in the United States. An additional complicating factor in the management of tuberculosis is the increasing incidence of coinfection with HIV. HIV-associated tuberculosis remains a significant challenge to world health, with an estimated 1.1 million individuals living with HIV-associated tuberculosis. In the United States, tuberculosis is typically found among the poor, the homeless, intravenous drug users, alcoholics, the elderly—in general, medically underserved populations. Another area of concern is the increased identification of multidrug-resistant tuberculosis (MDR-TB) and extensively drug-resistant tuberculosis (XDR-TB). Although the organisms belonging to the *M. tuberculosis* complex have numerous characteristics in common, including extreme genetic homogeneity, they differ in certain epidemiologic aspects (Table 42.1).

TABLE 42.1 **Epidemiology of Organisms Belonging to *Mycobacterium tuberculosis* Complex That Cause Human Infections**

Organism	Habitat	Primary Route of Transmission	Distribution
Mycobacterium tuberculosis	Patients with cavitary disease are primary reservoir.	Person-to-person by inhalation of droplet nuclei: droplet nuclei containing the organism (infectious aerosols, 1–5 μm) are produced when people with pulmonary tuberculosis cough, sneeze, speak, or sing; infectious aerosols may also be produced by manipulation of lesions or processing of clinical specimens in the laboratory. Droplets are so small that air currents keep them airborne for long periods; once inhaled, they are small enough to reach the lungs' alveoli.[a]	Worldwide
Mycobacterium bovis	Humans and a wide range of host animals, such as cattle, nonhuman primates, goats, cats, buffalo, badgers, possums, dogs, pigs, and deer.	Ingestion of contaminated milk from infected cows[b]; airborne transmission.[c]	Worldwide
Mycobacterium bovis BCG	Commercial vaccine strain that has been maintained by serial passage *in vitro.*	A heterogenous population of strains currently exist and are transmitted via immunization. They are attenuated strains that react similar to *M. bovis.*	Worldwide
Mycobacterium africanum	Humans.[d]	Inhalation of droplet nuclei.	East and West tropical Africa; some cases have been identified in the United States
Mycobacterium caprae	Predominately infects a wide range of animals: goats, cattle, sheep, pigs, wild boars, red deer, and foxes. Endemic in wild ruminants and dairy cattle in Australia.	Inhalation of droplet nuclei, leading to pulmonary manifestations.	Europe
Mycobacterium microti	Humans rarely; small animals (e.g., voles and other wild rodents); domestic cats, wild boars, badgers, and goats.	Inhalation of droplet nuclei; potentially transmitted by the ingestion of contaminated raw goat milk cheese or other animal products.	Europe; Great Britain, Netherlands
Mycobacterium mungi	Natural reservoir is the banded mongoose; rarely infects humans.	Unclear; likely inhalation of droplet nuclei.	Africa
Mycobacterium canettii	Natural reservoir has not been clearly defined. Rarely infects humans.	Unclear; inhalation of droplet nuclei most likely.	Africa
Mycobacterium orygis	Larger mammals; oryxes, gazelles, antelopes, and waterbucks.	Unclear; likely inhalation of droplet nuclei or direct contact; zoonotic.	Africa
Mycobacterium pinnipedii	Humans rarely; predominantly infects a wide range of animals (pigs, rabbits, camels, tapirs, and sea lions; possibly cattle).	Inhalation of droplet nuclei; however, transmission from sea lions to humans has been demonstrated in zoologic settings.	Europe

BCG, Bacillus Calmette-Guérin.

[a] Infection can occasionally occur through the gastrointestinal tract or skin.

[b] The incidence has decreased significantly in developed countries since the introduction of universal pasteurization of milk and milk products and the institution of effective control programs for cattle.

[c] Can be transmitted human to human, animal to human, and human to animal.

[d] Infections in animals have not been totally excluded.

Pathogenesis

The pathogenesis of tuberculosis caused by organisms of the *M. tuberculosis* complex is discussed in Chapter 68. Inhalation of a single viable organism has been shown to lead to infection, although close contact is usually necessary. Of those who become infected with *M. tuberculosis,* 15% to 20% develop disease. The disease usually occurs some years after the initial infection, when the patient's immune system breaks down for some reason other than the presence of tuberculosis bacilli in the lung. In a small percentage of infected hosts, the disease becomes systemic, affecting a variety of organs.

After the ingestion of unpasteurized dairy products from infected cows, *M. bovis* may penetrate the gastrointestinal mucosa or invade the lymphatic tissue of the oropharynx. The organism is also often transmitted by the inhalation of infectious droplets from infected cattle. An attenuated strain of *M. bovis,* **bacillus Calmette-Guérin (BCG)**, has been used extensively in many parts of the world to immunize susceptible individuals against tuberculosis. Because mycobacteria are the classic examples of intracellular pathogens and the body's response to BCG hinges on cell-mediated immunoreactivity, immunized individuals are expected to react more aggressively against all antigens that elicit cell-mediated immunity. In rare cases, an individual's immune system is so compromised that it cannot handle the BCG, so that systemic BCG infection may develop.

M. africanum demonstrates physiologic and biochemical properties that place it intermediately between *M. tuberculosis* and *M. bovis.* This organism has been primarily identified as the cause of approximately half of the cases of tuberculosis in West Africa, but it has also been found in the United States in patients who previously resided in Africa. *M. caprae* can be identified by its susceptibility to pyrazinamide. This organism is associated with approximately 31% of the cases of human tuberculosis. Reservoir hosts for the organism include goats, cattle, sheep, pigs, wild boars, deer, and fox. *M. microti,* typically found in rodents, guinea pigs, rabbits, cats, llamas, and meerkats, usually fails to grow in culture. It has been identified in tuberculosis in both immunocompetent and immunosuppressed patients. *M. canettii* has been primarily identified in cases of lymphadenitis and generalized tuberculosis in immunocompromised individuals. This organism has also been primarily associated with infections in individuals who previously resided or currently reside in Africa. *M. pinnipedii* is transmitted from sea lions to humans and has been associated with granulomatous lesions in the lymph nodes, lungs, pleura, and spleen. It is also pathogenic in guinea pigs, rabbits, camels, and possibly cattle. The two additional species in the *M. tuberculosis* complex reservoir hosts include the banded mongoose *(M. mungi)* or large mammals such as gazelles, antelopes, waterbucks, and oryxes *(M. orygis)*. The latter causes a disease in humans that is indistinguishable from tuberculosis.

Spectrum of Disease

Tuberculosis may mimic other diseases, such as pneumonia, neoplasm, or fungal infections. In addition, clinical manifestations in patients infected with *M. tuberculosis* complex may range from asymptomatic to acutely symptomatic. Patients who are symptomatic can have systemic symptoms, pulmonary signs and symptoms, signs and symptoms related to other organ involvement (e.g., the kidneys), or a combination of these features. Cases of pulmonary disease caused by *M. tuberculosis* complex organisms are clinically, radiologically, and pathologically indistinguishable.

Primary tuberculosis typically is considered a disease of the respiratory tract. Common presenting symptoms include low-grade fever, night sweats, fatigue, anorexia (loss of appetite), and weight loss. A patient who presents with pulmonary tuberculosis usually has a productive cough, along with low-grade fever, chills, myalgias (aches), and sweating; however, these signs and symptoms are similar for influenza, acute bronchitis, and pneumonia.

Upon respiratory infection with *M. tuberculosis* complex organisms, the cellular immune system's T cells and macrophages migrate to the lungs, where the organisms are phagocytized by the macrophages. However, these organisms are capable of intracellular multiplication in the macrophages. Often the host is unable to eliminate the organisms, and the result is a systemic hypersensitivity to *Mycobacterium* antigens. **Granulomas,** or hard tubercles, form in the lung from the lymphocytes, macrophages, and cellular pathology, including the formation of **giant cells** (cellular fusion displaying multiple nuclei). If the *Mycobacterium* antigen concentration is high, the hypersensitivity reaction may result in tissue necrosis caused by enzymes released from the macrophages. In this case no granuloma forms, and a solid or semisolid **caseous** material is left at the site of the primary lesion.

In some patients infected with primary active tuberculosis, the disease may spread via the lymph system or hematogenously, leading to **meningeal** or **miliary (disseminated) tuberculosis.** This most often occurs in patients with depressed or ineffective cellular immunity.

As previously mentioned, in a small percentage of patients, organs besides the lungs can become involved after infection with *M. tuberculosis* complex organisms. These organs include the following:

- Genitourinary tract
- Lymph nodes (cervical lymphadenitis)
- Central nervous system (meningitis)
- Bone and joint (arthritis and osteomyelitis)
- Peritoneum
- Pericardium
- Larynx
- Pleural lining (pleuritis)

Disseminated tuberculosis can be diagnosed by a positive tuberculin skin test (described later in the chapter).

Patients may also have **latent tuberculosis** (i.e., they have no apparent signs, symptoms, or pathologic condition).

A patient with latent tuberculosis is not infectious and does not have active disease, although the organism is present in granulomas. Patients with latent tuberculosis may progress to active disease (also referred to as **reactivation tuberculosis**) at any time. Reactivation tuberculosis typically occurs after an incident in which cellular immunity is suppressed or damaged as a result of a change in lifestyle or other health condition.

Individuals infected with HIV are particularly susceptible to developing active tuberculosis. These patients are likely to have rapidly progressive primary disease instead of a subclinical infection.

Diagnosing tuberculosis is more difficult in people infected with HIV because chest radiographs of the pulmonary disease often lack specificity, and patients frequently are **anergic** (lack a biologic response) to tuberculin skin testing, a primary means of identifying individuals infected with *M. tuberculosis.* The **tuberculin skin test,** or **purified protein derivative (PPD) test,** is based on the premise that after infection with *M. tuberculosis,* an individual develops a delayed hypersensitivity cell-mediated immunity to certain antigenic components of the organism. To determine whether a person has been infected with *M. tuberculosis,* a culture extract of *M. tuberculosis* (i.e., PPD of tuberculin) is injected intracutaneously. After 48 to 72 hours, an infected individual will show a delayed hypersensitivity reaction to the PPD, characterized by erythema (redness) and, most important, induration (firmness because of the influx of immune cells). The diameter of induration is measured and then interpreted as to whether the patient has been infected with *M. tuberculosis;* different interpretive criteria are used for different patient populations (e.g., immunosuppressed individuals, such as those infected with HIV). The PPD test is not 100% sensitive or specific, and a positive reaction to the skin test does not necessarily signify the presence of disease.

Immunodiagnostic methods that measure the release of interferon gamma by T cells following stimulation with MTBC antigens provide specific and rapid results that demonstrate equivalent and increased sensitivity compared to the PPD test. Two commercially available interferon gamma release assays (IGRAs) approved by the US Food and Drug Administration (FDA) are available in the United States. The T-Spot TB test (Oxford Immunotec, Oxford, UK) offers next-day results and does not require a follow-up visit with a physician. The assay measures T cells that have been activated by *M. tuberculosis* antigens. Peripheral blood mononuclear cells (PBMCs) are incubated with *M. tuberculosis*–specific antigens, thus stimulating any sensitized T cells in the patient sample. T-cell cytokines released in the sample are measured, using antibody to capture them, and then detected with a secondary antibody conjugated to alkaline phosphatase. This assay should be interpreted in correlation with the patient's signs and symptoms.

An enzyme-linked immunosorbent assay (ELISA) called QuantiFERON-TB Gold Plus (Qiagen, Germantown, MD) is also available. The assay measures a component of the cell-mediated immune response to *M. tuberculosis* to diagnose latent tuberculosis infection and is not generally used to identify active tuberculosis disease. It is based on the quantification of interferon-gamma released from sensitized lymphocytes in heparinized whole blood that has been incubated overnight with a mixture of synthetic peptides simulating two proteins in *M. tuberculosis.* The test assesses responses to multiple antigens, can be performed in a single patient visit, and is less subject to reader bias and error. An important feature is that the results of the assay are unaffected by previous BCG vaccination. Guidelines published by the Centers for Disease Control and Prevention (CDC) recommend the use of this assay in all circumstances in which the tuberculin skin test is currently used (e.g., contact investigations and the evaluation of recent immigrants). The guidelines also provide specific cautions for interpreting negative results in individuals from selected populations.

Nontuberculous Mycobacteria

The NTM include all mycobacterial species that do not belong to the *M. tuberculosis* complex. Currently approximately 180 species of NTM have been recognized, with about 90 species classified as slow growing. The members of this large group of mycobacteria are often opportunistic pathogens. Those most often isolated from clinical specimens are discussed in this chapter. Significant geographic variability is seen both in the prevalence of NTM disease and the species responsible. As previously mentioned, NTM are present everywhere in the environment and sometimes colonize the skin as well as the respiratory and gastrointestinal tracts of healthy individuals. Little is known about how infection is acquired, but some mechanisms appear to be trauma, inhalation of infectious aerosols, and ingestion; a few diseases are nosocomial or are acquired as an iatrogenic infection. In contrast to *M. tuberculosis* complex, NTM are not usually transmitted from person to person, nor does isolation of these organisms necessarily mean that they are associated with a disease process. Interpretation of a positive NTM culture is complicated because these organisms are widely distributed in nature, their pathogenic potential varies greatly from one species to another, and humans can be colonized by these mycobacteria without necessarily developing infection or disease. With few exceptions, little is known about the pathogenesis of infections caused by these bacterial agents.

In 1959, Runyon classified NTM into four groups (**Runyon groups I to IV**) based on the phenotypic characteristics of the various species, most notably their growth rates and colonial pigmentation (Table 42.2). Runyon's system first categorizes the slow-growing NTM (Runyon groups I to III) and then the rapid growers (Runyon group IV). One other NTM, *M. leprae,* which cannot be cultivated on artificial media, is also reviewed. As with many classification schemes, the Runyon classification does not always hold true. For example, some NTM can be either a photochromogen or a nonphotochromogen.

TABLE 42.2 **Runyon Classification of Nontuberculous Mycobacteria**

Runyon Group Number	Group Name	Description
I	Photochromogens	NTM colonies that develop pigment on exposure to light after being grown in the dark and take longer than 7 days to appear on solid media
II	Scotochromogens	NTM colonies that develop pigment in the dark or light and take longer than 7 days to appear on solid media
III	Nonphotochromogens	NTM colonies that are nonpigmented regardless of whether they are grown in the dark or light and take longer than 7 days to appear on solid media
IV	Rapid growers	NTM colonies that grow on solid media and take fewer than 7 days to appear

NTM, Nontuberculous mycobacteria.

Because it is difficult to determine the clinical significance of an NTM that has been isolated from a clinical sample, several clinical classification schemes have also been proposed. One such scheme classifies NTM recovered from humans into four major groups (pulmonary, lymphadenitic, cutaneous, or disseminated) based on the clinical disease they cause. Other NTM classifications are based on the pathogenic potential of a species.

Slow-Growing Nontuberculous Mycobacteria

The slow-growing NTM can be subdivided into three groups based on the phenotypic characteristics of the species. *Mycobacterium* spp. synthesize **carotenoids** (a group of yellow to red pigments) in varying amounts and thus can be categorized into three groups—photochromogens, scotochromogens, and nonphotochromogens—based on the production of those pigments Some of these NTM are considered potentially pathogenic for humans, whereas others are rarely associated with disease.

Photochromogens

The **photochromogens** (Table 42.3) are slow-growing NTM that produce colonies requiring light to form pigment.

Scotochromogens

The **scotochromogens** (Table 42.4) are slow-growing NTM that produce pigmented colonies whether grown in the dark or the light. The epidemiology of the potentially pathogenic scotochromogens has not been definitively described. In contrast to potentially pathogenic nonphotochromogens, these agents are rarely recovered in the clinical laboratory.

Nonphotochromogens

The **nonphotochromogens** (Table 42.5) are slow-growing NTM that produce unpigmented colonies whether grown in the dark or the light. Of the organisms in this group, *Mycobacterium terrae* complex (*M. terrae* and *M. nonchromogenicum*) and *Mycobacterium gastri* are considered nonpathogenic for humans. *M. arupense, M. kumamotonense, M. heraklionense,* and *M. virginiense* are pathogenic when associated with tenosynovitis or osteomyelitis. The other nonphotochromogens are considered potentially pathogenic, and many are commonly recovered in the clinical laboratory. The nonphotochromogens belong to *M. avium* complex (MAC); they are commonly isolated in the clinical laboratory and able to cause infection in the human host.

Mycobacterium avium Complex

Largely because of the increasing populations of immunosuppressed patients, the incidence of infection caused by MAC—as well as these organisms' clinical significance—has changed significantly since they were first recognized as human pathogens in the 1950s. The introduction of **highly active antiretroviral therapy (HAART)** has dramatically reduced the infections caused by these organisms in patients with AIDS.

General Characteristics. Taxonomically, MAC comprises *M. avium, Mycobacterium intracellulare, M. avium* subsp. *avium, M. avium* subsp. *paratuberculosis, M. avium* subsp. *silvaticum* (wood pigeon bacillus), *M. avium* subsp. *hominissuis, M. arosiense, M. vulneris, M. marseillense, M. bouchedurhonense, M. chimaera, M. colombiense, M. yogonense,* and *M. timonense.* Although *M. avium* and *M. intracellulare* are clearly different organisms, they so closely resemble each other that the distinction cannot be made by routine laboratory determinations or on clinical grounds. As a result, these organisms are sometimes referred to as *M. avium-intracellulare.* Furthermore, because isolation of *M. avium* subsp. *paratuberculosis* in a routine laboratory setting is exceedingly rare, the term MAC is most commonly used to report the isolation of *M. avium-intracellulare.*

Epidemiology and Pathogenesis. MAC is an important pathogen in both immunocompromised and immunocompetent populations. These organisms are among the most commonly isolated NTM in the United States. MAC is particularly noteworthy for its potentially pathogenic role in pulmonary infections in patients with AIDS and in those who

TABLE 42.3 **Characteristics of Representative Nontuberculous Mycobacteria—Photochromogens**

Organism	Epidemiology	Pathogenicity	Type of Infection
Mycobacterium kansasii	Infection more common in white males; natural reservoir is tap water; aerosols are involved in transmission.	Potentially pathogenic	Chronic pulmonary disease; extrapulmonary diseases, such as cervical lymphadenitis and cutaneous disease
Mycobacterium asiaticum	Not commonly encountered, tropical climates and commonly found in environmental water (primarily seen in Australia). No human-to-human transmission has been reported.	Frequent colonizer, potentially pathogenic	Pulmonary disease and extrapulmonary disease in a variety of organs and musculoskeletal system bursitis and tenosynovitis
Mycobacterium branderi	Unclear, environmental exposure suspected.	Potentially pathogenic	Ulcerative tenosynovitis, pulmonary disease, and wound infections
Mycobacterium marinum	Natural reservoirs are freshwater and saltwater as a result of contamination from infected fish and other marine life. Transmission is by contact with contaminated water and organism entry by means of trauma or small breaks in the skin; associated with aquatic activity usually involving fish.	Potentially pathogenic	Cutaneous disease; bacteremia
Mycobacterium intermedium	Environmental water sources.	Potentially pathogenic	Pulmonary disease (chronic bronchitis) and dermatitis
Mycobacterium nebraskense	Cutaneous infections have been identified in dogs and cats.	Potentially pathogenic	Pulmonary disease and cutaneous infections

are not infected with HIV. The organisms are ubiquitous in the environment and have been isolated from natural water, soil, dairy products, pigs, chickens, cats, and dogs. As a result of extensive studies, it is generally accepted that natural waters serve as the major reservoir for most human infections.

Infections caused by MAC are acquired by inhalation or ingestion. The pathogenesis of MAC infections is not clearly understood. The organisms are commonly associated with respiratory disease clinically similar to tuberculosis in adults, lymphadenitis in children, and disseminated infection in patients with HIV. However, these organisms and other environmental NTM have extraordinary starvation survival. They can persist well over a year in tap water, and MAC tolerates temperature extremes. In addition, similar to legionellae, *M. avium* can infect and replicate in protozoa. Amoeba-grown *M. avium* is more invasive toward human epithelial and macrophage cells.

MAC cultures can have an opaque glossy-white colony morphology or can produce a smaller translucent colony morphology. Studies suggest that transparent colonies are more virulent because they are more drug resistant, are isolated more commonly from the blood of patients with AIDS and appear more virulent in macrophage and animal models. In addition, a third morphology appears as a dry flat colony that can be confused with *M. tuberculosis.* Some colonies may also produce a yellow pigment as they age.

M. avium subsp. *paratuberculosis* is known to cause an inflammatory bowel disease (known as **Johne disease**) in cattle, sheep, and goats. It has also been isolated from the bowel mucosa of patients with Crohn disease, a chronic inflammatory bowel disease of humans. The organism is extremely fastidious, seems to require a growth factor (mycobactin, produced by other species of mycobacteria), and may take as long as 6 to 18 months for primary isolation. Whether these and other mycobacteria contribute to the development of Crohn disease or are simply colonizing an environmental niche in the bowel of these patients remains to be elucidated.

Clinical Spectrum of Disease. The clinical manifestations of MAC infections are summarized in Table 42.5.

Other Nonphotochromogens

Several other mycobacterial species that are considered nonphotochromogens are potentially pathogenic in humans. The

TABLE 42.4 Characteristics of Representative Nontuberculous Mycobacteria—Scotochromogens

Organism	Epidemiology/Habitat	Pathogenicity	Type of Infection
Mycobacterium europaeum	May be a colonizer that leads to infection	Potentially pathogenic	Pulmonary disease and lymphadenitis; infections are most often associated with immunocompromised individuals with other respiratory diseases or comorbidities
Mycobacterium szulgai	Water and soil	Potentially pathogenic	Pulmonary disease, and extrapulmonary infections; cervical adenitis; bursitis
Mycobacterium scrofulaceum	Raw milk, soil, water, dairy products	Potentially pathogenic	Cervical adenitis in children, bacteremia, pulmonary disease, skin infections
Mycobacterium interjectum	Unknown; respiratory likely	Potentially pathogenic	Chronic lymphadenitis, pulmonary disease and polyangiitis; may lead to disseminated disease
Mycobacterium heckeshornense	Unknown; environmental	Potentially pathogenic	Pulmonary disease (cavitary and nodular), lymphadenitis, tenosynovitis and osteomyelitis
Mycobacterium lentiflavum	Environmental water	Potentially pathogenic	Pulmonary disease, lymphadenitis, spondylodiscitis, skin and disseminated disease. Frequently isolated from patients with cystic fibrosis.
Mycobacterium mantenii	Environmental water	Potentially pathogenic	Pulmonary disease and lymphadenitis
Mycobacterium palustre	Unknown	Potentially pathogenic	Lymphadenitis
Mycobacterium parmense	Unknown	Potentially pathogenic	Lymphadenitis
Mycobacterium tusciae	Unknown—isolated from tap water	Potentially pathogenic	Cervical lymphadenitis (rare)
Mycobacterium kubicae	Unknown	Potentially pathogenic	Pulmonary disease
Mycobacterium gordonae	Tap water (pipelines and laboratory faucets), fresh water, soil	Potentially pathogenic	Pulmonary pneumonitis and other hypersensitivity lung disease primarily in immunocompromised patients
Mycobacterium cookii	Sphagnum moss, surface waters in New Zealand	Nonpathogenic[a]	NA
Mycobacterium hiberniae	Sphagnum moss, soil in Ireland	Nonpathogenic[a]	NA

[a] Rarely if ever causes disease.
NA, Not applicable.

epidemiology and spectrum of disease for these organisms are summarized in Table 42.5. In addition to the species in this table, other more recently characterized species of mycobacteria that are nonphotochromogens have been described, such as *Mycobacterium celatum* and *Mycobacterium conspicuum.* These agents appear to be potentially pathogenic in humans.

Rapidly Growing Nontuberculous Mycobacteria

Mycobacteria that produce colonies on solid media in 7 days or earlier constitute the second major group of NTM, or rapidly growing mycobacteria (RGM). Currently approximately 89 species have been classified into this group.

General Characteristics

The large group of organisms that constitute the RGM is divided into six major groups of potentially pathogenic species based on pigmentation and molecular studies. The common human pathogens in this group include *Mycobacterium abscessus* subsp. *abscessus, Mycobacterium chelonae,* and *Mycobacterium fortuitum*. Two new species—*M. celeriflabum* and *M saopaulense*—have been isolated from human samples. Unlike most other mycobacteria, most RGM can grow on

TABLE 42.5 **Characteristics of the Representative Nontuberculous Mycobacteria—Nonphotochromogens and Species Considered Potential Pathogens**

Organism	Epidemiology	Type of Infection
Mycobacterium avium complex	Environmental sources, including natural waters and soil	Patients without AIDS: pulmonary infections in patients with preexisting pulmonary disease; cervical lymphadenitis; and disseminated disease[a] in immunocompromised patients who are HIV negative Patients with AIDS: disseminated disease.
Mycobacterium celatum	Unknown	Immunocompetent patients: primarily children and the elderly. Immunocompromised: 32% of patients also infected with HIV; pulmonary disease and lymphadenitis.
Mycobacterium xenopi[b]	Water, especially hot water taps in hospitals; believed to be transmitted in aerosols	Primarily pulmonary infections in adults; less common, extrapulmonary infections (bone, lymph nodes, sinus tract) and disseminated disease
Mycobacterium ulcerans	Stagnant tropical waters; also harbored in an aquatic insect's salivary glands; infections occur in tropical or temperate climates. Third most common mycobacterial disease worldwide.	Indolent cutaneous and subcutaneous infections (African Buruli ulcer or Australian Bairnsdale ulcer); severe limb deformities with contractures and scarring are common
Mycobacterium lacus	Unknown; genetically related to *M. malmoense* and *M. marinum*	Bursitis with caseating granulomas after trauma
Mycobacterium malmoense	Most cases from England, Wales, and Sweden. Little is known about epidemiology; to date, isolated only from humans and captured armadillos.	Chronic pulmonary infections, primarily in patients with preexisting disease; cervical lymphadenitis in children; less common, infections of the skin or bursae
Mycobacterium genavense	Isolated from pet birds (parrots and parakeets), dogs, and tap water	Disseminated disease in patients with AIDS (wasting disease characterized by fever, weight loss, hepatosplenomegaly, anemia)
Mycobacterium haemophilum	Unknown; optimal growth temperature is 28°C–30°C and requires hemin or hemoglobin	Disseminated disease; cutaneous infections that appear as multiple skin lesions or ulcerations and associated with abscesses, fistulas, or osteomyelitis, cervical lymphadenitis, or pulmonary nodules
Mycobacterium heidelbergense	Unknown	Lymphadenitis in children; also isolated from sputum, urine, and gastric aspirate
Mycobacterium shimoidei	To date, has not been isolated from environmental sources; widespread geographically	Tuberculosis-like pulmonary infection; disseminated disease
Mycobacterium simiae	Tap water and hospital water tanks; rarely isolated	Tuberculosis-like pulmonary infection
Mycobacterium terrae complex	Trauma and respiratory routes; may be found in aquatic environments	Tenosynovitis and pulmonary disease

[a] Disseminated disease can involve multiple sites, such as bone marrow, lungs, liver, lymph nodes.
[b] Can be either nonphotochromogenic or scotochromogenic.
AIDS, Acquired immunodeficiency syndrome; *HIV,* human immunodeficiency virus.

routine bacteriologic media and on media specific for the cultivation of mycobacteria. On Gram staining, these organisms appear as weakly gram-positive rods resembling diphtheroids.

Epidemiology and Pathogenesis

The rapidly growing mycobacteria considered potentially pathogenic can cause disease in either healthy or immunocompromised patients. Like many other NTM, these organisms are ubiquitous in the environment and are present worldwide. They have been found in soil, marshes, rivers, and municipal water supplies (tap water) and in marine and terrestrial life forms. Infections caused by RGM can be acquired in the community from environmental sources. They can also be health care–associated infections resulting from medical interventions (including bone marrow transplantation), wound infections, and catheter sepsis. These organisms may be commensals on the skin. They gain entry into the host through inoculation into the skin and subcutaneous tissues as a result of trauma, injections, or surgery and may also be acquired through animal contact or from posttraumatic wound infections.

The RGM can also cause disseminated cutaneous infections. The description of chronic pulmonary infections caused by RGM suggests a possible respiratory route for the acquisition of organisms present in the environment. Of the potentially pathogenic rapidly growing NTM, *M. fortuitum* group, *M. chelonae,* and *M. abscessus* subsp. *abscessus* are commonly encountered; these three account for approximately 90% of clinical disease. Little is known about the pathogenesis of these organisms.

Spectrum of Disease

The spectrum of disease caused by the most commonly encountered rapid growers is summarized in Table 42.6. The most common infection associated with RGM is posttraumatic wound infection. An increase in wound infections has been associated with planktonic *M. abscessus* subsp. *abscessus,* which can be identified as a rough colonial phenotype on artificial media; these organisms are capable of infecting macrophages. The smooth colonial phenotype is typically identified in biofilms and lacks infectivity. Disseminated cutaneous infection due to *M. abscessus* and *M. chelonae* is common and presents as multiple chronic and painful red draining nodules often in the lower extremities. *M. abscessus* subsp. *abscessus* and *M. abscessus* subsp. *massiliense* are increasingly identified in the respiratory tracts of patients with cystic fibrosis.

Noncultivatable Nontuberculous Mycobacteria—*Mycobacterium leprae*

The nontuberculous mycobacterium *M. leprae* is a close relative of *M. tuberculosis.* This organism causes **leprosy** (also called **Hansen disease**)—a chronic disease of the skin, mucous membranes, and nerve tissue. Leprosy remains a worldwide public health concern owing to the development of drug-resistant isolates.

General Characteristics

M. leprae has not yet been cultivated *in vitro,* although it can be cultivated in the armadillo and in the footpads of mice. Molecular biologic techniques have provided most of the information about this organism's genomic structure and its various genes and their products. Polymerase chain reaction (PCR) assays have been used to detect and identify *M. leprae* in infected tissues, blood, and urine. A line probe assay, GenoType Leprae DR (Hain Lifescience, Nehren, Germany), has been developed that can detect the organism and resistance patterns to rifampicin, ofloxacin, and dapsone in clinical specimens. Paucibacillary patients require highly sensitive methods for the identification of organisms and diagnosis. Droplet digital PCR (ddPCR) can detect infectious disease in samples that have very low copy numbers of nucleic acid. Routine diagnosis of leprosy is based on distinct clinical manifestations, such as hypopigmented skin lesions and peripheral nerve involvement, in conjunction with a skin smear that tests positive for acid-fast bacilli (AFB).

Epidemiology and Pathogenesis

Understanding of the epidemiology and pathogenesis of leprosy is hampered by the inability to grow the organism in culture. In tropical countries, where the disease is most prevalent, it may be acquired from infected humans; however, infectivity is very low. Prolonged close contact and the host's immunologic status play important roles in infectivity.

Epidemiology

The primary reservoir for *M. leprae* is infected humans. The disease is transmitted person to person through inhalation or contact with infected skin. The more important mode of transmission appears to be inhalation of *M. leprae* discharged in the nasal secretions of an infected individual.

Pathogenesis

Although the host's immune response to *M. leprae* plays a key role in the control of infection, the immune response is also responsible for the damage to skin and nerves; in other words, leprosy is both a bacterial and an immunologic disease. After acquisition of *M. leprae,* the infection passes through many stages characterized by their histopathologic and clinical features. Although the infection has many intermediate stages, the two primary phases are a **silent phase,** during which the leprosy bacilli multiply in the skin in macrophages, and an **intermediate phase,** in which the bacilli multiply in peripheral nerves and begin to cause sensory impairment. More severe disease states may follow. A patient may recover spontaneously at any stage.

Spectrum of Disease

Based on the host's response, the spectrum of disease caused by *M. leprae* ranges from subclinical infection to intermediate stages of disease to full-blown and serious clinical manifestations involving the skin, upper respiratory system, testes, and peripheral nerves. The two major forms of the disease are a localized form, called **tuberculoid leprosy,** and a more disseminated form, called **lepromatous leprosy.** Patients with lepromatous leprosy are anergic to *M. leprae* because of a defect in their cell-mediated immunity. Because the organisms' growth is unimpeded, these individuals develop extensive skin lesions containing numerous AFB; the organisms can spill over into the blood and disseminate. In contrast, individuals with tuberculoid leprosy do not have an immune defect; the disease is localized to the skin and nerves. In tuberculoid leprosy, a few organisms may be observed in the skin lesions. Most of the serious sequelae associated with leprosy are the result of this organism's tropism for peripheral nerves.

TABLE 42.6 Common Types of Infections Caused by Rapidly Growing Mycobacteria

Organism	Common Types of Infection
Mycobacterium abscessus subsp. *abscessus* *Mycobacterium abscessus* subsp. *bolletii* *Mycobacterium abscessus* subsp. *massiliense*	Disseminated disease, primarily in immunocompromised individuals; skin and soft tissue infections; pulmonary infections; postoperative infections; health care–associated infections
Mycobacterium fortuitum	Postoperative infections in breast augmentation and median sternotomy; skin and soft tissue infections; pulmonary infections, usually single, localized lesions Central nervous system (CNS) disease is rare but has high morbidity and mortality
Mycobacterium chelonae	Skin and soft tissue infections, postoperative wound infections, keratitis
Less Common Types of Infection (More Than 10 Cases)	
Mycobacterium bacteremicum	Skin and soft tissue infections, postoperative wound infections
Mycobacterium franklinii	Sinopulmonary disease and extrapulmonary sites
Mycobacterium mageritense	Pulmonary disease, endocarditis, and disseminated infection
Mycobacterium peregrinum	Skin and soft tissue infections; bacteremia
Mycobacterium mucogenicum	Posttraumatic wound infections, catheter-related sepsis, health care–associated infections
Mycobacterium smegmatis	Skin or soft tissue infections; less frequently, pulmonary infections
Mycobacterium boenickei	Bone and joint infections
Mycobacterium canariasense	Bacteremia
Mycobacterium cosmeticum	Pulmonary and urosepsis
Mycobacterium goodii	Bone and joint infections, osteomyelitis
Mycobacterium houstonense	Bone and joint infections
Mycobacterium immunogenum	Hypersensitivity pneumonitis
Mycobacterium neoaurum (closely related to *M. lacticola*)	Catheter-related sepsis
Mycobacterium phocaicum	Catheter-related sepsis
Mycobacterium porcinum	Surgical site infection
Mycobacterium senegalense	Catheter-related sepsis
Rare Infections (Fewer Than 10 Cases)	
Mycobacterium aubagnense	Various opportunistic health care–associated infections
Mycobacterium brisbanense	Various opportunistic health care–associated infections
Mycobacterium brumae	Various opportunistic health care–associated infections
Mycobacterium celeriflavum	Various opportunistic health care–associated infections
Mycobacterium elephantis	Various opportunistic health care–associated infections
Mycobacterium iranicum	Various opportunistic health care-associated infections
Mycobacterium monacense	Various opportunistic health care–associated infections
Mycobacterium moriokaense	Various opportunistic health care–associated infections
Mycobacterium neworleansense	Various opportunistic health care–associated infections
Mycobacterium novocastrense	Various types of opportunistic health care–associated infections
Mycobacterium saopaulense	Cervical abscess and various opportunistic health care–associated infections
Mycobacterium septicum	Various opportunistic health care–associated infections
Mycobacterium setense	Bone and joint infections
Mycobacterium wolinskyi	Skin and soft tissue infections, bone infection, osteomyelitis

Laboratory Diagnosis of Mycobacterial Infections

Specimens received by the laboratory for mycobacterial smear and culture must be handled in a safe manner. Tuberculosis ranks high among laboratory-acquired infections; therefore laboratory and hospital administrators must provide laboratory personnel with the facilities, equipment, and supplies needed to reduce this risk to a minimum. *M. tuberculosis* has a very low infective dose for humans (i.e., an infection rate of approximately 50% with exposure to fewer than 10 AFB). All tuberculin-negative personnel should have a skin test or one of the IGRAs at least annually and more frequently if any laboratory incidents have been identified within the facility. The CDC recommends Biosafety Level 2 practices, containment equipment, and facilities for preparing acid-fast smears and culture for nonaerosolizing manipulations. If *M. tuberculosis* is grown and then propagated and manipulated, biologic safety cabinet (BSC) class II safety precautions are required; however, Biosafety Level 3 practices are recommended. BSC Level 3 practices are recommended for opening centrifuge vials, adding reagents to biochemical testing media, setting up molecular tests, and sonication; these practices include restricted laboratory access, negative-pressure airflow, and special personal protective equipment (e.g., certified respirators). Respiratory devices should be certified through the National Institute for Occupational Safety and Health (NIOSH). All work surfaces should be disinfected before and after working with specimen samples. Effective disinfectants for *Mycobacterium* spp. include Amphyl (Reckitt Benckiser North America, Wayne, NJ), 0.05% to 0.5% sodium hypochlorite, and phenol-soap mixtures.

Specimen Collection and Transport

AFB can infect almost any tissue or organ of the body. Successful isolation of these organisms depends on the quality of the specimen obtained and the use of appropriate processing and culture techniques by the mycobacteriology laboratory. In suspected mycobacterial disease, as in all other infectious diseases, the diagnostic procedure begins at the patient's bedside. Collection of proper clinical specimens requires careful attention to detail by health care professionals. Most specimens are respiratory samples such as sputum, tracheal or bronchial aspirates, and specimens obtained by bronchial alveolar lavage. Other samples may include urine, gastric aspirates, tissue (biopsy) specimens, cerebrospinal fluid (CSF), and pleural and pericardial fluid. Blood or fecal specimens may be collected from immunocompromised patients. Specimens should be collected in sterile, leakproof, disposable, and appropriately labeled containers without fixatives and placed in bags to contain leakage. If transport and processing will be delayed longer than 1 hour, all specimens except blood should be refrigerated at 4°C until processed.

Pulmonary Specimens

Pulmonary secretions may be obtained by any of the following methods: spontaneously produced or induced sputum, gastric lavage, transtracheal aspiration, bronchoscopy, and laryngeal swabbing. Most specimens submitted for examination are sputum, aerosol-induced sputum, bronchoscopic aspirations, or gastric lavage samples. Spontaneously produced sputum is the specimen of choice. To raise sputum, patients must be instructed to take a deep breath, hold it momentarily, and then cough deeply and vigorously. Patients must also be instructed to cover their mouths carefully while coughing and to discard tissues in an appropriate receptacle. Saliva and nasal secretions should not be collected, nor should the patient use oral antiseptics during the collection period. Sputum specimens must be free of food particles, residues, and other extraneous matter.

The aerosol (saline) induction procedure can best be used on ambulatory patients who are able to follow instructions. Aerosol-induced sputum specimens have been collected from children as young as 5 years of age. This procedure should be performed in an enclosed area with appropriate airflow. Operators should wear particulate respirators and take appropriate safety measures to prevent exposure. The patient is told that the procedure is being performed to induce coughing and thus to raise sputum that the patient cannot raise spontaneously and that the salt solution is irritating. The patient is instructed to inhale slowly and deeply through the mouth and to cough at will, vigorously and deeply, coughing and expectorating into a collection tube. The procedure is discontinued if the patient fails to raise sputum after 10 minutes or feels discomfort. Ten milliliters of sputum should be collected; if the patient continues to raise sputum, a second specimen should be collected and submitted. Specimens should be delivered to the laboratory promptly and refrigerated if processing is to be delayed.

Sputum collection guidelines recommend the collection of three specimens at least 8 hours apart. One of the three specimens should be an early morning sample. In many cases, the third specimen demonstrates minimal recovery of organisms, and this collection may not be recommended in some laboratories. Pooled specimens are unacceptable because of the increased risk of contamination.

Gastric Lavage Specimens

Gastric lavage is used to collect sputum from patients who may have swallowed sputum during the night. The procedure is limited to senile, nonambulatory patients; children younger than 12 years of age (specimen of choice); and patients who fail to produce sputum by aerosol induction. The most desirable gastric lavage is collected at the patient's bedside before the patient arises and before exertion empties the stomach. Gastric lavage cannot be performed as an office or clinic procedure.

The collector should wear a cap, gown, and particulate respirator mask and should stand beside (not in front of) the patient, who should sit up on the edge of the bed or in a chair if possible. The Levine collection tube is inserted through a nostril, and the patient is instructed to swallow the tube. When the tube has been fully inserted, a syringe is attached to the end of the tube and filtered distilled water is injected into the tube. The syringe is then used to withdraw 5 to 10 mL of gastric secretions, which is expelled slowly down the sides of the 50-mL conical collecting tube. Samples should be adjusted to a neutral pH. The laboratory may choose to provide sterile receptacles containing 100 mg of sodium carbonate to reduce the acidity; this improves the recovery of organisms. The top of the collection tube is screwed on tightly, and the tube is held upright during prompt delivery to the laboratory. Three specimens should be collected over a period of consecutive days. Specimens should be processed within 4 hours.

Bronchial lavages, washings, and brushings are collected and submitted by medical personnel. These are the specimens of choice for detecting NTM and other opportunistic pathogens in patients with immune dysfunction.

Urine Specimens

The incidence of urogenital infections shows little sign of decreasing. About 2% to 3% of patients with pulmonary tuberculosis show urinary tract involvement, but 30% to 40% of patients with genitourinary disease have tuberculosis at some other site. The clinical manifestations of urinary tuberculosis, which are variable, include frequency of urination (most common), dysuria, hematuria, and flank pain. Definitive diagnosis requires recovery of AFB from the urine.

Early morning voided urine specimens (40 mL minimum) in sterile containers should be submitted daily for at least 3 consecutive days. The collection procedure is the same as for collecting a clean-catch midstream urine specimen (Chapter 72). The 24-hour urine specimen is undesirable because of excessive dilution, higher contamination, and difficulty in concentrating. Catheterization should be used only if a midstream voided specimen cannot be collected.

Fecal Specimens

Acid-fast staining or culture (or both) of stool from patients with AIDS or from other immunocompromised patients has been used to identify patients who may be at risk for developing disseminated MAC disease. The clinical utility of this practice remains controversial; however, if screening stains or cultures are positive, dissemination often follows. Feces should be submitted in a clean, dry, wax-free container without preservative or diluent. Contamination with urine should be avoided.

Tissue and Body Fluid Specimens

Tuberculous meningitis is uncommon but occurs in both immunocompetent and immunosuppressed patients. A sufficient quantity of specimen is crucial for the isolation of AFB from CSF. Very few organisms may be present in the spinal fluid, which makes their detection difficult. At least 10 mL of CSF is recommended for the recovery of mycobacteria. Similarly, as much as possible of other body fluids (5 to 10 mL minimum)—such as pleural, peritoneal, and pericardial fluids—should be collected in a sterile container or syringe with a Luer-tip cap. Tissues must not be immersed in saline or wrapped in gauze. Swabs are discouraged because the recovery of organisms is decreased. Two cultures should be set up so that one set may be incubated at 30°C for *Mycobacterium* spp. that grow at lower temperatures (*Mycobacterium haemophilum, M. marinum, M. terrae* complex, *M. lentiflavum,* and *M. ulcerans*).

Blood Specimens

Immunocompromised patients, particularly those infected with HIV, can have disseminated mycobacterial infections; most of these are caused by MAC. A blood culture positive for MAC is always associated with clinical evidence of disease. Recovery of mycobacteria is improved with blood collection in either a broth or the Isolator lysis-centrifugation system (Chapter 67). Some studies have indicated that the lysis-centrifugation system is advantageous because quantitative data can be obtained with each blood culture; in patients with AIDS, quantitation of such organisms can be used to monitor therapy and determine prognosis. However, the necessity of quantitative blood cultures remains unclear.

Blood for culture of mycobacteria should be collected as for routine blood cultures. Blood collected in regular phlebotomy procedures in anticoagulants such as sodium polyanethol sulfonate (SPS), heparin, and citrate may be used to inoculate cultures for the recovery of *Mycobacterium* spp. Conventional blood culture collection systems are unacceptable for the isolation of *Mycobacterium* spp. However, specialized automated systems and culture media are available for growth of *Mycobacterium* spp., including the Myco/F Lytic Bottles (Becton-Dickinson, Franklin Lakes, NJ) and the BacT/ALERT MB Blood medium (bioMérieux, Durham, NC).

Wounds, Skin Lesions, and Aspirates

An aspirate is the best type of specimen for culturing a skin lesion or wound. The skin should be cleansed with alcohol before aspiration of the material into a syringe. If the volume is insufficient for aspiration, pus and exudates may be obtained on a swab and then placed in a transport medium, such as Amie or Stuart medium (dry swabs are unacceptable). However, a negative culture of a specimen obtained on a swab is not considered reliable, and this should be noted in the culture report.

Specimen Processing

Processing to recover AFB from clinical specimens involves several complex steps, each of which must be carried out with precision. Body fluid specimens from sterile sites can be inoculated directly to media (small volume) or concentrated (≥3000 *g* for 15 minutes) to reduce volume. Sterile tissue samples may be ground in sterile 0.85% saline or 0.2%

bovine albumin and inoculated directly to media. Other specimens require decontamination and concentration. A processing scheme is shown in Fig. 42.1, and the procedures are explored in detail in the following discussions.

Contaminated Specimens

Most specimens submitted for mycobacterial culture consist of organic debris, such as mucin, tissue, serum, and other proteinaceous material contaminated with organisms. A typical example of such a specimen is sputum. Laboratories must process these specimens to kill or reduce contaminating bacteria that can rapidly outgrow mycobacteria, and mycobacteria are released from mucin and/or cells. After decontamination, mycobacteria are concentrated, usually by centrifugation, to enhance their detection by acid-fast stain and culture. Unfortunately, there is no single ideal method for decontaminating and digesting clinical specimens. Although they are continuously faced with the inherent limitations of various methods, laboratories must strive to maximize the survival and detection of mycobacteria while maximizing the elimination of contaminating organisms. RGM are especially susceptible to high or prolonged exposure to 2% or more of sodium hydroxide (NaOH). Digestion-decontamination procedures should be as gentle as possible.

Inadequate Specimens and Rejection Criteria

The identification and detection of *Mycobacterium* spp. is costly and time consuming. It is essential that the laboratory have a detailed policy regarding the rejection of inadequate specimens for the identification of these organisms. Specimens should be rejected according to the following guidelines: (1) insufficient volume, (2) contamination with saliva, (3) dried swabs, (4) pooled sputum or urine, (5) container has been compromised or is broken or leaking, and (6) length of time from collection to processing is too long.

Overview

Commonly used digestion-decontamination methods are the NaOH method, the Zephiran-trisodium phosphate method, and the *N*-acetyl-L-cysteine (NALC)–2% NaOH method. The NALC-NaOH method is presented in detail in Evolve Procedure 42.1. Another decontaminating procedure that uses oxalic acid is very useful for treating specimens known to harbor gram-negative rods, particularly *Pseudomonas* and *Proteus* spp., which are extremely troublesome contaminants. It is important to note that oxalic acid, NaOH, and mild hydrogen chloride (HCl) may reduce the recovery of *M. ulcerans.*

NaOH, a commonly used decontaminant that is also mucolytic, should be used with caution. It not only reduces contamination but also reduces recovery of *Mycobacterium* spp. as alkalinity increases, temperature rises, and exposure time increases. The sample should be homogenized by centrifugal swirling, minimizing physical agitation. The container should then be allowed to sit for 15 minutes so that aerosolized droplets can fall to the bottom, thus reducing the risk of infection for the laboratory professional.

Several agents can be used to liquefy a clinical specimen, including NALC, dithiothreitol (Sputolysin), and enzymes. None of these agents are inhibitory to bacterial cells. In most procedures, liquefaction (release of the organisms from mucin or cells) is enhanced by vigorous mixing with a vortex-type mixer in a closed container. After mixing as previously described, the container should be allowed to stand for 15 minutes before opening so as to prevent the dispersion of fine aerosols generated during mixing. Of utmost importance during processing is strict adherence to processing and laboratory safety protocols. All these procedures should be carried out in a BSC.

After digestion and decontamination, specimens are concentrated by centrifugation at greater than or equal to 3000 *g*. See Evolve Procedure 42.2 for specimen preparation considerations.

Special Considerations

Many specimen types besides respiratory samples contain normal microbiota and require decontamination and concentration.

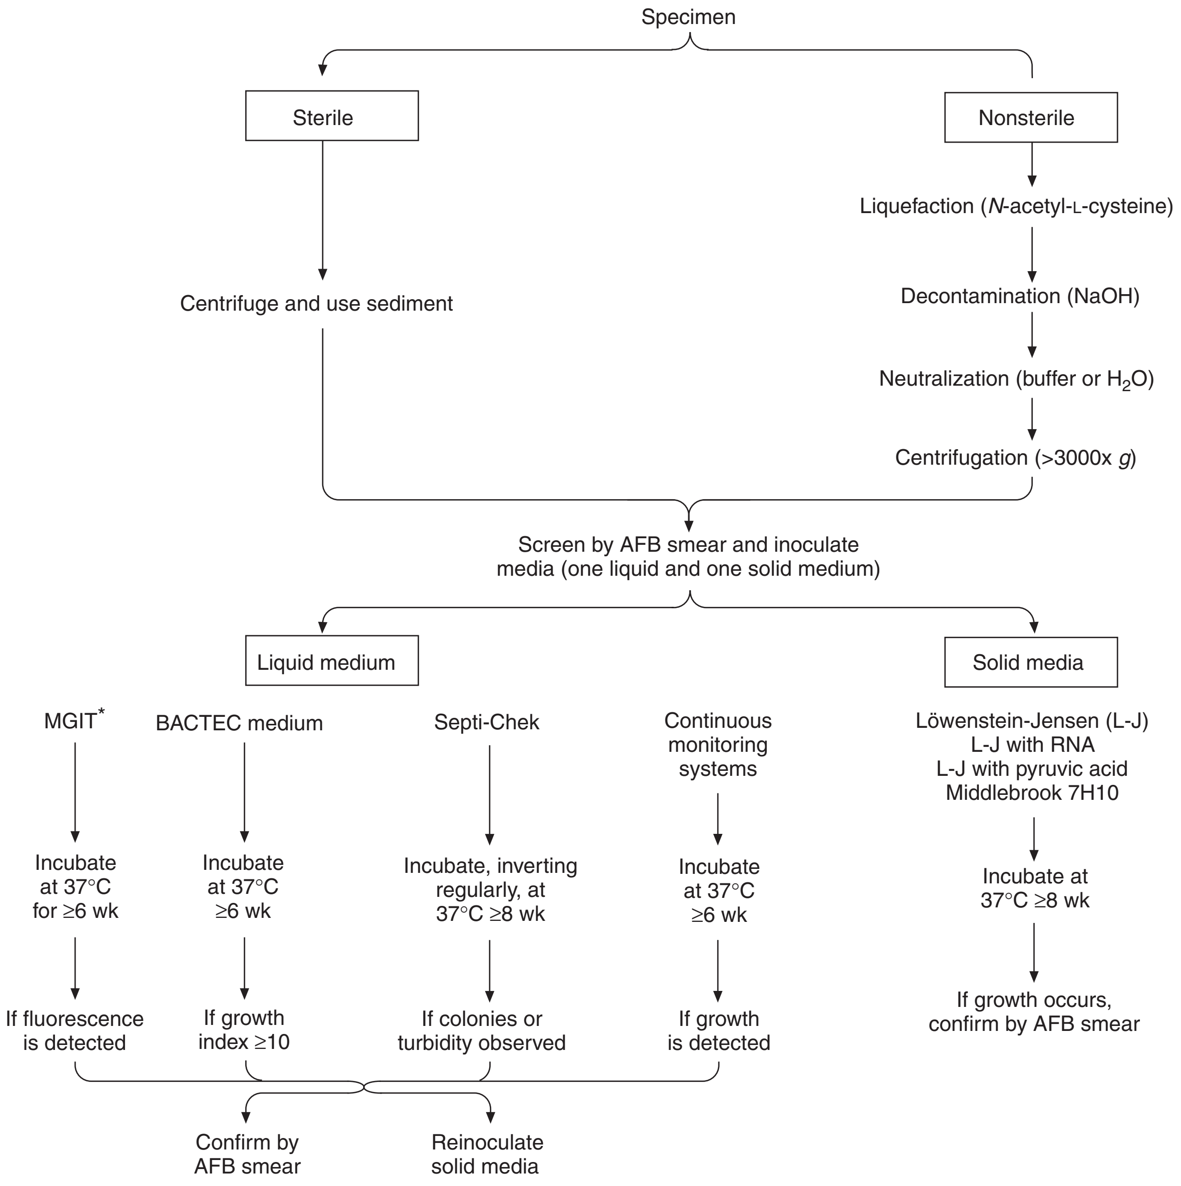
Aerosol-induced sputum should be treated as sputum. Gastric lavages should be processed within 4 hours of collection or neutralized with 10% sodium carbonate (check with pH paper to make sure the specimen is at neutral pH) and refrigerated until processed, as for sputum. If more than 10 mL of watery-appearing aspirate was obtained, the specimen can be centrifuged at 3600× *g* for 30 minutes, the supernatant decanted, and the sediment processed as for sputum.

Urine specimens should be divided into a maximum of four 50-mL centrifuge tubes and centrifuged at 3600× *g* for 30 minutes. The supernatant should be decanted, leaving approximately 2 mL of sediment in each tube. The tubes are vortexed to suspend the sediments, and sediments are combined. If necessary, distilled water can be added to a total volume of 10 mL. This urine concentrate is treated as for sputum or with the Sputolysin–oxalic acid method.

For fecal specimens, approximately 0.2 g of stool (a portion about the size of a pea) is emulsified in 11 mL of sterile filtered distilled water. The suspension is vortexed thoroughly, and particulate matter is allowed to settle for 15 minutes. Ten milliliters of the supernatant is then transferred to a 50-mL conical centrifuge tube and decontaminated using the oxalic acid or the NALC-NaOH method.

Swabs and wound aspirates should be transferred to a sterile 50-mL conical centrifuge tube containing a liquid medium (Middlebrook 7H9, Dubos Tween albumin broth) at a ratio of 1 part specimen to 5 to 10 parts liquid media. The specimen is vortexed vigorously and allowed to stand for 20 minutes. The swab is removed, and the resulting suspension is processed as for sputum.

Large pieces of tissue should be finely minced with a sterile scalpel and scissors. This material is homogenized in a sterile tissue grinder with a small amount of sterile saline (0.85%) or sterile 0.2% bovine albumin; the suspension is then processed as for sputum. If the tissue is not known to be sterile, it is homogenized and half is directly inoculated



Specimen
Sterile
Nonsterile
Liquefaction (N-acetyl-L-cysteine)
Centrifuge and use sediment
Decontamination (NaOH)
Neutralization (buffer or H2O)
Centrifugation (>3000x g)
Screen by AFB smear and inoculate media (one liquid and one solid medium)
Liquid medium
Solid media
MGIT*
BACTEC medium
Septi-Chek
Continuous monitoring systems
Löwenstein-Jensen (L-J)
L-J with RNA
L-J with pyruvic acid
Middlebrook 7H10
Incubate at 37°C for ≥6 wk
Incubate at 37°C ≥6 wk
Incubate, inverting regularly, at 37°C ≥8 wk
Incubate at 37°C ≥6 wk
Incubate at 37°C ≥8 wk

to solid and liquid media. The other half is processed as for sputum. If the tissue is collected aseptically (i.e., it is sterile), it may be processed without being treated with NALC-NaOH.

Specimens Not Requiring Decontamination

Tissues or body fluids collected aseptically usually do not require the digestion and decontamination methods used with contaminated specimens. The processing of clinical specimens that do not routinely require decontamination for acid-fast culture is described here. If such a specimen appears contaminated because of color, cloudiness, or foul odor, Gram staining is performed to detect bacteria other than AFB. Specimens found to be contaminated should be processed as described in the preceding section.

CSF should be handled aseptically and centrifuged for 30 minutes at 3600× *g* to concentrate the bacteria. The supernatant is decanted and the sediment is vortexed thoroughly before the smear is prepared and the media inoculated. If an insufficient quantity of CSF is received, the specimen should be used directly for smear and culture. Recovery of AFB from CSF is difficult; additional solid or liquid media should be inoculated if material is available.

Pleural fluid should be collected in sterile anticoagulant (1 mg/mL ethylenediaminetetraacetic acid [EDTA] or 0.1 mg/mL heparin). If the fluid becomes clotted, it should be liquefied with an equal volume of Sputolysin and vigorously mixed. To lower the specific gravity and density of pleural fluid, 20 mL is transferred to a sterile 50-mL centrifuge tube and the specimen is diluted by filling the tube with distilled water. The tube is inverted several times to mix the suspension and then centrifuged at 3600× *g* for 30 minutes. The supernatant should be removed and the sediment suspended for smear and culture.

Joint fluid and other sterile exudates can be handled aseptically and inoculated directly to media. Bone marrow aspirates may be injected into Pediatric Isolator tubes (Alere, Waltham, MA), which help to prevent clotting; the specimen can be removed with a needle and syringe for the preparation of smears and cultures. As an alternative, these specimens can either be inoculated directly to media or, if clotted, treated with Sputolysin or glass beads and distilled water before concentration.

Direct Detection Methods

Microscopy

Microscopy is considered a reasonably sensitive and rapid procedure for the presumptive identification of *Mycobacterium* spp. in clinical specimens. The preferred specimens are pretreated and/or concentrated before microscopy.

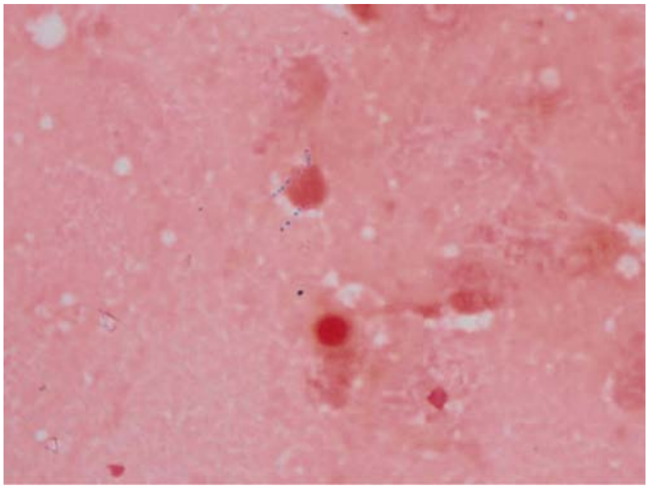
Acid-Fast Stains

The cell walls of mycobacteria contain long-chain multiple cross-linked fatty acids called **mycolic acids**. These contribute to the characteristic of acid-fastness that distinguishes mycobacteria from other bacteria. Mycobacteria are not the only group with this unique feature. Species of *Nocardia* and *Rhodococcus* are also partially acid fast; *Legionella micdadei,* a causative agent in pneumonia, is partially acid fast in tissue. Cysts of the genera *Cryptosporidium* and *Isospora* are distinctly acid fast. The mycolic acids and lipids in the mycobacterial cell wall account for the unusual resistance of these organisms to the effects of drying and harsh decontaminating agents in addition to the property of acid fastness.

When Gram stained, mycobacteria usually appear as slender, poorly stained and beaded gram-positive bacilli (Fig. 42.2); sometimes they appear as "gram neutral" or "gram ghosts" by failing to take up either crystal violet or safranin. Acid fastness is affected by the age of colonies, the medium on which growth occurs, and exposure to ultraviolet light. Rapidly growing species appear to be acid-fast variable.

Three types of staining procedures are used in the laboratory for the rapid detection and confirmation of AFB: fluorochrome, Ziehl-Neelsen, and Kinyoun. Smears for all methods are prepared in the same way. A modified Ziehl-Neelsen stain has improved the detection of organisms in CSF and of intracellular organisms in WBCs.

Visualization of AFB in sputum or other clinical material should be considered presumptive evidence of tuberculosis because staining does not specifically identify *M. tuberculosis.* The report form should indicate this. For example, *M. gordonae,* a nonpathogenic scotochromogen commonly found in tap water, has been identified when tap water or deionized water has been used in the preparation of smears or even when patients have rinsed their mouths with tap water before using an aerosolized saline solution to induce sputum. However, the incidence of false-positive smears is very low when good quality control is maintained. Conversely, acid fast–stained smears of clinical specimens require at least 10^4 AFB per milliliter for detection from concentrated specimens.



• **Fig. 42.2** Gram staining of *Mycobacterium marinum* demonstrates a beaded appearance. (Courtesy Stacie Lansink, Sioux Falls, SD.)

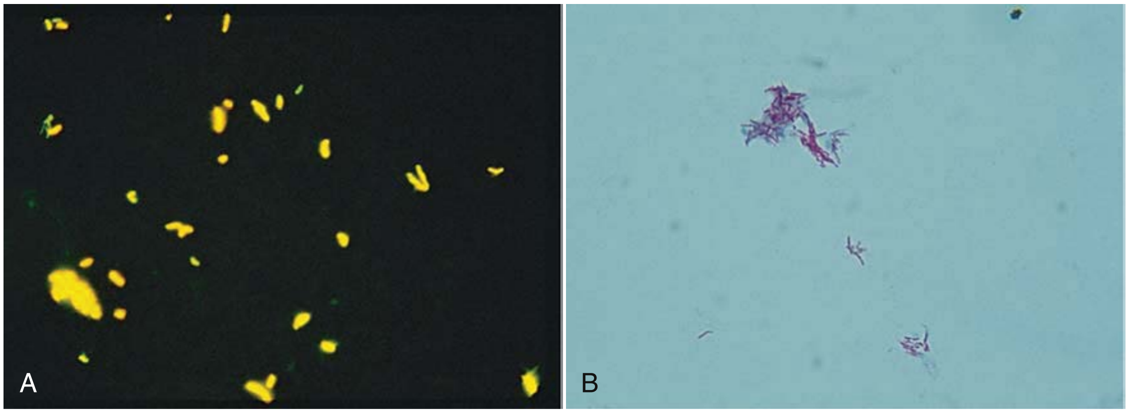
AFB direct detection is less expensive than nucleic acid detection (NAAT) methods and can enhance the NAAT interpretations. AFB microscopy remains useful in determining infectiousness, monitoring treatment, and arriving at decisions on when to release patients from respiratory isolation.

Methods

Fluorochrome Stain. Fluorochrome staining is the screening procedure recommended for laboratories that have a fluorescent (ultraviolet) microscope (Evolve Procedure 42.3). Fluorochrome stain is more sensitive than the conventional carbolfuchsin stains because the fluorescent bacilli stand out brightly against the background (Fig. 42.3). Because the smear can be examined initially at lower magnifications (250–400×), more fields can be visualized in a short period. In addition, a positive fluorescent smear may be restained using the conventional Ziehl-Neelsen or Kinyoun procedure, thereby saving the time needed to make a fresh smear. Screening of specimens with rhodamine or rhodamine-auramine B results in a higher yield of positive smears and substantially reduces the time needed to examine smears.

One drawback of the fluorochrome stains is that many rapid growers may not appear fluorescent with these reagents. All positive fluorescent smears should be confirmed with a Ziehl-Neelsen stain or by having them examined by another laboratory professional. It is important to wipe the immersion oil from the objective lens after examining a positive smear because stained bacilli can float off the slide into the oil, possibly contributing to a false-positive reading for the next smear examined.

Fuchsin Acid-Fast Stains. The classic carbolfuchsin stain (Ziehl-Neelsen) requires heating of the slide for



• **Fig. 42.3** *Mycobacterium tuberculosis* stained with (A) fluorochrome stain (×400) and (B) Kinyoun acid-fast stain (×1000).

better penetration of the stain into the mycobacterial cell wall; hence it is also known as the **hot stain procedure** (Evolve Procedure 6.3). With Ziehl-Neelsen staining, *Mycobacterium* spp. appear red or have a red-blue beaded appearance, whereas nonmycobacteria appear blue.

Evolve Procedure 6.4), describes the Kinyoun acid-fast stain. The method is similar to Ziehl-Neelsen staining but no heat is used (Fig. 42.3); this is known as the **cold stain procedure.** If present, typical AFB appear as purple to red, slightly curved, short or long rods (2 to 8 µm); they also may appear beaded or banded *(Mycobacterium kansasii).* For some nontuberculous species, such as MAC, they appear pleomorphic and usually coccoid.

Examination, Interpretation, and Reporting of Smears

Before a smear is reported as negative, it should be examined carefully by scanning at least 300 oil immersion fields (magnification 1000×), equivalent to three full horizontal sweeps of a smear that is 2 cm long and 1 cm wide. Because the fluorescent stain can be examined using a lower magnification (250 or 450×) than that required for a fuchsin-stained smear, the equivalent number of fields (30) can be examined in less time, which makes the fluorochrome stain the preferred method.

When acid-fast organisms are observed on a smear, the report should include information about the type of staining method used and the quantity of organisms. The recommended interpretations and ways to report smear results are shown in Table 42.7.

The overall sensitivity of an acid-fast smear ranges from 20% to 80%. Factors such as specimen type, staining method, and culture method can influence the sensitivity of an acid-fast smear. In general, the specificity of an acid-fast smear examination is very high. However, cross-contamination of slides during the staining process and use of water contaminated with saprophytic mycobacteria can lead to false-positive results. Staining receptacles should not be used; AFB can also be transferred from one slide to another in immersion oil. For these reasons, the best course is to confirm a positive result.

Although not without some limitations because of its simplicity and speed, the stained smear is an important and useful test, particularly for the detection of smear-positive patients ("infectious reservoirs"), who pose the greatest risk to others in their environment.

Antigen-Protein Detection

The detection of microbial products or components has been used in recent years to diagnose infections caused by *M. tuberculosis.* For example, **lipoarabinomannan (LAM),** which is a major cell-wall component in *M. tuberculosis,* has been developed into an ELISA (Clearview TB ELISA, Alere Inc., Waltham, MA) and a point-of-care lateral flow assay (Determine TB; Alere). A point-of-care urine lipoarabinomannan assay has been successfully used to diagnose intrathoracic tuberculosis (ITTB) and latent tuberculosis. The test is approximately 73% to 76% sensitive but demonstrates a high specificity of approximately 93%.

Immunodiagnostic Testing

As previously discussed, interferon-gamma release assays have become more widely used for the diagnosis of tuberculosis. The available test systems, T-SPOT-TB (Oxford Immunotec, Oxford, UK and QuantiFERON Gold TB Plus (QFT-Plus; Qiagen, Germantown, MD), do not typically cross react with nontuberculous mycobacterium, are not affected by the BCG vaccine, and are not as variable as the historical serologic tuberculin skin tests. The T-SPOT-TB assay is an enzyme-linked immunospot assay that requires isolation and incubation of PBMCs. It takes approximately 2 days and is technically complicated. The QuantiFERON assay measure IFN-gamma by an ELISA. The QFT-Plus assay measures the stimulation of T-cell interferon-gamma in whole blood in a tube precoated with *M. tuberculosis* antigens. It yields results in approximately 8 hours. Neither assay distinguishes between latent and active infections, nor can they predict the likelihood that a patient will progress to active disease. In addition, specificity and sensitivity vary in the population tested, including immunocompromised patients and children. Variation is associated

TABLE 42.7 Acid-Fast Smear Reporting

Number of AFB Seen, Fuchsin Stain (1000× Magnification)	Number of AFB Seen, Fluorochrome Stain (450× Magnification)	Number of AFB Seen, Fluorochrome Stain (250× Magnification)	Report

AFB, Acid-fast bacilli.
Modified from Kent PT, Kubica GP. *Public Health Mycobacteriology: A Guide for the Level III Laboratory,* Washington, DC: Centers for Disease Control and Prevention; 1985; Carroll KC, Pfaller MA. *Manual of Clinical Microbiology*. 12th ed. Washington, DC: ASM Press; 2019.

with the patient's CD4 cell count; therefore, interpretations and results should be evaluated with caution.

Nucleic Acid Detection

Nucleic acid probes for the indirect detection and identification of *M. tuberculosis* complex and the *M. avium* complex from culture media are available (AccuProbe, Hologic, San Diego, CA). This technique can detect *M. avium, M. intracellulare, M. tuberculosis, M. africanum, M. microti, M. pinnipedii*, and *M. canettii*, but it cannot differentiate them at the species level. The assay also lacks enough sensitivity to be used for direct detection of the organisms in clinical samples.

Genetic Sequencing and Nucleic Acid Amplification

PCR-based sequencing for mycobacterial identification consists of PCR amplification of mycobacterial DNA with genus-specific primers and sequencing of the amplicons. The organism is identified by comparison of the nucleotide sequence with reference sequences. The most reliable sequence for identification of mycobacteria to the genus level is the approximately 1500 bp 16S ribosomal ribonucleic acid (rRNA) gene. However, only a 600-bp sequence at the 5′ end is required for identification. The sequence homogeneity in the *M. tuberculosis* complex prevents the use of this sequence to differentiate these species. This region contains both conserved and variable regions, which makes it an ideal target for identification purposes.

Despite the accuracy of PCR-based sequencing to identify mycobacteria, problems remain: the sequences in some databases are not accurate, no present consensus exists as to the quantitative definition of a genus or species based on 16S rRNA gene sequence data, and procedures are not standardized. In addition, the 16S rRNA 5′ region contains two hypervariable regions, A and B. The A region provides the signature sequences for species identification. However, *M. chelonae* and *M. abscessus* both require additional sequencing, because the A and B regions are identical and the 3′ end of the 16S rRNA contains a 4-bp sequence difference.

Several other genes have also been used to identify mycobacterial species, including the 23S rRNA, ITS 1, *hsp65, rpoB,* and *gyrB* gene. The 23S rRNA sequence is 3100 bp in length, which limits accurate sequencing. ITS 1 is a spacer sequence located between the 16S and 23S rRNA genes. This sequence, which is 200 to 330 bp, is more easily analyzed. The limitation of this sequence is that it is not a genus-specific sequence; therefore results may be affected by contaminating bacteria. The 65-kDa heat shock protein, also referred to as the *groEL2* gene, is a 440-bp fragment that can be amplified and analyzed with restriction digestion followed by agarose electrophoresis. The *hsp65* is highly conserved but contains a greater variation in polymorphisms than the 16S rRNA, particularly in a 441-bp region referred to as the "Telanti fragment." This allows for the differentiation of *Mycobacterium* spp. based on the variation in restriction fragment length polymorphisms (RFLPs). Repetitive sequence–based PCR, Diversilab (bioMérieux, Durham, NC), demonstrates better species discrimination than RFLP.

Line probe assays (DNA strip assays) involve PCR amplification coupled with a reverse hybridization step. The target sequence is amplified using biotinylated primers. The amplicon is then hybridized to membrane-immobilized sequence-specific probes for each species. The membrane is developed using an enzyme-mediated reaction and color indicator to analyze the banding pattern. Banding patterns are species-specific based on the immobilized probe map on the membrane. A commercially available system in which the 16S-to-23S rRNA spacer region of mycobacterial species (INNO-LiPA v2 Mycobacteria; Innogenetics, Ghent, Belgium) has been successfully used to directly detect and identify several of the most clinically relevant mycobacterial species in aliquots of positive liquid culture. The assay can be used to identify the MTBC and 13 NTM species. However, the results should be interpreted cautiously because some cross-reactivity has occurred with closely related species.

Another commercial system, GenoType Mycobacterium (Hain Lifescience GmbH, Nehren, Germany), which uses a similar format, has additional probes for *M. celatum, Mycobacterium malmoense, Mycobacterium peregrinum, M. phlei,* and two subgroups of *M. fortuitum,* in addition to a supplemental kit that allows for the identification of 16 additional mycobacterial species.

The *rpoB* gene encodes the beta-subunit in the organism's RNA polymerase. Mutations in this gene confer rifampin resistance in *M. tuberculosis.* Different regions in this gene have been used to identify rapid-growing isolates, but little data are available for the slow-growing species. Finally, the *gyrB* gene encodes the beta-subunit in the organism's topoisomerase II. Several single nucleotide polymorphisms have been identified in this gene that are useful in distinguishing species in the *M. tuberculosis* complex. After amplification, identification and differentiation of species require restriction analysis and gel electrophoresis.

Additional molecular techniques, such as conventional and real-time PCR, have been used to detect *M. tuberculosis* directly in clinical specimens. The Xpert MTB/RIF (Cepheid, Sunnyvale, CA) is a real-time PCR, cartridge-based molecular beacon probe assay that also detects the mutations associated with rifampin resistance. The assay can detect the presence or absence of mutations and is unable to recognize silent mutations resulting in incorrect interpretations as rifampin resistance. The CDC recommends follow-up confirmation should be completed using sequencing technology. The Xpert MTB/Rif Ultra (Cepheid, Sunnyvale, CA), is capable of detecting some of the mutations that would previously go undetected. The Xpert MTB/RIF assay is approved on both smear-positive and smear-negative respiratory specimens only.

The Amplified *M. tuberculosis* Direct Test (AMTD; Gen-Probe Hologic, San Diego CA) uses rRNA released from the mycobacteria by means of a lysing agent, sonication, and heat. The specific DNA probe is allowed to react with the extracted rRNA to form a stable DNA-RNA hybrid. Any nonhybridized DNA acridinium ester probes are chemically degraded. When an alkaline hydrogen peroxide solution is added to activate the chemiluminescence, only the hybrid bound acridinium ester emits light. The amount of light emitted is directly proportional to the amount of hybridized probe. The light is measured using a chemiluminometer.

As previously indicated, the commercially available tests are limited in the number of species they can identify. Some clinical laboratories have developed their own PCR assays to detect *M. tuberculosis* directly in clinical specimens.

Due to the limitation associated with amplified probe assays, sequencing-based methods—including traditional Sanger sequencing, pyrosequencing, next-generation sequencing and whole genome sequencing—are being used to resolve discrepancies associated with detecting drug resistance in *Mycobacterium* spp. In addition, genome sequencing is important for epidemiologic students to resolve the transmission of clustered patients and identify false-positive cultures that cause patients to undergo unnecessary treatment. Genotyping and sequencing are essential for tuberculosis control programs. The CDC has established a national tuberculosis genotyping system and a National TB Molecular Surveillance Center that performs whole genome sequencing on all newly diagnosed patients in the United States. Details and updates are available at https://www.cdc.gov/tb/topic/laboratory/default.htm.

DNA Microarrays

DNA microarrays are also attractive for rapid examination of large numbers of DNA sequences by a single hybridization step. This approach has been used to simultaneously identify mycobacterial species and detect mutations that confer rifampin resistance in mycobacteria. Fluorescent-labeled PCR amplicons generated from bacterial colonies are hybridized to a DNA array containing nucleotide probes. The bound amplicons emit a fluorescent signal that is detected with a scanner. With this approach, 82 unique 16S rRNA sequences allow for the differentiation of 54 mycobacterial species and 51 sequences that contain unique *rpoB* gene mutations (rifampin resistance).

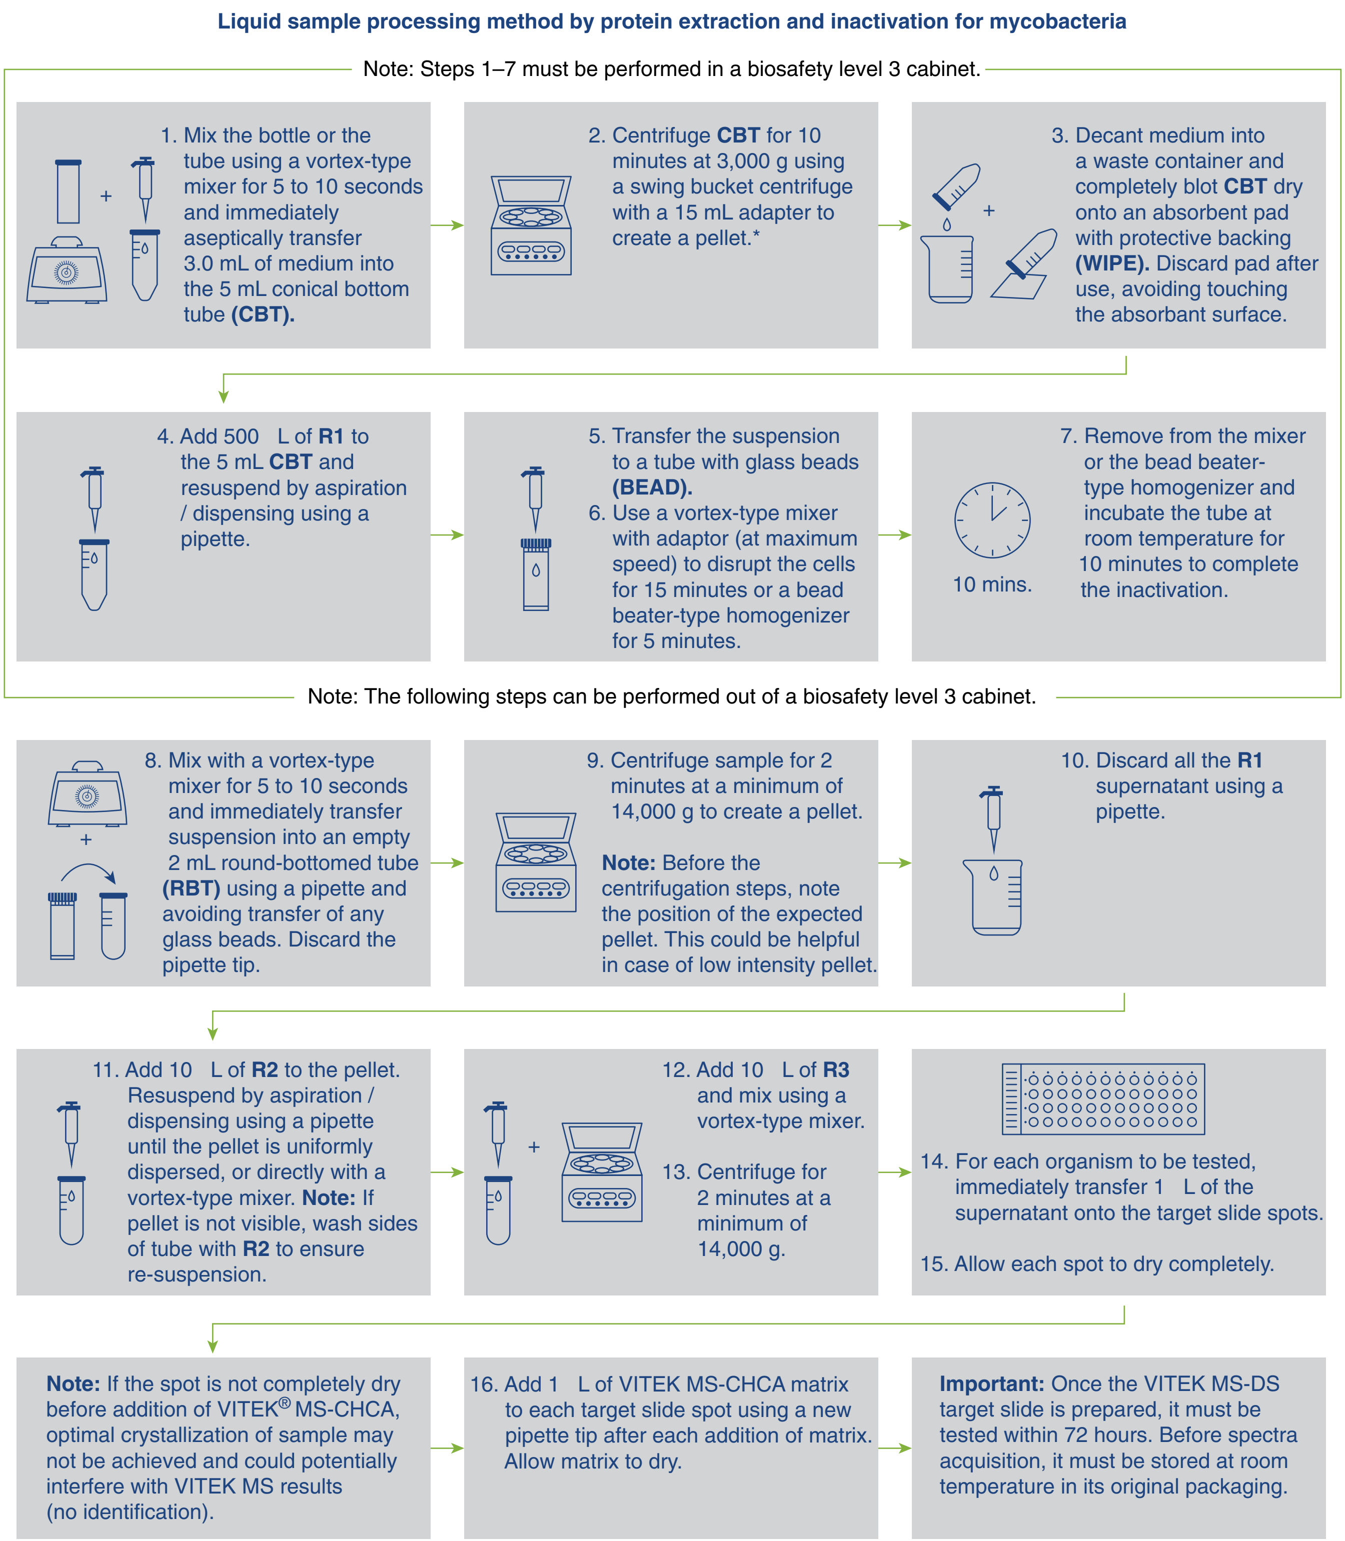
Matrix-Assisted Laser Desorption Ionization Time-of-Flight Mass Spectrometry

The current approaches for early identification of *Mycobacterium* spp. in culture include PCR and traditional phenotypic identification schemes. MALDI-TOF MS uses a proteomic-based technique to identify clinical mycobacterial isolates by protein profiling and can be used for accurate and rapid identification of various microorganisms. (See Chapter 7 for more information on MALDI-TOF MS.) Isolates of *M. tuberculosis* are consistently identified using MALDI-TOF MS; however, discrimination of the other species included in the *M. tuberculosis* complex is limited. Correct identification of clinically relevant strains of tuberculoid and NTM species has also been demonstrated; however, the capacity to identify all the species is limited to the information available in the current databases. In addition, identification is limited based on successful cultivation *in vitro.* Moderate growth in culture is required from a specimen to have sufficient sample size for the application to MALDI-TOF MS, whereas sequencing techniques require minimal or scant growth.

The application of MALDI-TOF MS to the identification of mycobacterial species requires an extraction process prior to placing the organism on the target plate. This involves chemical and physical disruption of the mycobacterial cell wall. See Fig. 42.4 for the processing of mycobacterial species and extraction required for identification using MALDI-TOF MS. Extraction should be completed in a BSL-3 or BSL-2 using BSL-3 practices.

Cultivation

A combination of different culture media is required to optimize recovery of mycobacteria from culture; at least one solid



Liquid sample processing method by protein extraction and inactivation for mycobacteria

Note: Steps 1–7 must be performed in a biosafety level 3 cabinet.

1. Mix the bottle or the tube using a vortex-type mixer for 5 to 10 seconds and immediately aseptically transfer 3.0 mL of medium into the 5 mL conical bottom tube **(CBT).**

2. Centrifuge **CBT** for 10 minutes at 3,000 g using a swing bucket centrifuge with a 15 mL adapter to create a pellet.*

3. Decant medium into a waste container and completely blot **CBT** dry onto an absorbent pad with protective backing **(WIPE).** Discard pad after use, avoiding touching the absorbant surface.

4. Add 500 μL of **R1** to the 5 mL **CBT** and resuspend by aspiration / dispensing using a pipette.

5. Transfer the suspension to a tube with glass beads **(BEAD).**
6. Use a vortex-type mixer with adaptor (at maximum speed) to disrupt the cells for 15 minutes or a bead beater-type homogenizer for 5 minutes.

7. Remove from the mixer or the bead beater-type homogenizer and incubate the tube at room temperature for 10 minutes to complete the inactivation.

Note: The following steps can be performed out of a biosafety level 3 cabinet.

8. Mix with a vortex-type mixer for 5 to 10 seconds and immediately transfer suspension into an empty 2 mL round-bottomed tube **(RBT)** using a pipette and avoiding transfer of any glass beads. Discard the pipette tip.

9. Centrifuge sample for 2 minutes at a minimum of 14,000 g to create a pellet.

Note: Before the centrifugation steps, note the position of the expected pellet. This could be helpful in case of low intensity pellet.

10. Discard all the **R1** supernatant using a pipette.

11. Add 10 μL of **R2** to the pellet. Resuspend by aspiration / dispensing using a pipette until the pellet is uniformly dispersed, or directly with a vortex-type mixer. **Note:** If pellet is not visible, wash sides of tube with **R2** to ensure re-suspension.

12. Add 10 μL of **R3** and mix using a vortex-type mixer.

13. Centrifuge for 2 minutes at a minimum of 14,000 g.

14. For each organism to be tested, immediately transfer 1 μL of the supernatant onto the target slide spots.

15. Allow each spot to dry completely.

Note: If the spot is not completely dry before addition of VITEK® MS-CHCA, optimal crystallization of sample may not be achieved and could potentially interfere with VITEK MS results (no identification).

16. Add 1 μL of VITEK MS-CHCA matrix to each target slide spot using a new pipette tip after each addition of matrix. Allow matrix to dry.

Important: Once the VITEK MS-DS target slide is prepared, it must be tested within 72 hours. Before spectra acquisition, it must be stored at room temperature in its original packaging.

• **Fig. 42.4** Matrix-assisted desorption ionization time-of-flight workflow for extraction and processing *Mycobacterium* isolates. (Courtesy Biomerieux Inc., Durham, NC.)

medium in addition to a liquid medium should be used. The ideal media combination should be economical and should support the most rapid and abundant growth of mycobacteria, allow for the study of colony morphology and pigment production, and inhibit the growth of contaminants.

Solid Media

Solid media, such as those listed in Box 42.1, are recommended because of the development of characteristic reproducible colonial morphology, good growth from small inocula, and a low rate of contamination. Optimally, at

• BOX 42.1 Suggested Media for Cultivation of Mycobacteria From Clinical Specimens[a]

Media	Comments
Solid	
Agar Based—Growth Within 10–12 Days	
Middlebrook	Contains 2% glycerol, which enhances the growth of *Mycobacterium avium* complex (MAC)
Middlebrook 7H10 Middlebrook 7H10 selective	Supplemented with carbenicillin (for inhibition of pseudomonads), polymyxin B, trimethoprim lactate, and amphotericin B
Middlebrook 7H11 Middlebrook 7H11 selective	Contains 0.1% enzymatic hydrolysate of casein, which improves recovery of isoniazid-resistant *Mycobacterium tuberculosis*
Middlebrook 7H11	Supplemented with mycobactin J, which provides for growth of *Mycobacterium genavense*
Middlebrook 7H11 thin pour plates, 10 × 90 mm (Remel, Lenexa, KS)	Enhances visibility of colonies within 11 days
Middlebrook biplate (7H10/7H11S agar)	
Egg Based—Growth Within 18–24 Days	
Löwenstein-Jensen (L-J)	Commonly used medium; good recovery of *M. tuberculosis* but poor recovery of many other species; *M. genavense* fails to grow
L-J Gruft	Supplemented with penicillin and nalidixic acid
L-J Mycobactosel	Supplemented with cycloheximide, lincomycin, and nalidixic acid
L-J with pyruvic acid	Enhances recovery of *Mycobacterium bovis*
L-J with glycerol	Enhances recovery of *Mycobacterium ulcerans*
Petragnani medium	Contains twice the concentration of malachite than Löwenstein-Jensen green (an inhibitor of contaminating organisms); improves recovery from heavily contaminated specimens
Heme-supplemented media (egg or agar based)	Supplemented with hemin, hemoglobin, or ferric ammonium citrate; increases recovery of *Mycobacterium haemophilum*
Liquid[b]	
BACTEC 12B medium	Used in the MGIT960 system; PANTA is added before incubation; ^{14}C-labeled palmitic acid is metabolized to produce $^{14}CO_2$, which is detected by the instrument
Middlebrook 7H9 broth	
Dubos Tween albumin	
Septi-Chek AFB	20 mL of Middlebrook 7H9 broth is incubated in 20% CO_2; solid phase contains three media: modified L-J, Middlebrook 7H11, and a chocolate agar slab
Media Used in Commercially Supplied Growth and Semiautomated or Fully Automated Systems	
Mycobacteria Growth Indicator Tube [MGIT] (Becton Dickinson Microbiology Systems, Cockeysville, MD)	MGIT 960 (fully automated system); MGIT is a modified Middlebrook 7H9 broth that incorporates a fluorescence-quenching–based oxygen sensor for detection
Versa TREK Culture System (Trek Diagnostic Systems, Cleveland, OH)	Modified Middlebrook 7H9 broth
MB/BacT Alert 3D (bioMérieux, Durham, NC)	Uses Middlebrook 7H9 broth

[a] For optimal recovery of mycobacteria, a minimum combination of liquid medium and solid media is recommended.

[b] Tween 80 added to liquid media acts as a surfactant, breaking up clumps of organisms and increasing recovery rates.

least two solid media (a serum [albumin] agar base medium, [e.g., Middlebrook 7H10] and an egg-potato base medium [e.g., Löwenstein-Jensen, or L-J]) should be used for each specimen (these media are available from commercial sources). All specimens must be processed appropriately before inoculation. It is imperative to inoculate test organisms to commercially available products for quality control (Evolve Procedure 42.4). An example of interpreting

• BOX 42.2 Example of Interpreting Quality Control Test Results of Decontamination and Concentration Procedure

Sputum Sample	SPUTUM SPECIMEN Unprocessed Quantification of Growth 10^4	10^3	10^2	Processed Quantification of Growth 10^4	10^3	10^2	Interpretation
1	3+	2+	50–100 colonies	2+	1+ or 2+	Approximately 10 colonies	Media and decontamination procedures acceptable
2	3+	2+	50–100 colonies	1+	0	0	Media acceptable; procedures too toxic
3	2+ or 1+	2+ or 1+	0	1+ or 0	1+ or 0	0	One or more of the media are not supporting growth of acid-fast bacilli (AFB) adequately

0, No growth; *1+*, scanty, barely discernible countable colonies; *2+*, dense, discrete growth, not countable; *3+*, confluent, abundant growth

quality-control test results of decontamination and concentration procedures associated with culture is provided in Box 42.2.

Cultures are incubated at 35°C in the dark in an atmosphere of 5% to 10% carbon dioxide (CO_2) and high humidity. Tube media are incubated in a slanted position with screw caps loose for at least 1 week to allow for the evaporation of excess fluid and the entry of CO_2; plated media are either placed in a CO_2-permeable plastic bag or wrapped with CO_2-permeable tape. If specimens obtained from the skin or superficial lesions are suspected to contain *M. marinum* or *M. ulcerans,* an additional set of solid media should be inoculated and incubated at 25°C to 30°C. In addition, a chocolate agar plate (or placement of an X-factor [hemin] disk on conventional media) and incubation at 25°C to 33°C is needed for recovery of *M. haemophilum* from these specimens. RGM optimally require incubation at 28°C to 30°C.

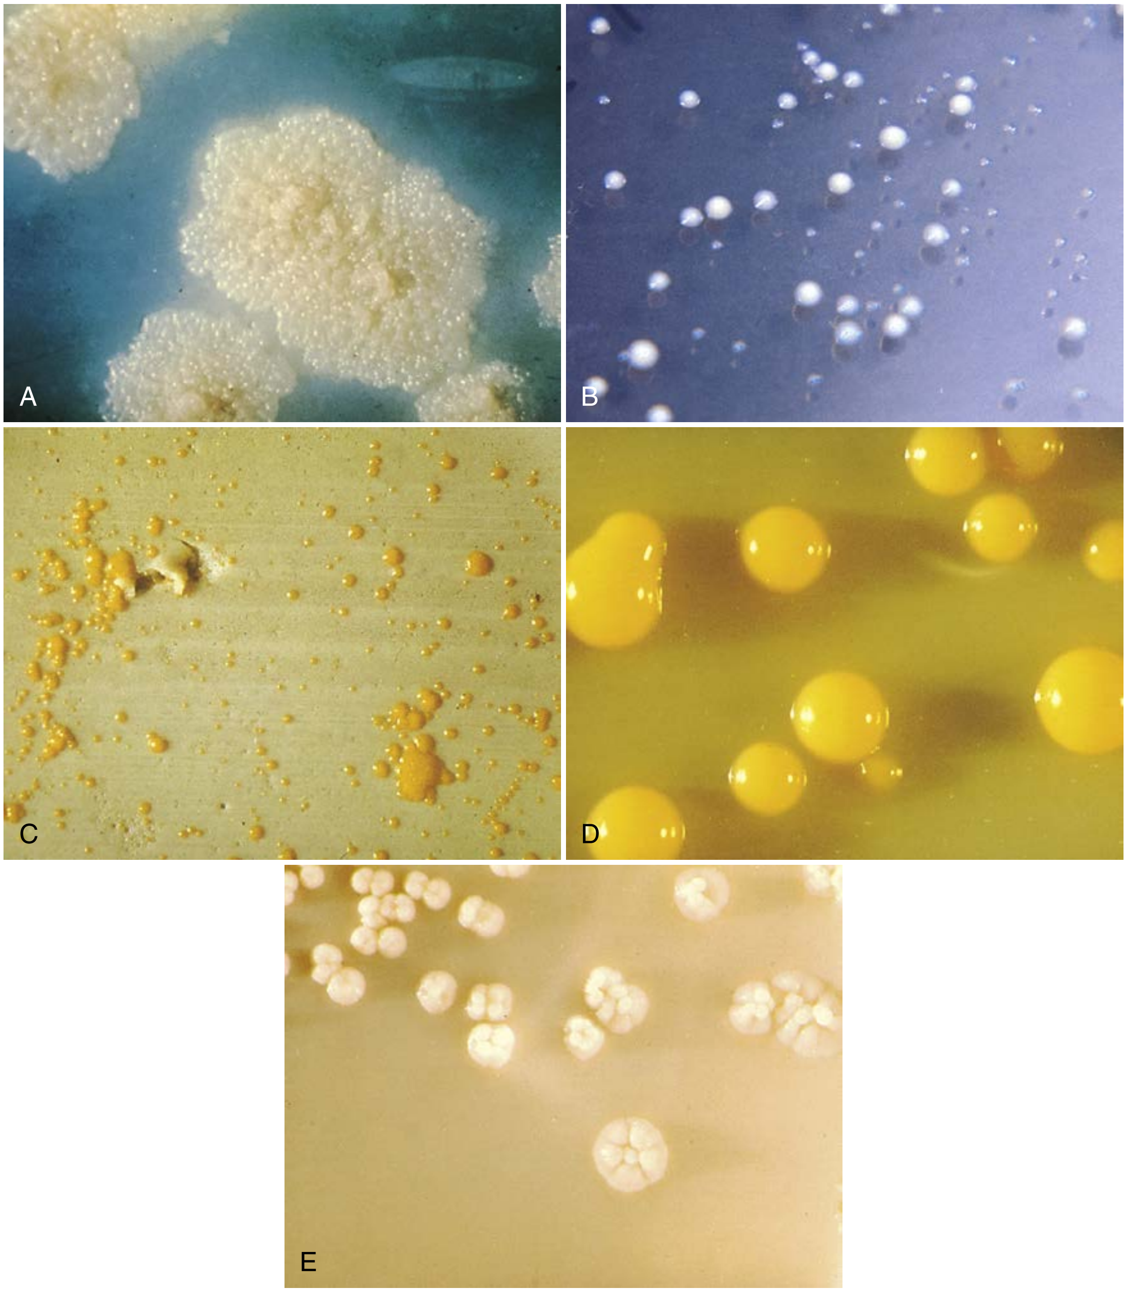
Cultures are examined weekly for growth. Contaminated cultures are discarded and reported as "contaminated, unable to detect presence of mycobacteria"; additional specimens are also requested. If available, sediment may be recultured after enhanced decontamination or by inoculating the sediment to a more selective medium. Most isolates appear between 3 and 6 weeks; a few isolates appear after 7 or 8 weeks of incubation. When growth appears, the rates of growth, pigmentation, and colonial morphology are recorded. The typical colonial appearance of *M. tuberculosis* and other mycobacteria is shown in Fig. 42.5. After 8 weeks of incubation, negative cultures (those showing no growth) are reported, and the cultures are discarded.

Liquid Media

In general, use of a liquid media system reduces the turnaround time for the isolation of AFB to approximately 10 days, compared with 17 days or longer for conventional solid media. Several different systems are available for culturing and detecting the growth of mycobacteria in liquid media. Growth of mycobacteria in liquid media, regardless of the type, requires 5% to 10% CO_2; CO_2 is either already provided in the culture vials or is added according to the manufacturer's instructions. When growth is detected in a liquid medium, acid-fast staining of a culture aliquot is performed to confirm the presence of AFB, and the material is subcultured to solid agar. Gram staining can also be performed if contamination is suspected.

Interpretation

Although isolation of MAC organisms indicates infection, the clinician must determine the clinical significance of isolating NTM in most cases; in other words, does the organism represent mere colonization or significant infection? Because these organisms vary greatly in their pathogenic potential, can colonize an individual without causing infection, and are ubiquitous in the environment, interpretation of a positive NTM culture is complicated; therefore the American Thoracic Society has recommended diagnostic criteria for NTM disease to help physicians interpret culture results.



• Fig. 42.5 Typical appearance of some mycobacteria on solid agar media. (A) *Mycobacterium tuberculosis* colonies on Löwenstein-Jensen agar after 8 weeks of incubation. (B) A different colonial morphology is seen on culture of one strain of *Mycobacterium avium* complex. (C) *Mycobacterium kansasii* colonies exposed to light. (D) Scotochromogen *Mycobacterium gordonae* showing yellow colonies. (E) Smooth, multilobate colonies of *Mycobacterium fortuitum* on Löwenstein-Jensen medium.

Approach to Identification

Regardless of the identification methods used, the first test always performed on organisms growing on solid or liquid mycobacterial media is acid-fast staining to confirm that the organisms are indeed mycobacteria. Identification of species other than MAC and the more commonly isolated NTM (MAC, *M. avium, M. intracellulare, M. gordonae,* and *M. kansasii*) has become challenging for routine clinical microbiology laboratories, particularly considering the ever-increasing number of new mycobacterial species.

Traditional methods (i.e., phenotypic methods) for identifying mycobacteria, particularly the NTM, are based on growth parameters, biochemical characteristics, and analysis of cell wall lipids, all of which are slow, cumbersome, and often inconclusive procedures. Over the past decade, the rate of non–AIDS-associated infections have been increasing, and many of the newly identified NTM species have been associated with various diseases. As a result, identification of species is vital to selecting effective antimicrobial therapy and to deciding whether to perform susceptibility testing on accurately speciated NTM. Newer species have been identified using nucleic acid sequencing with limited published phenotypic characteristics. Because of these issues and limitations with conventional phenotypic methods for identification, molecular and genetic investigations are becoming indispensable to identifying the NTM accurately. Therefore, for timely and accurate identification of mycobacteria, molecular approaches in conjunction with some phenotypic characteristics should be used.

Regardless of whether molecular or phenotypic methods are used, when growth is detected, broth subcultures of colonies growing in liquid media or on solid media (several colonies inoculated to Middlebrook 7H9 broth [5 mL] and incubated at 35°C for 5 to 7 days with daily agitation to enhance growth) are then used to determine pigmentation and growth rate and to inoculate all test media for biochemical tests if performed. Additional cultures may be inoculated and then incubated at different temperatures when more definitive identification is needed.

Conventional Phenotypic Tests

Growth Characteristics

Preliminary identification of mycobacterial isolates depends on the organisms' rate of growth, colonial morphology (Fig. 42.5), colonial texture, pigmentation, and, in some instances, the permissive incubation temperatures of mycobacteria. Despite the limitations of phenotypic tests, the mycobacterial growth characteristics are helpful for determining a preliminary identification (e.g., an isolate appears to represent RGM). To perform identification procedures, quality-control organisms should be tested along with unknowns (Table 42.8). The commonly used quality-control organisms can be maintained in broth at room temperature and transferred monthly. In this way they are always available for inoculation to test media along with suspensions of the unknown mycobacteria being tested.

Growth Rate. The rate of growth is an important criterion for determining the initial category of an isolate. Rapid growers usually produce colonies within 3 to 4 days after subculture. However, even a rapid grower may take longer than 7 days to initially produce colonies because of inhibition by a harsh decontaminating procedure; therefore the growth rate (and pigment production) must be determined by subculture (Evolve Procedure 42.5). The dilution of the organism used to assess the growth rate is critical. Even slow-growing mycobacteria appear to produce colonies in less than 7 days if the inoculum is too heavy. One organism particularly likely to exhibit false-positive rapid growth is *Mycobacterium flavescens.* It therefore serves as an excellent quality-control organism for this procedure.

Pigment Production. As previously discussed, mycobacteria can be categorized into three groups based on pigment production. Evolve Procedure 42.5 describes how to determine pigment production. To achieve optimum photochromogenicity, colonies should be young, actively metabolizing, isolated, and well aerated. Although some species (e.g., *M. kansasii*) turn yellow after a few hours of light exposure, others (e.g., *Mycobacterium simiae*) may require prolonged exposure to light. Scotochromogens produce pigmented colonies even in the absence of light, and colonies often become darker with prolonged exposure to light (Fig. 42.6). One member of this group, *Mycobacterium szulgai,* is peculiar in that it is a scotochromogen at 35°C and nonpigmented when grown at 25°C to 30°C. For this reason, all pigmented colonies should be subcultured to test for photoactivated pigment at both 35°C and 25°C to 30°C. Nonchromogens are not affected by light.

Biochemical Testing

Once categorized into a preliminary subgroup based on its growth characteristics, an organism must be definitively identified to species or complex level. Although conventional biochemical tests can be used for this purpose, molecular methods have replaced biochemical tests for identifying mycobacterial species because of the previously discussed limitations of phenotypic testing. Although key biochemical tests are still discussed in this edition, the reader must be aware that this approach to identification will ultimately be replaced by molecular methods or at the very least be utilized to resolve unusual cases in the absence of availability of whole genome sequencing and/or database limitations. Table 42.9 summarizes distinctive properties of the more commonly cultivable mycobacteria isolated from clinical specimens; key biochemical tests for each of the major mycobacterial groupings, including *M. tuberculosis* complex, are listed in Table 42.10. The following sections address key biochemical tests.

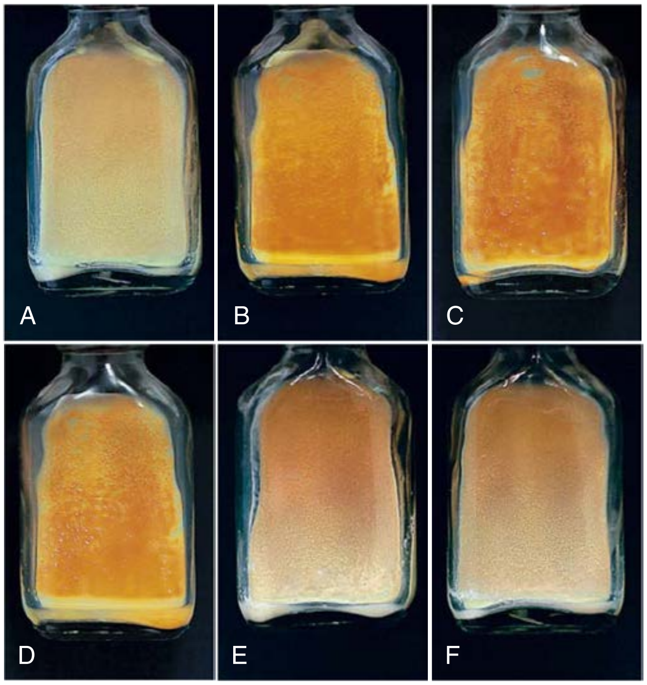
Niacin. Niacin (nicotinic acid) plays an important role in the oxidation-reduction reactions that occur during mycobacterial metabolism. Although all species produce nicotinic acid, *M. tuberculosis* accumulates the largest amount. (*M. simiae* and some strains of *M. chelonae* also produce niacin.) Niacin therefore accumulates in the medium in which these organisms are growing. A positive niacin test (Evolve Procedure 42.6) is preliminary evidence that an organism that exhibits a buff-colored, slow-growing, rough colony may be *M. tuberculosis* (Fig. 42.7). However, this test is not sufficient to confirm identification. If sufficient growth is present on an initial L-J slant (the egg-base medium enhances accumulation of free niacin), a niacin test can be performed immediately. If growth on the initial culture is scant, the subculture used for growth rate determination can be used. If this culture yields rare colonies, the colonies should be spread around with a sterile cotton swab (after the growth rate has been determined) to distribute the inoculum over the entire slant. The slant then is incubated until light growth over the surface of the medium is visible. For reliable results, the niacin test should be performed from cultures on L-J medium that are at least 3 weeks old and show at least 50 colonies; otherwise, enough detectable niacin might not have been produced.

Nitrate Reduction. A nitrate reduction test is valuable for identifying *M. tuberculosis, M. kansasii, M. szulgai,* and

TABLE 42.8 Controls and Media Used for Biochemical Identification of Mycobacteria

	Control Organisms		Result				
Biochemical Test Tables Are Difficult to Review in This Format	**Positive**	**Negative**	**Positive**	**Negative**	**Medium Used**	**Duration**	**Incubation Conditions**
Niacin	*Mycobacterium tuberculosis*	*Mycobacterium intracellulare*	Yellow	No color change	0.5 mL DH_2O	15–30 min	Room temperature
Nitrate	*Mycobacterium tuberculosis*	*Mycobacterium intracellulare*	Pink or red	No color change	0.3 mL DH_2O	2 h	37°C bath
Urease	*Mycobacterium fortuitum*	*Mycobacterium avium*	Pink or red	No color change	Urea broth for AFB	1, 3, and 5 days	37°C incubator (without CO_2)
68°C Catalase	*Mycobacterium fortuitum* or *Mycobacterium gordonae*	*Mycobacterium tuberculosis*	Bubbles	No bubbles	0.5 mL phosphate buffer (pH, 7.0)	20 min	68°C bath
SQ Catalase	*Mycobacterium kansasii* or *M. gordonae*	*Mycobacterium avium*	>45 mm	<45 mm	Commercial medium	14 days	37°C incubator (with CO_2)
Tween 80	*Mycobacterium kansasii*	*Mycobacterium intracellulare*	Pink or red	No color change	1 mL DH_2O	5 or 10 days	37°C incubator (in the dark, without CO_2)
Tellurite	*Mycobacterium avium*	*Mycobacterium tuberculosis*	Smooth, fine, black precipitate (smokelike action)	Gray clumps (no smokelike action)	Middlebrook 7H9 broth	7, then 3 additional days	37°C incubator (with CO_2)
Arylsulfatase	*Mycobacterium fortuitum*	*Mycobacterium intracellulare*	Pink or red	No color change	Wayne's arylsulfatase medium	3 days	37°C incubator (without CO_2)
5% NaCl	*Mycobacterium fortuitum*	*Mycobacterium gordonae*	Substantial growth	Little or no growth	Commercial slant with and without 5% NaCl	28 days	37°C incubator (with CO_2)
TCH	*Mycobacterium bovis*	*Mycobacterium tuberculosis*	No growth (i.e., susceptible)	Growth (i.e., resistant or ≥1% of colonies are resistant)	TCH slant	3 weeks	37°C incubator (with CO_2)

AFB, Acid-fast bacilli; *CO_2*, carbon dioxide; *DH_2O*, distilled water; *NaCl,* sodium chloride; *SQ,* semiquantitative; *TCH,* thiophene-2-carboxylic acid hydrazide.



• **Fig. 42.6** Initial grouping of mycobacteria based on pigment production before and after exposure to light. In one test system, subcultures of each isolate are grown on two agar slants. One tube is wrapped in aluminum foil to prevent exposure of the organism to light, and the other tube is allowed light exposure. After sufficient growth has occurred, the wrapped tube is unwrapped, and the tubes are examined together. Photochromogens are nonpigmented when grown in the dark (A) and develop pigment after light exposure (B). Scotochromogens are pigmented in the dark (C); the color does not intensify after exposure to light (D). Nonphotochromogens are nonpigmented when grown in the dark (E) and remain so even after light exposure (F).

M. fortuitum. The ability of AFB to reduce nitrate is influenced by the age of the colonies, temperature, pH, and enzyme inhibitors. Although rapid growers can be tested within 2 weeks, slow growers should be tested after 3 to 4 weeks of luxuriant growth. Commercially available nitrate strips yield acceptable results with strongly nitrate-positive organisms, such as *M. tuberculosis.* This test may be tried first because of its ease of performance. The *M. tuberculosis*–positive control must be strongly positive in the strip test, or the test results are unreliable. If the paper strip test is negative or if the control test result is not strongly positive, the chemical procedure (Evolve Procedure 42.7) must be carried out using strongly and weakly positive controls.

Catalase. Most species of mycobacteria except for certain strains of *M. tuberculosis* complex (some isoniazid-resistant strains) and *M. gastri* produce the intracellular enzyme catalase, which splits hydrogen peroxide into water and oxygen. Catalase can be assessed by using the semiquantitative catalase test or the heat-stable catalase test.

- The semiquantitative catalase test is based on the relative activity of the enzyme, as determined by the height of a column of bubbles of oxygen (Fig. 42.8) formed by the action of untreated enzyme produced by the organism. Based on the semiquantitative catalase test, mycobacteria are divided into two groups: those that produce less than 45 mm of bubbles and those that produce more than 45 mm of bubbles.
- The heat-stable catalase test is based on the ability of the catalase enzyme to remain active after heating (i.e., it is a measure of the enzyme's heat stability). When heated to 68°C for 20 minutes, the catalase of *M. tuberculosis, M. bovis, M. gastri,* and *M. haemophilum* becomes inactivated.

Tween 80 Hydrolysis. The commonly nonpathogenic, slow-growing scotochromogens and nonphotochromogens produce a lipase that can hydrolyze Tween 80 (the detergent polyoxyethylene sorbitan monooleate) into oleic acid and polyoxyethylated sorbitol, whereas pathogenic species do not. Tween 80 hydrolysis is useful for differentiating species of photochromogens, nonchromogens, and scotochromogens. Because laboratory-prepared media have a very short shelf life, the CDC recommends use of a commercial Tween 80 hydrolysis substrate (Becton-Dickinson, Franklin Lakes, NJ, or Remel Laboratories, Lenexa, KS) that is stable for up to 1 year.

Tellurite Reduction. Some species of mycobacteria reduce potassium tellurite at variable rates. The ability to reduce tellurite in 3 to 4 days distinguishes members of MAC from most other nonchromogenic species. All rapid growers reduce tellurite in 3 days.

Arylsulfatase. The enzyme arylsulfatase is present in most mycobacteria. Test conditions can be varied to distinguish the different forms of the enzyme. The rate at which the enzyme breaks down phenolphthalein disulfate into phenolphthalein (which forms a red color in the presence of sodium bicarbonate) and other salts helps to differentiate certain strains of mycobacteria. The 3-day test is particularly useful for identifying the potentially pathogenic rapid growers *M. fortuitum* and *M. chelonae.* Slow-growing *M. marinum* and *M. szulgai* are positive in the 14-day test (Fig. 42.9).

Growth Inhibition by Thiophene-2-Carboxylic Acid Hydrazide. The thiophene-2-carboxylic acid hydrazide (TCH) growth-inhibition test is used to distinguish *M. bovis* from *M. tuberculosis* because only *M. bovis* is unable to grow in the presence of 10 mg/mL of TCH.

Other Tests. Other tests are often performed to make more subtle distinctions between species (Table 42.10). However, performing all the procedures necessary for definitive identification of mycobacteria is not cost-effective for routine clinical microbiology laboratories; therefore specimens that require further testing can be forwarded to regional laboratories.

Antimicrobial Susceptibility Testing and Therapy

Drug-resistant tuberculosis is a major health threat; more than 500,000 cases of multidrug-resistant (MDR) tuberculosis occur each year. MDR tuberculosis is resistant to rifampin and isoniazid, the two drugs most often used as

TABLE 42.9 Distinctive Properties of Commonly Cultivable Mycobacteria Encountered in Clinical Specimens

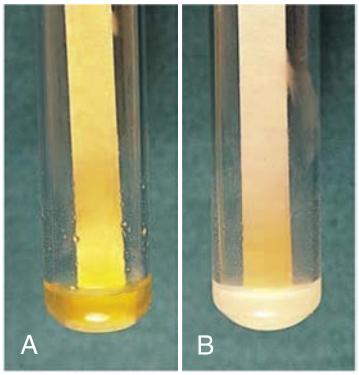
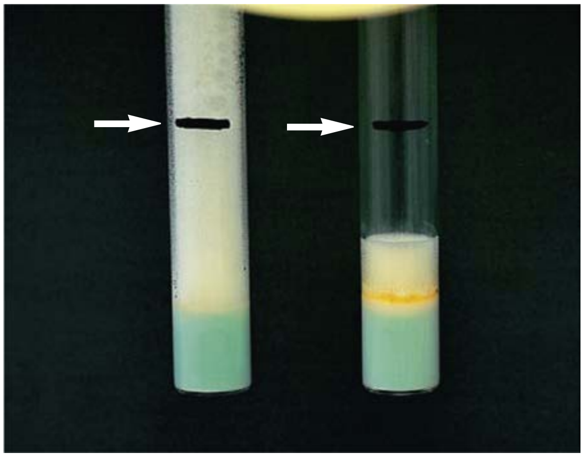
TABLE 42.10 Key Biochemical Reactions to Help Differentiate Organisms Belonging to the Same Mycobacterial Group

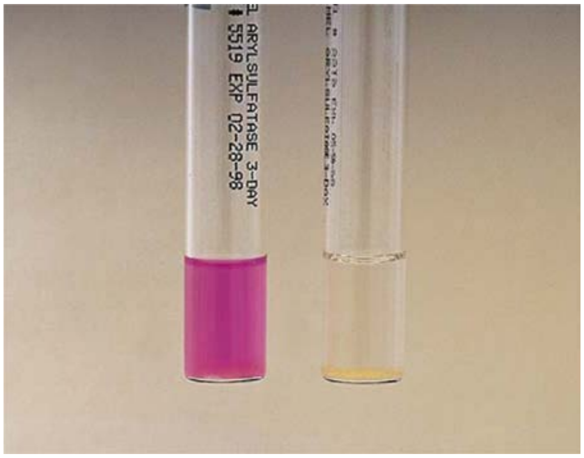
Mycobacterial Group	Key Biochemical Tests
Mycobacterium tuberculosis complex	Niacin, nitrate reduction; susceptibility to thiophene-2-carboxylic acid hydrazide (TCH) if *Mycobacterium bovis* is suspected
Photochromogens	Tween 80 hydrolysis, nitrate reduction, pyrazinamidase, 14-day arylsulfatase, urease, niacin
Scotochromogens	Permissive growth temperature, Tween 80 hydrolysis, nitrate reduction, semiquantitative catalase, urease, 14-day arylsulfatase
Nonphotochromogens	Heat-resistant and semiquantitative catalase activity, nitrate reduction, Tween 80 hydrolysis, urease, 14-day arylsulfatase, tellurite reduction, acid phosphatase activity
Rapidly growing	Growth on MacConkey agar, nitrate reduction, Tween 80 hydrolysis, 3-day arylsulfatase, iron uptake



• **Fig. 42.7** Niacin test performed with filter paper strips. (A) With a positive test result, the liquid turns yellow. (B) With a negative result, the liquid remains milky white or clear.



• **Fig. 42.8** Semiquantitative catalase test. The tube on the *left* contains a column of bubbles that has risen past the line *(arrow),* indicating 45-mm height (a positive test result). The tube on the *right* is the negative control.



• **Fig. 42.9** A positive arylsulfatase test result is shown on the *left;* the tube containing the negative control is on the *right.*

effective treatment against tuberculosis. In addition, strains of XDR TB are emerging that are resistant not only to rifampin and isoniazid, but also to quinolones and other drugs, such as aminoglycosides and capreomycin.

Standardized methods for susceptibility testing, including direct and indirect testing and new molecular tools, currently are available for susceptibility testing.

M. tuberculosis Complex

In vitro drug susceptibility testing should be performed on the first isolate of *M. tuberculosis* from all patients. Susceptibility testing of *M. tuberculosis* requires meticulous care in the preparation of the medium, selection of adequate samples of colonies, standardization of the inoculum, use of appropriate controls, and interpretation of results. Laboratories that see very few positive cultures should consider sending isolates to a reference laboratory for testing. Isolates must be saved in sterile 10% skim milk in distilled water at −70°C for possible future additional studies (e.g., susceptibilities if the patient does not respond well to treatment).

Direct Versus Indirect Susceptibility Testing

Susceptibility tests may be performed by either the direct or indirect method. The direct method uses the smear-positive concentrate containing more than 50 AFB per 100 oil immersion fields as the inoculum; the indirect method uses a culture as the inoculum source. Although direct testing provides more rapid results, it is less standardized and contamination may occur.

Conventional Methods

The development of primary drug resistance in tuberculosis represents an increase in the proportion of resistant organisms. The increase in resistant organisms results from a spontaneous mutation and subsequent selection to predominance of the drug-resistant mutants by the action of a single or ineffective drug therapy. A poor clinical outcome is predicted with an agent when more than 1% of bacilli in the test population are resistant. If an isolate is reported as resistant to a drug, treatment failure is likely if this drug is used for therapy.

Drug resistance is defined for *M. tuberculosis* complex in terms of the critical concentration of the drug. The **critical concentration** of a drug is the amount of drug required to prevent growth above the 1% threshold of the test population of tubercle bacilli. Initial isolates of *M. tuberculosis* are tested against five antimicrobials, which are referred to as **primary drugs** (Box 42.3). If resistance to any of the primary drugs is detected, a second battery of agents is tested (Box 42.3).

Molecular Methods for the Determination of Susceptibility

Several technologies show promise of being faster, more reliable, and/or easier to perform than most conventional methods of susceptibility testing. As previously indicated,

• BOX 42.3 Antitubercular Agents Commonly Tested Against *Mycobacterium tuberculosis*

Primary Drugs

Isoniazid
Rifampin
Ethambutol
Pyrazinamide

Secondary Drugs

Amikacin
Amithiozones
Bedaquiline
Ethionamide
Capreomycin

Secondary Drugs—cont'd

Clofazimine
Doxycycline or minocycline
Linezolid
Levofloxacin
Moxifloxacin
Kanamycin
Cycloserine
p-Aminosalicylic acid
Rifabutin
Streptomycin

the Cepheid Xpert is FDA approved in the United States for the detection of rifampicin mutations in *M. tuberculosis.* Another molecular method as previously discussed, the line probe assay (INNO-LiPA Rif TB; Innogenetics, Ghent, Belgium), is a commercially available reverse hybridization–based probe assay for rapid detection of rifampin mutations leading to rifampin resistance in *M. tuberculosis.* Many different genotypic assays are currently available for drug susceptibility testing. Most are based on PCR amplification of a specific region of an *M. tuberculosis* gene, followed by analysis of the amplicon for specific mutations associated with resistance to a drug. The presence or absence of mutations can then be detected by several methods, such as automated sequencing.

As previously mentioned, high-density DNA probe assays (Chapter 8) have been used to detect rifampin resistance and to identify mycobacterial species identification.

The CDC currently offers a molecular drug resistance sequencing method for culture isolates or nucleic acid test sediments positive for *M. tuberculosis* complex organisms. Susceptibility testing should be repeated if the patient remains culture positive after 3 months following appropriate therapy or fails to respond clinically to therapy.

Therapy

Therapy directed against *M. tuberculosis* depends on the susceptibility of the isolate to various antimicrobial agents. To prevent the selection of resistant mutants, treatment of tuberculosis requires four drugs: isoniazid, rifampin, ethambutol, and pyrazinamide. Initial therapy includes all four drugs for 8 weeks. However, if drug susceptibility is determined for isoniazid, rifampin, and pyrazinamide, ethambutol may be discontinued. This is the preferred therapy for initial treatment, followed by isoniazid and rifampin for an additional 18 weeks. The most common two-drug regimen is isoniazid (INH, also known as **isonicotinoylhydrazine**) and rifampin. The combination is administered for 9 months in cases of uncomplicated tuberculosis; if pyrazinamide is added to this regimen during the first 2 months, the total duration of therapy can be shortened to 6 months. Ethambutol may also be added to the regimen. INH prophylaxis is recommended for individuals with a recent skin test conversion who are disease free.

Nontuberculous Mycobacteria

In general, the treatment of patients infected with NTM requires more individualized therapy than does the treatment of patients with tuberculosis. This individualization is based on the species of mycobacteria recovered, the site and severity of infection, antimicrobial drug susceptibility results, concurrent diseases, and the patient's general condition.

Susceptibility testing should be performed on clinically significant, rapidly growing mycobacteria. Skin and soft tissue infections, if susceptible, are treated with clarithromycin and at least one additional drug based on susceptibility testing. Pulmonary infections with *M. abscessus* should also be treated with a multidrug regimen that includes clarithromycin, if susceptible, and then additional drugs based on susceptibility testing.

Prevention

As previously mentioned, prophylactic chemotherapy with INH is used when known or suspected primary tuberculous infection poses a risk of clinical disease. At present, the BCG vaccine is the only vaccine available against tuberculosis. The effectiveness of this live vaccine is controversial, because studies have demonstrated ineffectiveness to 80% protection. The greatest potential value for this vaccine is in developing countries with high prevalence rates for tuberculosis. At least four types of antituberculosis vaccines are currently being evaluated in experimental studies in animals.

CASE STUDY 42.1

A 40-year-old male who has tested positive for human immunodeficiency virus (HIV) infection and is undergoing highly active antiretroviral therapy (HAART) presented with progressive encephalomyeloradiculopathy. He complained of severe headaches but had no evidence of fever, cough, or weakness. Cerebrospinal fluid (CSF) was collected. The test result for white blood cells (WBCs) in the specimen was 25/mm^3 (25 WBCs per cubic millimeter); low glucose, elevated protein, and no organisms on Gram stain or acid-fast stain. His studies were negative for cryptococcal antigen, *Toxoplasma* spp. (by serology), and herpes simplex virus (HSV) (by polymerase chain reaction [PCR]). Routine bacterial culture was negative. Despite therapy for HSV and routine aerobic bacterial causes of meningitis, over the next 4 days the patient spiked fevers. A second CSF specimen demonstrated WBCs at 415/mm^3, with no diagnosis. A battery of viral encephalitis serology tests was completed, and all were negative. In-house PCR testing on a third CSF specimen was positive for *Mycobacterium tuberculosis,* which grows in culture after 4 weeks.

Questions

1. Why were the acid-fast smear results from all three of the specimens negative with the second PCR result positive?
2. How can *M. tuberculosis* be identified to the species level?
3. List the organisms present in the *M. tuberculosis* complex.
4. Sometimes in processing for mycobacterial culture, an aerosol is created and one specimen splashes into another tube and contaminates it. If the physician states that the patient does not appear to have tuberculosis, how can the laboratory confirm that the positive culture does not represent contamination?

Chapter Review

1. Photochromogens are capable of pigment production when they are
  a. Exposed to light for approximately 1 hour
  b. Grown in the presence of CO_2
  c. Incubated in ultraviolet radiation
  d. Incubated in the dark at 30°C, followed by brief exposure to regular light

2. The medium most often used for the isolation and cultivation of *Mycobacterium* spp. is
  a. Cystine blood agar
  b. Loeffler medium
  c. Sheep blood agar
  d. Löwenstein-Jensen medium

3. In patients who are HIV positive or who have AIDS, chronic pulmonary disease may be associated with infection as a result of
  a. *M. gordonae*
  b. *M. kansasii*
  c. *M. avium* complex
  d. *M. fortuitum*

4. The disease-producing capability of *M. tuberculosis* is associated with the ability to
  a. Produce a massive burst of exotoxin, destroying lung tissue
  b. Escape death by multiplication in alveolar macrophages
  c. Produce a complex endotoxin more deadly than gram-negative organisms
  d. Trick the humoral immune response in the host

5. For the recovery of *Mycobacterium* spp., which of the following is useful as a mucolytic alkaline reagent that digests and decontaminates a sputum sample?
  a. Zephiran-trisodium phosphate
  b. *N*-acetyl-L-cystine
  c. NaOH and oxalic acid
  d. *N*-acetyl-L-cystine and NaOH

6. Which of the following tests is most definitive for the identification of *M. tuberculosis*?
  a. Catalase production
  b. Tween 80 hydrolysis
  c. Production of niacin
  d. Reduction of nitrate

7. An acid-fast bacillus has been isolated from sputum in a patient suspected of having active pulmonary tuberculosis. After incubation in the dark and exposure to light, the isolated organism appears to be a slow-growing cream- to tan-colored colony. An SQ catalase reaction of 42 mm is noted. The organism is most likely
  a. *M. kansasii*
  b. *M. fortuitum*
  c. *M. avium* complex
  d. *M. tuberculosis*

8. A clinical *Mycobacterium* isolate is grown in the dark for approximately 21 days. After exposure to light for 8 hours, the organism produces a yellow pigment. The organism is most likely
  a. *M. tuberculosis*
  b. *M. fortuitum*
  c. *M. bovis*
  d. *M. kansasii*

9. A urine culture produces a few colonies of acid-fast bacilli after approximately 14 days. The colonies are rough and nonpigmented. The niacin test is weakly positive, and the nitrate test is positive. The most appropriate action for the technologist considering the potential isolate is to
  a. Report the organism as *M. tuberculosis* so that the physician may initiate therapy.
  b. Set up a sensitivity test to determine whether the patient requires treatment or the organism is simply a contaminant.

- **c.** Repeat the niacin test and report presumptive identification of *M. tuberculosis* if the test appears positive.
- **d.** Subculture the isolate and carry out a series of biochemical tests—including niacin, nitrate, and Tween 80—and notify the physician that no results are available at this time.

10. The unique chemical structure of the cell wall of *Mycobacterium* spp. is associated with the presence of

- **a.** N-glycolylmuramic acid and a decrease in lipid content
- **b.** N-acetylmuramic acid and a decrease in lipid content
- **c.** N-glycolylmuramic acid and an increase in lipid content
- **d.** N-acetylmuramic acid and an increase in lipid content

11. A patient suspected of having an *M. tuberculosis* infection is admitted to the hospital at 7 a.m. A sputum specimen is collected at that time. The acid-fast stain reveals acid-fast bacilli. Two days later, a specimen collected after lunch reveals no acid-fast bacilli. The laboratory technologist should

- **a.** Reexamine the initial specimen and notify the physician of the laboratory error.
- **b.** Report the second stain as negative for the presence of acid-fast bacilli.
- **c.** Reject the second specimen and request that a new specimen be collected immediately.
- **d.** Report the results of the second specimen, noting the error in the collection, and request a new specimen.

12. True/False

_____ All *Mycobacterium* spp. demonstrate a strong acid-fast staining reaction during all phases of growth.

_____ The term *complex* is used when species distinction is complicated and of no medical consequence.

_____ A blood culture that is positive for MAC is considered likely to be contaminated and should be reported as such.

_____ Screening of specimens using a fluorescent stain may reduce the laboratory time required to diagnose tuberculosis and may improve detection of positive smears.

_____ Extraction and processing of *Mycobacterium* spp. for MALDI-TOF MS can be completed in a BSL-2 facility.

13. Matching: *Match each term with the appropriate phrase or description.*

______ *M. leprae*
______ NTM
______ *M. bovis*
______ Primary tuberculosis
______ Latent tuberculosis
______ Disseminated tuberculosis
______ Reactivation tuberculosis
______ Oxalic acid
______ Gram stain

a. contaminated milk
b. positive PPD (tuberculin skin test)
c. noncultivatable NTM
d. removes gram-negative contaminating organisms
e. no person-to-person transmission noted
f. lacks signs and symptoms
g. beaded or neutral staining of organisms
h. results of suppressed cellular immunity
i. pulmonary disease

14. Short Answer

(1) Describe the limitations and reasons for rejection of a clinical specimen for the recovery of *Mycobacterium* species.
(2) Explain special considerations for processing gastric lavages, urine, and fecal specimens.
(3) For the isolation of *Mycobacterium* spp., what specimens do not require decontamination? Explain.
(4) Describe the limitations associated with the identification and speciation of *Mycobacterium* isolates using molecular methods, including PCR and sequencing procedures.
(5) Describe the recommended treatment for *M. tuberculosis* and concerns associated with multidrug-resistant isolates.

PROCEDURE 42.1

N-Acetyl-L-Cysteine–Sodium Hydroxide Method for the Liquefaction and Decontamination of Specimens

Principle

Sodium hydroxide (NaOH), a decontaminating agent, also acts as an emulsifier. Because of its potential toxicity, NaOH should be used at the lowest concentration that effectively digests and decontaminates the specimen. The addition of a mucolytic agent, *N*-acetyl-L-cysteine (NALC), reduces the concentration of NaOH required and shortens the time required for decontamination, aiding optimal recovery of acid-fast bacilli.

Method

1. Reagent preparation:
   A. NALC-NaOH preparation

   For each day's cultures, add up the total volume of specimens to be treated and prepare an equal volume of the digestant-decontamination mixture, as follows:
   - 1 N (4%) NaOH (50 mL)
   - 0.1 M (2.94%) trisodium citrate
   - 3 H_2O (50 mL)
   - NALC powder (0.5 g)

   Use sterile distilled water to prepare solutions to minimize the chance of inadvertently adding acid-fast tap water contaminants to the specimens. Mix, sterilize, and store the NaOH and the citrate in sterile screw-capped flasks for later use. This solution should be used within 24 h after the NALC is added.

   B. 0.67 M phosphate buffer, pH 6.8 preparation:

   Make the following solutions:
   - Solution A (0.067 M disodium phosphate)
     - Sodium monohydrogen phosphate (anhydrous) 9.47 g
     - Distilled water 1000 mL
   - Solution B (0.067 M monopotassium phosphate)
     - Potassium dihydrophosphate 9.07 g
     - Distilled water 1000 mL

   Add 50 mL of solution B to 50 mL of solution A and adjust the pH to 6.8.
2. Work in a biologic safety cabinet (BSC) and wear protective clothing, gloves, and a mask. Transfer a maximum of 10 mL of sputum, urine, or other fluid to be processed to a sterile disposable plastic 50-mL conical centrifuge tube with a leakproof aerosol-free plastic screw cap. Tubes with easily visible volume-indicator marks are best.
3. Add an equal volume of freshly prepared digestant to the tube; take great care when pouring the digestant so as not to touch the lip of the specimen container, because this might inadvertently transfer positive material to a negative specimen. Tighten the cap completely.
4. Vortex the specimen for approximately 15 s or for a maximum of 30 s; make sure to create a vortex in the liquid and not merely agitate the material. Check for homogeneity by inverting the tube. If clumps remain, vortex the specimen intermittently while the rest of the specimens are being digested. An extra pinch of NALC crystals may be necessary to liquefy mucoid sputa.
5. Start a 15-min timer when the first specimen has been vortexed. Continue digesting the other specimens, noting the time required for the entire run. The digestant should remain on the specimens for a maximum exposure of 20 min.
6. After 15 min of digestion, add enough phosphate buffer to reach within 1 cm of the top, screw the cap tightly closed, and invert the tube to mix the solutions and stop the digestion process. Addition of this solution also reduces the specific gravity of the specimen, aiding sedimentation of the bacilli during centrifugation.
7. Centrifuge all tubes at 3600× *g* for 15 min, using aerosol-free sealed centrifuge cups.
8. Carefully pour off the supernatant into a splashproof container. To ensure that the specimen does not run down the outside of the tube after pouring, wipe the lip of the tube with Amphyl- or phenol-soaked gauze to absorb drips. Be careful not to touch the lip of any tube to another container. It is helpful to watch the sediment carefully as the supernatant is being decanted, because a very mucoid sediment may be loose and may pour out with the supernatant. If the sediment begins to slip, stop decanting and use a sterile capillary pipette to remove the supernatant without losing the sediment.
9. Suspend the sediment in 1 to 2 mL of phosphate buffer, pH to 6.8 with bovine serum albumin [BSA].
10. Inoculate the sediment to culture media and prepare slides.

PROCEDURE 42.2

Preparation of Smears for Acid-Fast Stain From Direct or Concentrated Specimens

Method

1. Vortex concentrated sediment, unconcentrated sputum, other purulent material, or stool. Aspirate 0.1 to 0.2 mL into a Pasteur pipette and place 2 to 3 drops on the slide. Place the end of the pipette or a sterile applicator stick parallel to the slide and slowly spread the liquid uniformly to make a thin smear.
2. For cerebrospinal fluid (CSF) sediment, vortex thoroughly and apply to the slide in heaped drops. A heaped drop is allowed to air dry, and a second application of sediment is placed on the same spot and allowed to dry. A minimum of three layers, applied to the same 1 cm–diameter circle, should facilitate detection of small numbers of bacilli. (Note: Some laboratories have stopped performing acid-fast stains on CSF because positive stains are extremely rare.)
3. Fix the smear at 80°C for 15 min or for 2 h at 65°C to 70°C on an electric hot plate.

   Note: Survival of mycobacteria at this temperature has been reported; handle all specimens with proper precautions.
4. Stain slides using Ziehl-Neelsen or fluorochrome stain.

PROCEDURE 42.3

Auramine-Rhodamine Fluorochrome Stain

Principle

The fluorochrome dyes used in this stain complex to the mycolic acids in acid-fast cell walls. Detection of fluorescing cells is enhanced by the brightness against a dark background.

Method

1. Heat-fix slides at 80°C for at least 15 min or for 2 h at 65°C to 70°C.
2. Flood slides with auramine-rhodamine reagent and allow to stain for 15 to 20 min at room temperature.
3. Rinse with deionized water and tilt slide to drain.
4. Decolorize with 0.5% acid-alcohol (70% ethanol and 0.5% hydrochloric acid) for 2 to 3 min.
5. Rinse with deionized water and tilt slide to drain.
6. Flood slides with 0.5% potassium permanganate for 2 to 4 min.
7. Rinse with deionized water and air dry.
8. Examine under low power (250×) for fluorescence.

Expected Results

Mycobacterium spp. fluoresce yellow to orange, depending on the filter system used.

PROCEDURE 42.4

Quality Control for Mycobacteriology

Reagents

1. Media: routine media used for the cultivation of mycobacteria
2. Quality control organism: a recent isolate of *Mycobacterium tuberculosis* or *M. tuberculosis* strain H37Rv
3. Other materials:

- Autoclaved sputum (acid-fast bacilli [AFB]–negative)
- 7H9 liquid medium containing 15% glycerol
- Sterile buffer, pH 7.0
- 50-mL plastic, conical centrifuge tubes

Method

1. Suspend several colonies of H37Rv in a tube containing 3 mL of Middlebrook liquid medium and several plastic or glass beads. Mix vigorously on a test tube mixer, then allow large particles to settle for 15 min.
2. Prepare a dilution of approximately 10^6 organisms per milliliter (10^6/mL) by adding the cell suspension drop by drop to 1 mL of buffer until a barely turbid suspension occurs. Transfer 0.5 mL of the 10^6/mL dilution to 4.5 mL of glycerol broth to give a suspension of 10^5/mL. Repeat the procedure to make a 10^4/mL suspension and a 10^3/mL suspension.
3. Label fifteen 3-dram vials for each suspension (10^5, 10^4, and 10^3). Transfer 0.3 mL of the appropriate suspension to each vial. Store the vials at –70°C to use for future quality-control testing.
4. Thaw one vial of each of the three dilutions each time the quality control procedure is performed.
5. Add 2.7 mL of autoclaved sputum to each cell suspension to affect a 10-fold dilution and inoculate three sets of the media used for primary isolation with each of the three dilutions of sputum. Inoculate 0.1 mL of sputum per bottle.
6. Decontaminate and concentrate the remainder, as with sputum specimens. Reconstitute the sediments with sterile buffer to 2.6 mL, resuspend vigorously, and inoculate a second set of media with 0.1 mL of each of the concentrated and resuspended samples.
7. Incubate at 35°C in 5% to 10% carbon dioxide (CO_2) for 21 days.

Interpreting and Recording Results

Egg media should have been inoculated with approximately 10^4, 10^3, and 10^2 organisms, respectively. The first dilution should produce semiconfluent growth, and the second and third should produce countable colonies in each bottle. Because of the retrospective nature of these determinations, close comparisons must be made between current and previous results to note trends or developing deficiencies. Failures may be the result of faulty media, lethal effects of decontamination and concentration procedures, improperly prepared reagents, or overexposure of specimens to these reagents. Should deficiencies become evident, techniques should be reviewed, and attempts made to determine the source of the problem. New batches of media must be substituted for deficient media and the latter rechecked to verify deficiencies. Personnel should be included in all discussions of problems and corrective measures. All deficiencies and corrective actions should be recorded in the appropriate section of the quality control records.

PROCEDURE 42.5

Determination of Pigment Production and Growth Rate

Principle

Certain mycobacteria produce carotenoids, either dependently or independently of exposure to light. This characteristic, in addition to these species' doubling time under standard conditions, is useful for initial identification.

Method

1. After the broth culture has incubated for 5 to 7 days, adjust the turbidity to that of a McFarland 0.5 standard (10^4 concentration).
2. Inoculate 0.1 mL of the diluted broth to each of three tubes of Löwenstein-Jensen agar. Completely wrap two of the tubes in aluminum foil to block all light. If the isolate was obtained from a skin lesion or the initial colony was yellow pigmented (possible *Mycobacterium szulgai* colony), inoculate six tubes. If six tubes are used, the second set of tubes, two of them also wrapped with aluminum foil, is incubated at 30°C or at room temperature if a 30°C incubator is not available.
3. Examine the cultures after 5 and 7 days for grossly visible colonies. Examine again at intervals of 3 days. Interpretation: Rapid growers produce visible colonies in less than 7 days; slow growers require more than 7 days.
4. When the colonies are mature, expose the growth from a foil-wrapped tube to a bright light, such as a desk lamp, for 2 h. The cap must be loose during exposure, because pigment production is an oxygen-dependent reaction. Then rewrap the tube and return it to the incubator, leaving the cap loose.
5. Examine the three tubes 24 and 48 h after light exposure. For tubes incubating at 30°C, pigment may require 72 h for development.

Expected Results

Interpret as shown in Fig. 42.5.

PROCEDURE 42.6

Niacin Test Performed With Commercially Available Filter Paper Test Strips[a]

Principle

The accumulation of niacin in an egg-based medium, the result of lack of an enzyme that converts niacin to another metabolite in the coenzyme pathway, is characteristic of *M. tuberculosis* and a few other species. Niacin is measured by a colored end product.

Method

1. Add 1 mL of sterile distilled water to the surface of the egg-based medium on which the colonies to be tested are growing.
2. Lay the tube horizontally so that the fluid is in contact with the entire surface. Using a pipette, scratch or lightly poke through the surface of the agar; this allows the niacin in the medium to dissolve in the water.
3. Allow the tube to sit for up to 30 min at room temperature. It can incubate longer to achieve a stronger reaction.
4. Remove 0.6 mL of the distilled water (which appears cloudy at this point) to a clean 12- by 75-mm screw-cap or snap-top test tube. Insert a niacin test strip with the arrow down, following the manufacturer's instructions.
5. Cap the tube tightly and incubate at room temperature, occasionally shaking the tube to mix the fluid with the reagent on the bottom of the strip.
6. After 20 min, observe the color of the liquid against a white background (Fig. 42.7).

Expected Results

Yellow liquid indicates a positive test result. The color of the strip should not be considered when results are being evaluated. If the liquid is clear, the test result is negative. Discard the strip into an alkaline disinfectant (10% sodium hydroxide [NaOH]) to neutralize the cyanogen bromide.

[a] Manufactured by Remel, Lenexa, Kansas.

PROCEDURE 42.7

Nitrate Reduction Test Using Chemical Reagents

Principle

As in the conventional nitrate test, the presence of nitrite (the product of the nitroreductase enzyme) is detected by a red product that results with the addition of several reagents. If the enzyme has reduced nitrate past nitrite to gas, then addition of zinc dust (which converts nitrate to nitrite) will detect the lack of nitrate in the reaction medium.

Method

1. Prepare the dry crystalline reagent as follows:

Sulfanilic acid (Sigma Chemical Co., St. Louis, MO)	1 part
N-(1-Naphthyl) ethylenediamine dihydrochloride (Eastman Chemical Co., Rochester, NY)	1 part
L-tartaric acid (Sigma Chemical Co.)	10 parts

These crystals can be measured with any small scoop or tiny spoon, because the proportions are by volume, not weight. The mixture should be ground in a mortar and pestle to ensure adequate mixing, because the crystals have different textures. The reagent can be stored in a dark glass bottle at room temperature for at least 6 months.

2. Add 0.2 mL sterile distilled water to a 16- by 125-mm screw-cap tube. Emulsify two very large clumps of growth from a 4-week culture on Löwenstein-Jensen agar in the water. The suspension should be milky.
3. Add 2 mL nitrate substrate broth (Becton-Dickinson, Franklin Lakes, NJ, or Remel, Lenexa, KS) to the suspension and cap tightly. Shake gently and incubate upright for 2 h in a 35°C water bath.
4. Remove from water bath and add a small amount of the crystalline reagent. A wooden stick or a small spatula can be used to add crystals; the amount is not critical. Examine immediately.

Expected Results

Development of a pink to red color indicates the presence of nitrite, demonstrating the organism's ability to reduce nitrate to nitrite. If no color results, the organisms may have reduced nitrate beyond nitrite (as in the conventional nitrate test). Add a small amount of powdered zinc to the negative tube. The development of a red color indicates that unreduced nitrate was present in the tube, and the organism was nitroreductase negative.

43

Obligate Intracellular and Nonculturable Bacterial Agents

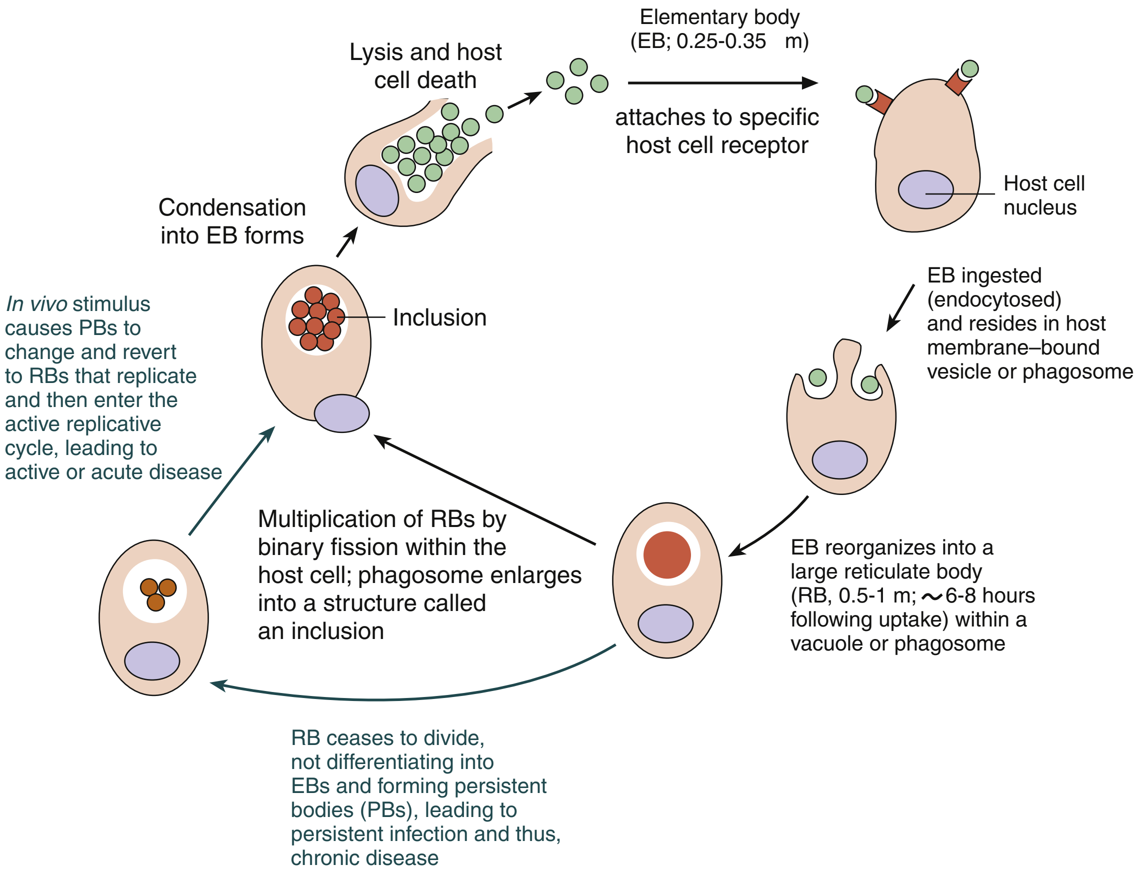
OBJECTIVES

1. Define the following: bubo, proctitis, bartholinitis, salpingitis, elementary body, reticulate body, Whipple disease, morulae, and Donovan body.
2. Describe the general characteristics for the organisms included in this chapter, including Gram stain characteristics, cultivation methods (media and growth conditions), transmission, and clinical significance.
3. Explain the mechanism and location for the replication of *Chlamydia* spp.
4. Compare the clinical manifestations and diagnosis of trachoma and other oculogenital infections associated with *Chlamydia* spp.
5. List the appropriate specimens used for the isolation of the organisms included in this chapter.
6. Describe the correct collection method for a specimen submitted for *Chlamydia trachomatis* screening from the female genital tract.
7. Explain the three stages associated with lymphogranuloma venereum, and compare the disease with other genital infections.
8. Describe the laboratory methods used for the diagnosis of *Chlamydia* infections, including sensitivity, limitations, and appropriate use for culture, cytology, antigen (direct fluorescent antibody), and nucleic acid amplification testing (NAAT).
9. Compare hybridization and amplification nucleic acid–based testing for chlamydia.
10. Describe the triad of symptoms associated with *Rickettsia* spp.
11. Compare human monocytic ehrlichiosis (HME) and granulocytic anaplasmosis (HGA).
12. Distinguish and describe the three groups of *Rickettsia* based on mode of transmission, clinical manifestations, and intracellular growth characteristics.
13. Describe the Weil-Felix reaction, including chemical principle and limitations.
14. Describe the clinical significance for *Coxiella burnetii* phase I and phase II forms, including laboratory diagnosis.
15. Explain the limitations of the laboratory tests used to diagnose disease caused by the obligate intracellular and nonculturable bacteria.
16. Correlate signs, symptoms, laboratory data, and antimicrobial susceptibility results for identification of organisms included in this chapter.

GENERA AND SPECIES TO BE CONSIDERED

Current Name	Previous Name
Chlamydia abortus	
Chlamydia trachomatis	
Chlamydia psittaci	*Chlamydophila psittaci*
Chlamydia pneumoniae	*Chlamydophila pneumoniae*
Rickettsia rickettsii	
Rickettsia parkeri	
Rickettsia prowazekii	
Rickettsia typhi	
Rickettsia spp.	
Orientia tsutsugamushi	
Ehrlichia chaffeensis	
Anaplasma phagocytophilum	*Ehrlichia phagocytophila, Ehrlichia equi,* and human granulocytic ehrlichiosis agent
"Candidatus neoehrlichia mikurensis"	Newly proposed genus and species
Neorickettsia sennetsu	*Ehrlichia sennetsu*
Coxiella burnetii	
Tropheryma whipplei	
Klebsiella granulomatis	*Calymmatobacterium granulomatis*

Organisms addressed in this chapter are obligate intracellular bacteria and considered either extremely difficult to culture or unable to be cultured. Organisms of the genera *Chlamydia, Rickettsia, Orientia, Anaplasma,* and *Ehrlichia* are prokaryotes that differ from most other bacteria with respect to their very small size and obligate intracellular development cycles. Three other organisms, *Coxiella, Klebsiella granulomatis,* and *Tropheryma whipplei,* are discussed in this chapter because they are difficult to cultivate or are nonculturable.



Lysis and host cell death
Elementary body (EB; 0.25-0.35 m)
attaches to specific host cell receptor
Host cell nucleus
Condensation into EB forms
Inclusion
EB ingested (endocytosed) and resides in host membrane–bound vesicle or phagosome
In vivo stimulus causes PBs to change and revert to RBs that replicate and then enter the active replicative cycle, leading to active or acute disease
Multiplication of RBs by binary fission within the host cell; phagosome enlarges into a structure called an inclusion
EB reorganizes into a large reticulate body (RB, 0.5-1 m; ~6-8 hours following uptake) within a vacuole or phagosome
RB ceases to divide, not differentiating into EBs and forming persistent bodies (PBs), leading to persistent infection and thus, chronic disease

• **Fig. 43.1** The life cycle of chlamydiae. The entire cycle takes approximately 48 to 72 hours.

Chlamydia

The *Chlamydia* spp. are members of the order Chlamydiales and the family *Chlamydiaceae.* Members of the order Chlamydiales are obligate intracellular bacteria once regarded as viruses because, like viruses, the chlamydiae require biochemical resources of eukaryotic host cells such as adenosine triphosphate to fuel intracellular growth and replication. *Chlamydia* spp. are similar to gram-negative bacilli in that they have lipopolysaccharide (LPS) as a component of the cell wall. However, the chlamydial LPS has little endotoxic activity. Chlamydiae have a major outer membrane protein (MOMP) that is antigenically diverse in *Chlamydia trachomatis* yet highly conserved in *Chlamydia pneumoniae*. MOMP variation in *C. trachomatis* is used to separate the species into 15 antigenically distinct serovars, designated A through L.

Chlamydiae have a unique developmental cycle characterized by an intracellular, replicative form, known as the **reticulate body (RB),** and a metabolically inert, infective form, known as the **elementary body (EB).** Upon infection of a host cell, the EB differentiates into an RB. The RB divides by binary fission within a vacuole. As the number of RBs increase, the vacuole expands, forming an intracytoplasmic inclusion. The RBs differentiate into EBs, and 48 to 72 hours postinfection, the EBs are released from the host cell (Fig. 43.1). In addition to the replicative cycle associated with acute chlamydial infections, there is evidence that *Chlamydia* can persist in an aberrant form *in vitro,* depending on the amount of interferon-gamma (IFN-γ) and tryptophan in the host cell, as well as function of the tryptophan synthase encoded by the organism. Removal of IFN-γ or increase in tryptophan will result in differentiation of chlamydiae into an active EB infection. Therapeutic implications of this persistence *in vivo* have not yet been completely defined. Evidence suggests that activity of the tryptophan synthase gene in *C. trachomatis* differs between isolates recovered from the eye versus the genital tract.

C. trachomatis, C. pneumoniae, and *Chlamydia psittaci* are important causes of human infection; *C. psittaci* and *Chlamydia pecorum* are common pathogens among animals. *Chlamydia abortus* is associated with spontaneous abortion and fetal loss in sheep and calves. There are reports of pregnant women who have experienced spontaneous abortions after exposure to animals infected with *C. abortus.* The three major species that infect humans differ with respect to their antigens, host cell preference, antibiotic susceptibility, EB morphology, and inclusion morphology (Table 43.1).

Chlamydia trachomatis

Over the past few decades, the importance of both acute and chronic infections caused by *C. trachomatis* has been recognized. *C. trachomatis* infections are often associated

TABLE 43.1 Differential Characteristics Among Chlamydiae That Cause Human Disease

Property	*Chlamydia trachomatis*	*Chlamydia psittaci*	*Chlamydia pneumoniae*
Host range	Humans (except one biovar that causes mouse pneumonitis)	Birds, lower mammals, humans (rare)	Humans
Elementary body morphology	Round	Round	Pear-shaped
Inclusion morphology	Round, vacuolar	Variable, dense	Round, dense
Glycogen-containing inclusions	Yes	No	No
Plasmid DNA	Yes	Yes	No
Susceptibility to sulfonamides	Yes	No	No

DNA, Deoxyribonucleic acid.

TABLE 43.2 Primary Syndromes Caused by *Chlamydia trachomatis*

Serovars	Clinical Syndrome	Route(s) of Transmission
A, B, Ba, C	Endemic trachoma (multiple or persistent infections that ultimately lead to blindness)	Hand to eye from fomites, flies
L1, L2, L3	Lymphogranuloma venereum	Sexual
D–K	Urethritis, cervicitis, pelvic inflammatory disease, epididymitis, infant pneumonia, and conjunctivitis (does not lead to blindness)	Sexual, hand to eye by autoinoculation of genital secretions; eye to eye by infected secretions; neonatal

with infertility and ectopic pregnancy, and frequently these infections are asymptomatic, which facilitates transmission and contributes to increased prevalence.

General Characteristics

C. trachomatis infects humans almost exclusively and is responsible for various clinical syndromes. Based on MOMP antigenic differences, *C. trachomatis* is divided into 15 different serovars associated with different primary clinical syndromes (Table 43.2).

Epidemiology and Pathogenesis

C. trachomatis causes significant infection and disease worldwide. In the United States, *C. trachomatis* is the most common sexually transmitted bacterial pathogen and a major cause of pelvic inflammatory disease (PID), ectopic pregnancy, and infertility (see Chapters 39 and 73 for more information on PID). An estimated 3 million cases of *C. trachomatis* infection occur annually in the United States. In 2017, more than 1.7 million cases of *C. trachomatis* infection were reported to the Centers for Disease Control and Prevention (CDC) from 50 states and the District of Columbia. However, the CDC estimates as many as 2.86 million cases of chlamydia occur annually. Genital tract infections caused by *C. trachomatis* were identified more frequently in females 14 and 24 years of age; the CDC estimates that 1 in 20 sexually active women in this age group have chlamydia. However, it is important to note that data reported to the CDC, especially with regard to *Chlamydia,* come as a result of screening programs that primarily target females between the ages of 15 and 24 years. In addition to young women, the CDC notes disparity in chlamydia infection according to race and ethnicity. Non-Hispanic blacks are 5.6 times more likely to be infected with chlamydia compared with non-Hispanic whites. Rectal and pharyngeal chlamydial infections disproportionately impact men who have sex with men (MSM).

Ocular trachoma is the leading infectious cause of blindness worldwide, with an estimated 84 million cases resulting in blindness for 7 to 9 million. Remote rural areas of Africa, Asia, Central and South America, Australia, and the Middle East are hyperendemic for trachoma, where the prevalence rate of *C. trachomatis* is 60% to 90% in preschool children. Trachoma causes 3% of the cases of blindness in individuals around the world, with females more likely to be affected as a result of their exposure to children, who serve as the major reservoir of the organism.

C. trachomatis infections are primarily transmitted from human to human by direct contact with infected secretions. Some infections, such as neonatal pneumonia or **inclusion conjunctivitis,** are transmitted from mother to infant during birth. The various routes of transmission for *C. trachomatis* infection are summarized in Table 43.2. The natural habitat of *C. trachomatis* is humans. The mechanisms by which

C. trachomatis causes inflammation and tissue destruction is not completely understood. The chlamydiae can infect a variety of different cells, including epithelial cells of the mucosa and blood vessels, smooth muscle cells, and monocytes. The chlamydial EB is phagocytosed into a host cell and resides in a vacuole that fails to fuse with a lysosome. This leads to the intracellular persistence of the organism and escape from the host immune response. Chlamydiae are able to either turn on or turn off apoptosis (programmed cell death pathways) in infected host cells. By inducing host cell death, the organism facilitates its transmission to neighboring host cells and downregulating inflammation in the acute disease process, whereas, by inhibiting apoptosis, the organism keeps the host cell alive, allowing for sustained survival in chronic infections.

The host's immune response accounts for the majority of the tissue destruction after infection with *C. trachomatis.* Infected epithelial cells secrete proinflammatory cytokines including interleukin (IL)-1α, tumor necrosis factor (TNF), and IL-6. Quickly upon infection, neutrophils and monocytes migrate to the mucosa and eliminate exposed EBs. Later, CD4 T helper cells migrate to the site of infection. Responding neutrophils and T helper cells release cytokines, resulting in the influx of additional immune cells. The importance of multiple, recurrent infections with *C. trachomatis* are associated with the development of ocular trachoma. Immunity provides little protection from reinfection and appears to be short lived after infection with *C. trachomatis.*

Spectrum of Disease

As previously mentioned, infection with different *C. trachomatis* serovars can lead to several clinical diseases. The diseases are summarized in Table 43.2.

Trachoma

Trachoma results from chronic inflammation of the conjunctiva and remains a major cause of preventable blindness worldwide. The organism is acquired through contact with infected secretions on towels or fingers or by flies. Early symptoms of infection include mild irritation and itching of the eyes and eyelids. There may also be some discharge from the infected eye. The infection progresses slowly with increasing eye pain, blurred vision, and photophobia. Repeated infections result in scarring of the inner eyelid that may then turn the eyelid in toward the eye (**entropion**). As the inner eyelid continues to turn in, the eyelashes follow (**trichiasis**), resulting in rubbing and scratching of the cornea. The combined effects of the mechanical damage to the cornea and inflammation result in ulceration, scarring, and loss of vision.

Lymphogranuloma Venereum

Lymphogranuloma venereum (LGV) is a sexually transmitted disease rarely identified in North America but is relatively frequent in Africa, Asia, and South America. It is reemerging in Europe, especially in homosexual males. In contrast to serovars A through K, which also cause sexually transmitted infections, *C. trachomatis* serovars L1, L2, L2b, and L3 are invasive, leading to regional lymphadenopathy. The disease is characterized by a brief appearance of a primary genital lesion at the initial infection site. This lesion is often small and may be unrecognized, especially by female patients. The second stage, acute lymphadenitis, often involves the inguinal lymph nodes, causing them to enlarge and become matted together, forming a large area of groin swelling, or **bubo.** During this stage, infection may become systemic and cause fever or may spread locally, causing granulomatous proctitis. Advanced disease, which is more common in females than males, can result in genital hyperplasia, rectal fistulas, rectal stricture, draining sinuses, and other manifestations.

Oculogenital Infections

C. trachomatis can cause acute inclusion conjunctivitis in adults and newborns. The organism is acquired when contaminated genital secretions get into the eyes such as during passage of the neonate through the birth canal. Autoinfection rarely occurs. The organism can be acquired from swimming pools and poorly chlorinated hot tubs or by sharing eye makeup. Inclusion conjunctivitis is associated with swollen eyes and a purulent discharge. In contrast to trachoma, inclusion conjunctivitis does not lead to blindness in adults (or newborns).

Genital tract infections caused by *C. trachomatis* have surpassed gonococcal *(Neisseria gonorrhoeae)* infections as a top cause of sexually transmitted disease in the United States. Similar to gonococci, *C. trachomatis* causes urethritis, cervicitis, bartholinitis (Bartholin glands or greater vestibular glands), proctitis, salpingitis (infection of the fallopian tubes), epididymitis, and acute urethral syndrome in females. In the United States, 60% of cases of nongonococcal urethritis are caused by chlamydiae. Both chlamydiae and gonococci are major causes of PID, contributing significantly to the rising rate of infertility and ectopic pregnancies in young women. After a single episode of PID, as many as 10% of women may become infertile because of tubal occlusion. The risk increases dramatically with each additional episode.

Many genital chlamydial infections in both sexes are asymptomatic or not easily recognized by clinical criteria; asymptomatic carriage in both males and females may persist, often for months. As many as 50% of males and 70% to 80% of females identified as having chlamydial genital tract infections have no symptoms. Of significance, these asymptomatic infected individuals serve as a large reservoir to sustain transmission of the organism within a community.

When symptomatic, patients with a genital chlamydial infection will have an unusual discharge and pain or a burning sensation, symptoms similar to those for gonorrhea.

Perinatal Infections

Approximately one-fourth to one-half of infants born to females infected with *C. trachomatis* develop inclusion conjunctivitis. Usually, the incubation period is 5 to 12 days after birth, but it may be as long as 6 weeks. Although most develop inclusion conjunctivitis, approximately 10% to 20% of infants develop pneumonia. Perinatal-acquired *C. trachomatis* infection may persist in the nasopharynx, urogenital tract, or rectum for more than 2 years.

Laboratory Diagnosis

C. trachomatis is commonly diagnosed by nucleic acid amplification tests (NAATs). Additional diagnostic methods for *C. trachomatis* infection include cytology, culture, direct detection of antigen, and serologic testing.

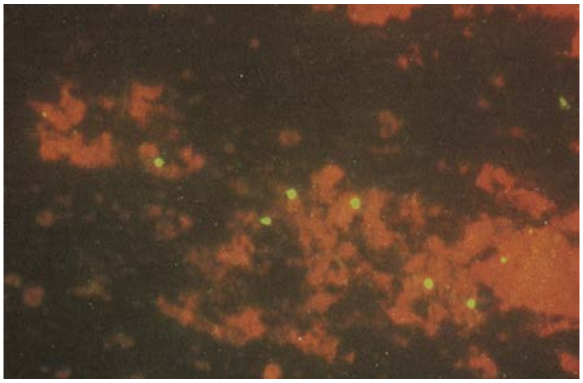
Specimen Collection and Transport

The organism can be recovered or detected in infected cells of the urethra, cervix, conjunctiva, nasopharynx, rectum, and material aspirated from the fallopian tubes and epididymis. The endocervix is the preferred anatomic site to collect screening specimens from female patients. The specimen for *C. trachomatis* culture should be collected after all other specimens (e.g., those for Gram-stained smear, *N. gonorrhoeae* culture, or Papanicolaou [Pap] smear). A large swab should be used to remove all secretions from the cervix. The swab supplied or specified by the manufacturer should be used for nonculture tests. The swab or endocervical brush is inserted 1 to 2 cm into the endocervical canal, rotated against the wall for 10 to 30 seconds, withdrawn without touching any vaginal surfaces, and placed in the appropriate transport medium or applied to a slide prepared for direct fluorescent antibody (DFA) testing.

Urethral specimens should not be collected until 2 hours after the patient has voided. A urogenital swab is gently inserted into the urethra (females, 1 to 2 cm; males, 2 to 4 cm), rotated at least once for 5 seconds, and then withdrawn. Swabs should be placed into the appropriate transport medium or onto a slide prepared for DFA testing. Screening of rectal or pharyngeal specimens for *C. trachomatis* by nucleic acid tests has proven useful in homosexual male patients. Urine specimens in appropriate transport media provided by manufacturers of nucleic acid testing methodologies are also available for both male and female patients. Because chlamydiae are relatively labile, viability can be maintained by keeping specimens cold and minimizing transport time to the laboratory. Specimens should be submitted in a chlamydial transport medium such as 2SP (0.2 M sucrose-phosphate transport medium with antibiotics); a number of commercial transport media are available. Specimens should be refrigerated upon receipt, and if the specimen cannot be processed for culture within 24 hours, they should be frozen at −70°C.

Direct Detection Methods

Cytologic Examination. Cytologic examination of cell scrapings from the conjunctiva of newborns or persons with ocular trachoma can be used to detect *C. trachomatis* inclusions, usually after Giemsa staining. Cytology has been used to evaluate endocervical and urethral scrapings, including those obtained for Pap smears. However, this method is insensitive compared with culture or other methods discussed in the following sections.



• **Fig. 43.2** Appearance of fluorescein-conjugated, monoclonal antibody–stained elementary bodies in direct smear of urethral cell scraping from a patient with chlamydial urethritis. (Courtesy Syva Co, San Jose, CA.)

Antigen Detection. Fluorescent monoclonal specific antibody antigen detection of *C. trachomatis* species-specific outer membrane proteins makes it possible to detect the organism within 30 minutes. These methods can be used to identify the organism in inclusion conjunctivitis in infants. DFA staining methods use fluorescein-isothiocyanate–conjugated monoclonal antibodies to either MOMP or LPS of *C. trachomatis* to detect EBs in smears of clinical material (Fig. 43.2). The sensitivity and specificity of DFA are similar to those of culture. Chlamydial antigen can be detected by enzyme immunoassays (EIAs). Numerous US Food and Drug Administration (FDA)-approved kits are commercially available. These assays use polyclonal or monoclonal antibodies that detect chlamydial LPS. These tests are not species-specific for *C. trachomatis* and may cross-react with LPS of other bacterial species present in the vagina or urinary tract and thereby produce a false-positive result.

Nucleic Acid Detection. FDA-approved NAATs for the laboratory diagnosis of *C. trachomatis* infection use three different formats: polymerase chain reaction (PCR), strand displacement amplification (SDA), and transcription-mediated amplification (TMA). The first two assay formats amplify DNA sequences present in the cryptic plasmid that is present in 7 to 10 copies in the chlamydial EB, whereas the last format amplifies 23s ribosomal RNA (rRNA) sequences. Studies clearly indicate that NAATs are more sensitive than culture and other non–nucleic acid amplification assays. Because of the increased sensitivity of detection, first-voided urine specimens from symptomatic and asymptomatic males and females are acceptable specimens to detect *C. trachomatis,* thereby affording a noninvasive means of chlamydia testing. NAATs are the preferred methodology for detecting *C. trachomatis* in most clinical situations because of increased sensitivity, ease of specimen collection, and the availability of automated high-volume methods. Table 43.3 summarizes the possible uses of the different methodologies available for the detection of *C. trachomatis;* however, NAATs are used almost exclusively for the laboratory detection of *C. trachomatis.*

Serodiagnosis

Serologic testing has limited value for diagnosis of urogenital infections in adults. Serology can be used to diagnose LGV. Antibodies to a genus-specific antigen can be detected by complement fixation (CF), and a single-point titer greater than 1:64 is indicative of LGV. This test is not useful in diagnosing trachoma, inclusion conjunctivitis, or neonatal infections. The microimmunofluorescence assay (micro-IF), a tedious and difficult test, is used for type-specific antibodies of *C. trachomatis* and can be used to diagnose LGV. A high titer of immunoglobulin M (IgM) (1:32) suggests a recent infection; however, not all patients produce IgM. In contrast to CF, micro-IF may be used to diagnose trachoma and inclusion conjunctivitis using acute and convalescent phase sera. Detection of *C. trachomatis*–specific IgM is useful in the diagnosis of neonatal infections. Negative serology can reliably exclude chlamydial infection.

Based on numerous studies, these culture-independent tests are more reliable for the detection of infection in patients who are symptomatic and shedding large numbers of organisms than in those who are asymptomatic and most likely shedding fewer organisms. For the most part, these assays have sensitivities of greater than 70% and specificities of 97% to 99% in populations with a prevalence of *C. trachomatis* infection of 5% or more. In a low-prevalence population (i.e., less than 5%), a significant proportion of positive tests will be falsely positive. A positive result in a low-prevalence population should be handled with care, and a positive result should be verified. Positive results can be validated by the following methods:

- Culture
- Performing a second culture-independent test that identifies a *C. trachomatis* antigen or nucleic acid sequence that is different from that used in the screening test
- Using a blocking antibody or competitive probe that verifies a positive test result by preventing attachment of a labeled antibody or probe used in the standard assay

Cultivation

Culture-independent methods for the diagnosis of *C. trachomatis* are frequently compared with culture. However, culture is not performed as frequently, with NAAT used almost exclusively for genital tract infections.

Several eukaryotic cell lines can be used to culture *C. trachomatis,* including cycloheximide-treated McCoy, HeLa, and monkey kidney cells. After shaking the clinical specimens with 5-mm glass beads, centrifugation of the specimen onto the cell monolayer (usually growing on a coverslip in the bottom of a vial, commonly called a **"shell vial"**) facilitates adherence of EBs. After 48 to 72 hours of incubation, monolayers are stained with a fluorescein-labeled monoclonal antibody that is either species specific, targeting the MOMP of *C. trachomatis,* or genus specific, targeting the LPS. The monolayers are examined microscopically for inclusion formation. Iodine can be used to detect inclusions but is less specific and not recommended.

TABLE 43.3 **Use of Different Laboratory Tests to Diagnose *Chlamydia trachomatis* Infections**

Patient Population	Specimen Type	Acceptable Diagnostic Test
Prepubertal girls	Vaginal	NAAT, culture
Neonates and infants	Nasopharyngeal	NAAT, culture, DFA
	Rectal	Culture
	Conjunctiva	Culture, DFA, EIA, NAAT
Women	Cervical	NAAT,[a] culture, DFA, EIA, NAH, NAAT
	Vaginal	NAAT[a]
	Urethral	NAAT, culture, DFA, EIA
	Urine	NAAT[a]
Children, women, and men	Rectal	Culture, DFA, NAAT[a]
Men	Urethral	NAAT[a] (DFA, EIA)
	Urine[b]	NAAT[a]

DFA, Direct fluorescent antibody staining; *EIA,* enzyme immunoassay; *NAAT,* nucleic acid amplification test; *NAH,* nucleic acid hybridization.

[a] Must be confirmed in a population with a low prevalence (<5%) of *C. trachomatis* infection.

[b] EIA can be used on urine from symptomatic men but not on urine from older men. A positive result must be confirmed in a population with a low prevalence of *C. trachomatis* infection.

Although culture specificity approaches 100%, the sensitivity of culture is estimated at between 70% and 90% in experienced laboratories. Limitations of *Chlamydia* culture contributing to the lack of sensitivity include prerequisites to maintain viability of patient specimens by either rapid or frozen transport and to ensure the quality of the specimen submitted for testing (i.e., endocervical specimens devoid of mucus and containing endocervical epithelial or metaplastic cells or urethral epithelial cells). In addition, successful culture requires a sensitive cell culture system and a minimum of at least 2 days turnaround time between specimen receipt and the availability of results. Despite these limitations, culture is still recommended as the method of choice in some situations (Table 43.3). As of this writing, only chlamydia cultures should be used in situations with legal implications (e.g., sexual abuse), when the possibility of a false-positive test is unacceptable. However, local and state requirements may vary.

Antibiotic Susceptibility Testing and Therapy

Because *C. trachomatis* is an obligate intracellular bacterium, susceptibility testing is not practical in the routine clinical microbiology laboratory setting and is performed in only a few laboratories. In addition, no standardized *in vitro* assay or an understanding of the relationship between *in vitro* test results and clinical outcome after treatment exist. Antibiotics typically used in infections with *C. trachomatis* include azithromycin, doxycycline, erythromycin and other macrolide antibiotics, tetracyclines, and fluoroquinolones.

Prevention

Because no effective vaccines are available, strategies to prevent chlamydial urogenital infections focus on trying to manifest behavioral changes. By identifying and treating individuals with genital chlamydia before infection is transmitted to sexual partners or from pregnant females to babies, the risk of acquiring or transmitting infection may be significantly decreased.

Chlamydia psittaci

Although members of this chlamydial species are common in birds and domestic animals, infections in humans are relatively uncommon.

General Characteristics

C. psittaci differs from *C. trachomatis* in that it is sulfonamide resistant and in the morphology of its EBs and inclusion bodies (Table 43.1).

Epidemiology and Pathogenesis

C. psittaci is an endemic pathogen of all bird species. Psittacine birds (e.g., parrots, parakeets) are a major reservoir for human disease, but outbreaks have occurred among turkey-processing workers and pigeon aficionados. The birds may show diarrheal illness or may be asymptomatic. Humans acquire the disease by inhalation of aerosols. The organisms are deposited in the alveoli; some are ingested by alveolar macrophages and carried to regional lymph nodes. From there they are disseminated systemically, growing within cells of the reticuloendothelial system. Human-to-human transmission is rare, thus obviating the need for isolating patients if admitted to the hospital.

Spectrum of Disease

Disease usually begins after an incubation period of 5 to 15 days. Onset may be insidious or abrupt. Clinical findings associated with this infection are diverse and include pneumonia, severe headache, mental status changes, and hepatosplenomegaly. The severity of infection ranges from unapparent or mild disease to a life-threatening systemic illness with significant respiratory problems.

Laboratory Diagnosis

Diagnosis of **psittacosis** is typically by serologic means. Because of hazards associated with working with the agent, only laboratories with Biosafety Level 3 biohazard containment facilities can culture *C. psittaci* safely. State health departments take an active role in consulting with clinicians about possible cases. CF and indirect immunofluorescence have been used to detect anti–*C. psittaci* antibodies in patients with suspected psittacosis. Either a fourfold rise in titer between acute and convalescent serum samples or a single IgM titer of 1:32 or greater in a patient with an appropriate illness is considered diagnostic of an infection.

Finally, amplification of rRNA sequences using a PCR assay followed by restriction fragment length polymorphism (RFLP) is able to identify and distinguish all nine chlamydial species, including *C. psittaci*. There are no current commercially available nucleic acid–based tests for the diagnosis of *C. psittaci.*

Antibiotic Susceptibility Testing and Therapy

Because *C. psittaci* is an obligate intracellular pathogen and its incidence of infection is rare, susceptibility testing is not practical in the routine clinical microbiology laboratory. Tetracycline is the drug of choice for psittacosis. If left untreated, the fatality rate is approximately 20%.

Prevention

Disease is prevented by treating infected birds or by quarantining imported birds for a month.

Chlamydia pneumoniae

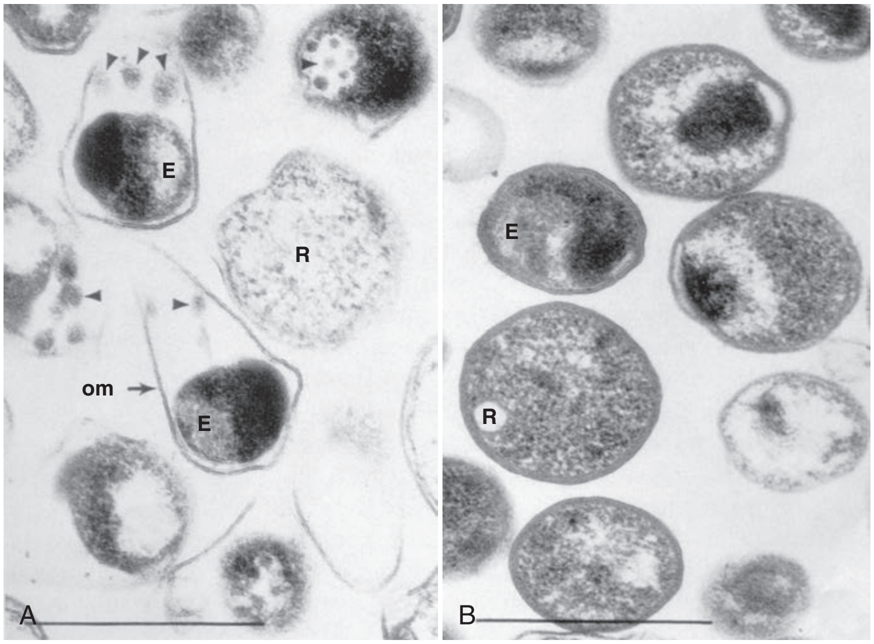
The TWAR strain of *C. pneumoniae* was first isolated from the conjunctiva of a child in Taiwan in 1965. It was initially considered a psittacosis strain because the inclusions produced in cell culture resembled those of *C. psittaci.* The Taiwan isolate (TW-183) is serologically related to a pharyngeal isolate (AR-39) isolated from a college student in the United States, and thus the new strain was called "TWAR," an acronym for TW and AR (acute respiratory). Only one serotype of *C. pneumoniae* has been identified.

General Characteristics

C. pneumoniae does not exhibit the antigenic diversity characteristic of *C. trachomatis* or *C. psittaci*; all *C. pneumoniae* isolates tested to date are immunologically similar based on MOMP homogeneity. One significant difference between *C. pneumoniae* and the other chlamydiae is the pear-shaped appearance of its EBs (Fig. 43.3).

Epidemiology and Pathogenesis

C. pneumoniae appears to be a strict human pathogen; there are no documented bird or animal reservoirs. The pathogen is transmitted from person to person by aerosolized droplets via the respiratory route. Although the spread of infection is low, antibody prevalence starts to rise in school-aged children and reaches 30% to 45% in adolescents. By adulthood, more than half of adults in the United States are seropositive for *C. pneumoniae* antibodies. Of interest, *C. pneumoniae* infections are both endemic and epidemic. Unfortunately, little is known about the pathogenesis of *C. pneumoniae* infections. However, *C. pneumoniae* infection is similar to *C. trachomatis* in that both infections elicit an inflammatory response that contributes to tissue damage.



• Fig. 43.3 Electron micrograph of *Chlamydia pneumoniae* (A) and *Chlamydia trachomatis* (B) (bar = 50.5 μm), *E,* Elementary body; *om,* outer membrane; *R,* reticulate body; *arrowhead,* small electron-dense bodies of undetermined function. (From Grayston JT, Kuo C-C, Campbell La, Wang S-P. *Chlamydia pneumoniae* sp. nov. for *Chlamydia* sp. strain TWAR. *Int J Syst Bacteriol.* 1989;39:88.)

Spectrum of Disease

C. pneumoniae has been associated with pneumonia, bronchitis, pharyngitis, sinusitis, and a flulike illness. It causes 5% to 10% of cases of community-acquired pneumonia. Infection in young adults is usually mild to moderate. The primary differential diagnosis of infectious origin is *Mycoplasma pneumoniae.* Severe pneumonia may occur in older or respiratory-compromised patients. Of note, asymptomatic infection or unrecognized, mild symptomatic illnesses caused by *C. pneumoniae* are common. In addition, an association exists between *C. pneumoniae* infection and the development of asthmatic symptoms. Finally, an association between coronary artery disease and other atherosclerotic syndromes and *C. pneumoniae* infection has been suggested by seroepidemiologic studies. The organism has been identified in atheromatous plaques, yellow deposits within arteries containing cholesterol and other lipid material. This etiologic role by this organism has been questioned and is still under intense scrutiny. An excellent and comprehensive review of the literature related to whether *C. pneumoniae* is a cause of atherosclerosis was published in 2008 by Watson and Alp. Their research indicated, "it is difficult to attribute causality to a common infectious agent in a highly prevalent multifactorial disease." They also stated that "*C. pneumoniae* is neither alone sufficient nor is it necessary to cause atherosclerosis or its clinical consequences in humans," but they allowed for the possibility that treatment of *C. pneumoniae* may reduce the risk of atherosclerosis development.

Laboratory Diagnosis

In the laboratory, *C. pneumoniae* infections are diagnosed using cell culture, serology, or NAAT methods.

Direct Detection Methods

Assays that directly detect *C. pneumoniae* antigens have poor sensitivity. A variety of NAATs, including conventional and real-time PCR assays, have been developed to detect *C. pneumoniae* in clinical specimens. Several of these amplification assays are commercially available, including at least on nested multiplex PCR test. NAATs have been used to detect *C. pneumoniae* in throat swabs and other specimens, such as nasopharyngeal, bronchoalveolar lavage fluids, and sputum.

Serodiagnosis

C. pneumoniae infection can also be diagnosed using serology. However, serologic testing has had variable success and questionable validity. CF using a genus-specific antigen is not specific for *C. pneumoniae.* A micro-IF test using *C. pneumoniae* EBs as antigen is more reliable. However, availability is limited to specialized laboratories. A four-fold rise in either IgG or IgM is diagnostic, and a single IgM titer of 16 or greater or an IgG titer of 512 or greater suggests recent infection

Cultivation

Specimens for isolation are usually swabs of the oropharynx; techniques for isolation of the organism from sputum are unsatisfactory. Swabs should be placed into chlamydial transport media, transported on ice, and stored at 4°C. Organisms are rapidly inactivated at room temperature or by rapid freezing or thawing. A cell culture procedure similar to *C. trachomatis* is available, but more sensitive HL or Hep-2 cell lines are often substituted for McCoy cells. Multiple blind passages might be necessary to improve recovery rates. *C. pneumoniae* species-specific monoclonal antibodies can detect the organism in cell culture.

Antibiotic Susceptibility Testing and Therapy

Methods for susceptibility testing of *C. pneumoniae* have been largely adapted from those used for *C. trachomatis.* Similar to *C. trachomatis,* susceptibility testing is not practical for the clinical microbiology laboratory, and the methods are not standardized. Treatment with tetracycline, doxycycline, macrolides, fluoroquinolones, and erythromycin has been successful.

Prevention

Little is known regarding effective ways to prevent *C. pneumoniae* infections beyond standard respiratory precautions.

Rickettsia, Orientia, Anaplasma, and *Ehrlichia*

The rickettsias and rickettsia-like organisms are members of two families: the *Rickettsiaceae* (*Rickettsia* and *Orientia tsutsugamushi*) and the *Anaplasmataceae (Ehrlichia, Anaplasma,* and *Neorickettsia). O. tsutsugamushi* (formerly called *Rickettsia tsutsugamushi*) was placed into its own genus primarily based on the lack of LPS, the presence of a 54- to 58-kDa major surface protein, and the lack of a 17-kDa lipoprotein, all of which make it different from the other species of *Rickettsia. "Candidatus neoehrlichia mikurensis"* is a new bacterium that is present in *Ixodes* ticks and has been documented in human infections.

Coxiella and *Bartonella,* two other genera of intracellular bacteria that cause human disease, were at one time included in the *Rickettsiaceae* family. However, based on phylogenetic differences, these two genera were removed from the *Rickettsiaceae* family and separated into two families, *Coxiellaceae* and *Bartonellaceae. Bartonella* spp. can be cultured on standard bacteriologic media; this group of organisms is discussed in Chapter 32. Because *Coxiella burnetii* can survive extracellularly, unlike the rickettsiae, yet requires cultivation in cell culture similar to the rickettsiae, this organism is discussed separately in this chapter.

General Characteristics

Rickettsiaceae and *Anaplasmataceae* are obligate, intracellular parasites. These bacterial agents survive briefly outside of a host (reservoir or vector) and multiply only intracellularly. Organisms are small (0.3 μm × 1 to 2 μm), pleomorphic, gram-negative bacilli that multiply by binary fission in the cytoplasm of host cells; the release of bacteria results in the lysis of the host cell.

Epidemiology and Pathogenesis

Rickettsiaceae and *Anaplasmataceae* are arthropod-borne pathogens typically spread by ticks, fleas, or lice. These pathogens principally infect animals, but humans can become accidental hosts if bitten by an infected arthropod. Human infection can also occur by inhalation of infectious aerosols. Characteristics, including the respective arthropod vector of the prominent species of *Rickettsia, Orientia, Anaplasma,* and *Ehrlichia,* are summarized in Table 43.4.

Members of the genus *Rickettsia* share genetic and antigenic properties that result in similar mechanisms of host cell infection and pathogenesis. The infection process typically begins with the introduction of rickettsiae into the host bloodstream following a bite by an arthropod vector. Rickettsiae then bind to endothelial cells lining the blood vessel wall. Endothelial cells engulf the bacteria, which results in the formation of a protective vacuolar niche in the host cell cytoplasm. The bacterium then escapes the vacuole and enters the host cell cytoplasm, where the bacterium multiplies, ultimately leading to cell injury and death. Subsequent vascular lesions caused by *Rickettsia*-induced damage to endothelial cells account for the changes that occur throughout the body, particularly in the skin, heart, brain, lung, and muscle. Rickettsiae also have numerous ways to evade human host defenses such as cell-to-cell spread, escaping from the phagosome, and entering into a latent state (primarily *Rickettsia prowazekii*).

Members of the family Anaplasmataceae, principally *Ehrlichia* and *Anaplasma,* are also obligate intracellular parasites. Similar to other obligate intracellular parasites, these pathogens have reduced viability outside host cells and, once released, must rapidly induce signals for their own uptake into another host cell that is unique to each genus. *Ehrlichia chaffeensis* primarily infects monocytes and causes **human monocytic ehrlichiosis (HME),** whereas *A. phagocytophilum* infects bone marrow–derived cells, primarily infecting neutrophils, causing **human granulocytic anaplasmosis (HGA).**

Candidatus neoehrlichiamikurensis is transmitted by ticks. The reservoir appears to be small mammals such as field mice and voles found in Europe and Asia. Cases have been reported predominantly in immunocompromised patients in Europe and immunocompetent patients in China.

Spectrum of Disease

Rickettsiaceae are divided into three groups: the spotted fever group, the typhus group, and the scrub typhus group *(O. tsutsugamushi),* based on the arthropod mode of transmission, clinical manifestations, rate of intracellular growth,

TABLE 43.4 Characteristics of *Rickettsia, Orientia, Anaplasma,* and *Ehrlichia* spp.

Agent	Disease	Vector	Distribution	Diagnostic Tests
Spotted Fever Group				
Rickettsia africae	African tick bite fever	Ticks	Sub-Saharan Africa, Caribbean	NAAT
Rickettsia conorii	Mediterranean and Israeli spotted fevers; Indian tick typhus; Kenya tick typhus	Ticks	Southern Europe, Middle East, Africa	Serology, immunohistology, NAAT
Rickettsia heilongjiangensis	Far Eastern tick-borne rickettsiosis	Ticks	Russia	NAAT
Rickettsia honei	Flinders Island spotted fever	Ticks	Australia and Thailand	NAAT and serology
Rickettsia japonica	Japanese spotted fever	Ticks	Japan and Korea	NAAT
Rickettsia rickettsii	Rocky Mountain spotted fever	Ticks (*Dermacentor* spp.)	North and South America; particularly in southeastern states and Oklahoma in the United States	Serology, immunohistology, NAAT
Rickettsia parkeri	Mild illness with no reported fatalities	Ticks	North and South America	Serology, immunohistochemical, NAAT
Rickettsia sibirica	North Asian tick typhus, lymphangitis-associated rickettsiosis	Ticks	Asia, Europe, and Africa	NAAT
Rickettsia slovaca	Tick-borne lymphadenopathy	Ticks	Eurasia	NAAT, serologic, and culture
Typhus Group				
Rickettsia prowazekii	Epidemic typhus	Lice	Worldwide	Serology, PCR, or RFLP
	Brill-Zinsser disease	None; recrudescent disease	Worldwide	Serology, PCR, or RFLP
Rickettsia typhi	Murine typhus	Fleas	Worldwide	Serology, PCR, or RFLP
Scrub Typhus Group				
Orientia tsutsugamushi	Scrub typhus	Chiggers	South and Southeast Asia, South Pacific	Serology, conventional or nested PCR
Ehrlichia/Anaplasma/Neorickettsia				
Ehrlichia chaffeensis	Human monocytic ehrlichiosis	Ticks (*Amblyomma americanum*—Lone Star tick)	Southeast, South Central, and mid-Atlantic United States	Serology, PCR, immunohistology, immunocytology
Ehrlichia ewingii		Ticks (*Amblyomma americanum*—Lone Star tick)	United States (overlapping with *E. chaffeensis*)	PCR with species-specific primers
Anaplasma	Human granulocytic anaplasmosis	Ticks (*Ixodes* spp.)	United States, Europe	Serology, PCR, immunohistology, phagocytophilum peripheral blood smear, immunocytology
Neorickettsia sennetsu	Sennetsu fever	Ticks	Southeast Asia (primarily Japan)	Serology

NAAT, Nucleic acid amplification tests; *PCR,* polymerase chain reaction; *RFLP,* restriction fragment length polymorphism.

rate of intracellular burden, and extent of intracellular growth (Table 43.4). *Rickettsiaceae* are often suspected when the triad of fever, headache, and rash is the primary clinical manifestation in patients with an exposure to insect vectors. Infections caused by these organisms may be severe and are sometimes fatal.

Although HME and HGA cause distinct infections, their clinical findings are similar. In general, patients with ehrlichial infections present with nonspecific symptoms such as fever, headache, and myalgias; rashes occur only rarely. The illness can range from asymptomatic to mild to severe.

Laboratory Diagnosis

Because rickettsial and ehrlichial infections can be severe or even fatal, a timely diagnosis is essential.

Direct Detection Methods

Immunohistology and conventional and real-time PCR have been used to diagnose rickettsial and ehrlichial infections. Biopsy of skin tissue from the rash caused by the spotted fever group rickettsiae is the preferred specimen. Organisms are detected using polyclonal fluorescein-labeled antibodies or enzyme-labeled antibodies using indirect procedures. The sensitivity of these techniques is approximately 70% and depends on correct tissue sampling, examination of multiple tissue levels, and biopsy before or during the first 24 hours of therapy (Table 43.4).

Direct detection of *Ehrlichia* and *Anaplasma* from peripheral blood or cerebrospinal fluid (CSF) includes PCR amplification, direct microscopic examination of Giemsa-stained or Wright-stained specimens, or immunocytologic or immunohistologic stains with *E. chaffeensis* or *Anaplasma* species-specific antibodies. Direct microscopic examination of Giemsa-stained or Diff-Quik–stained peripheral blood buffy-coat smears can detect **morulae** (cytoplasmic vacuoles containing enriched organisms) during the febrile stage of infection in ehrlichiosis. Morulae-like structures also can be observed in CSF cells and tissues. Finally, recent reports have described the development of rapid, species-specific real-time PCR assays to detect single or coinfections with *Anaplasma* spp. or *Ehrlichia* spp. in peripheral blood specimens.

Serodiagnosis

Serodiagnosis is the primary method used for the identification of rickettsial disease and ehrlichiosis. Serologic assays for the diagnosis of rickettsial infections include the indirect immunofluorescence assay (IFA), EIA, *Proteus vulgaris* OX-19 and OX-2 and *Proteus mirabilis* OX-K strain agglutination (**Weil-Felix reaction**), line blot, and Western immunoblotting. The Weil-Felix reaction (Evolve Procedure 43.1), the fortuitous agglutination of certain strains of *P. vulgaris* by serum from patients with rickettsial disease, may still be performed in developing countries, but because false-positive and false-negative tests are a continuing problem, these tests have been replaced by more accurate serologic methods such as IFA.

Except for latex agglutination, IFA, and DFA testing for diagnosing Rocky Mountain spotted fever (RMSF), no serologic test is useful for diagnosis of RMSF in time to influence therapy. Serologic diagnosis provides little clinical utility in the early stage of infection because antibodies to rickettsiae, other than *R. rickettsia,* cannot be reliably detected until at least 2 weeks following onset of symptoms. However, with new tests under development, the potential exists for improved serologic diagnosis of rickettsial diseases.

The sensitivity and specificity of serologic assays for ehrlichiosis remains unknown but are presumed to be relatively high; indirect immunofluorescent antibody testing is available for *E. chaffeensis* or *A. phagocytophilum.* A four-fold or greater rise in antibody titer during the course of disease is considered clinically significant.

Cultivation

Although the rickettsiae can be cultured in cell culture and embryonated eggs, the risk of laboratory-acquired infection is extremely high, limiting the availability of culture to a few specialized laboratories. Blood should be collected in a sterile, heparin-containing vial as early as possible following symptom onset. Similarly, punch biopsies of skin or eschars (slough or dead skin) are also acceptable but must be collected early in the course of disease. The same specimens are also acceptable for PCR.

Ehrlichia and *Anaplasma* cell culture conditions are not standardized and are not widely available. The preferred specimen for culture is peripheral blood obtained in a sterile, ethylenediaminetetraacetic acid (EDTA) or acid-citrate-dextrose (ACD) tube. If processing of specimens is delayed, they should be transported overnight at 4°C.

Antibiotic Susceptibility Testing and Therapy

Tetracyclines, especially doxycycline, are the primary drugs of choice for treatment of most infections caused by *Rickettsia, Ehrlichia,* or *Anaplasma* species. Depending on the specific species of *Rickettsia,* some fluoroquinolones or chloramphenicol have been used for successful treatment.

Prevention

The best means of preventing rickettsial and ehrlichial infection is to avoid contact with arthropod vectors.

Coxiella

C. burnetii is the causative agent of **Q fever,** an acute systemic infection that primarily affects the lungs.

General Characteristics

C. burnetii is smaller than *Rickettsia* spp. and is more resistant to various chemical and physical agents. Phylogenetic studies of this gram-negative coccobacillus have demonstrated that it is far removed from the rickettsiae and most closely related to *Legionella.* In contrast to the rickettsiae, *C. burnetii* can survive extracellularly and can only be cultured in lung cells. The organism has a sporelike life cycle and can exist in two antigenic states. When isolated from animals, *C. burnetii* is in phase I (**large-cell variant form**) and is highly infectious. In its phase II form (**small-cell variant**) the organism acts like a spore assisting in the extracellular survival of the organism. *C. burnetii* has been cultivated in cell lines and is not considered infectious in culture.

Epidemiology and Pathogenesis

The most common animal reservoirs for the zoonotic disease caused by *C. burnetii* are cattle, sheep, and goats. Organisms are shed in the urine, feces, milk, and birth products of infected animals. Usually, the infected animals are asymptomatic. Humans are infected through the inhalation of contaminated aerosols. Of significance, because of the resistance of the small-cell variant to desiccation and sunlight, *C. burnetii* is able to withstand harsh environmental conditions. Q fever is endemic worldwide except in New Zealand.

After infection, *C. burnetii* is phagocytized by host cells and multiplies within vacuoles. The incubation period is typically 2 to 4 weeks. After infection and proliferation in the lungs, organisms ingested by macrophages are carried to the lymph nodes and subsequently can disseminate hematogenously.

Spectrum of Disease

After the incubation period, initial clinical manifestations of *C. burnetii* infections are systemic and nonspecific: headache, fever, chills, and myalgias. In contrast to rickettsial infections, a rash does not develop. Both acute and chronic forms of the disease are recognized. The clinical manifestations are listed in Box 43.1.

• BOX 43.1 Clinical Manifestations of *Coxiella burnetii* Infection

Febrile, self-limited illness
Atypical pneumonia
Granulomatous hepatitis
Endocarditis
Neurologic manifestations (e.g., encephalitis, meningoencephalitis)
Osteomyelitis

Laboratory Diagnosis

Cultivation of *C. burnetii* must be performed in a Biosafety Level 3 containment facility to avoid laboratory-acquired infections. No laboratory-acquired infections have been documented with the use of a shell vial cultures. Shell vial cultures containing human lung fibroblasts can be inoculated with buffy coat or biopsy specimens for the isolation of *C. burnetii*. Once inoculated, cultures are incubated for 6 to 14 days at 37°C in carbon dioxide. The organism is detected using a direct immunofluorescent assay. Immunohistochemistry detection is useful for identification in cardiac valve tissues during chronic Q fever.

Nucleic acid amplification, PCR, is a useful technique for the diagnosis of Q fever. However, it is important that testing be performed within 4 weeks of symptom onset. Serology has been the most commonly used diagnostic tool. Three serologic techniques are available: IFA, CF, and EIA. IFA is considered the reference method for both acute and chronic Q fever. IFA is highly specific and sensitive and is recommended for its reliability, cost effectiveness, and ease of performance. Many reference and state health laboratories perform phase I and phase II IgG and IgM serologic assays. However, reports indicate that if completed early in the disease process, PCR provides a more sensitive diagnosis than serology.

Antibiotic Susceptibility Testing and Therapy

Because *C. burnetii* does not multiply in bacteriologic culture media, susceptibility testing is performed in a limited number of laboratories. Tetracyclines are recommended for the treatment of acute and chronic Q fever.

Prevention

The best way to prevent infection with *C. burnetii* is to avoid contact with infected animals. A vaccine is commercially available in Australia and Eastern European countries and under development in the United States.

Tropheryma whipplei

Although observed in diseased tissue, some organisms are nonculturable yet associated with specific disease processes, making the development of “traditional” diagnostic assays difficult (e.g., serology or antigen detection). With the ability to detect and classify bacteria using molecular techniques such as PCR to amplify ribosomal DNA sequences followed by sequencing and phylogenetic analysis, *T. whipplei* was identified as the causative agent of **Whipple disease.**

General Characteristics

Phylogenetic analysis shows that this organism is a gram-positive actinomycete not closely related to any other genus known to cause infection. The organism stains poorly with conventional Gram stain and is acid-fast negative.

Epidemiology, Pathogenesis, and Spectrum of Disease

Whipple disease, found primarily in middle-aged male patients, is characterized by the presence of periodic acid-Schiff (PAS)-staining macrophages (indicating mucopolysaccharide or glycoprotein) in almost every organ system. The bacillus is observed in macrophages and affected tissues, but it has never been cultured. Patients develop diarrhea, weight loss, arthralgia, lymphadenopathy, hyperpigmentation, often a long history of joint pain, and a distended and tender abdomen. Neurologic and sensory changes often occur. Although less common than intestinal or articular involvement, cardiac manifestations can also occur, including endocarditis. It has been suggested that a cellular immune defect is involved in the pathogenesis of this disease.

Colonization of healthy adults is well established by identification of the organism in stool and saliva of asymptomatic individuals. Additional specimens that may harbor the organism include dental plaque, intestinal biopsy tissue, and gastric juice.

Laboratory Diagnosis

Detection of *T. whipplei* is limited to a few laboratories using conventional and real-time PCR from any infected tissue or organ. Stool and saliva is used to screen and identify carriers. However, PCR should not be considered a definitive diagnosis because of the prevalence of carriage in otherwise healthy individuals.

Antibiotic Susceptibility Testing and Therapy

The organism is nonculturable, resulting in the inability to perform susceptibility testing. Patients usually respond well to long-term therapy with antibacterial agents, including trimethoprim-sulfamethoxazole, macrolides, aminoglycosides, tetracycline, and penicillin; however, tetracycline has been associated with serious relapses. Colchicine therapy appears to control symptoms. Without treatment, the disease is uniformly fatal.

Prevention

Little is known about the prevention of this disease.

Klebsiella granulomatis

K. granulomatis is the etiologic agent of **granuloma inguinale,** or **donovanosis,** a sexually transmitted disease.

General Characteristics

K. granulomatis is an encapsulated, pleomorphic, gram-negative bacillus that is usually observed in vacuoles in the cells of large mononuclear cells.

Epidemiology and Pathogenesis

Granuloma inguinale is uncommon in the United States but is recognized as a major cause of genital ulcers in India, Papua New Guinea, the Caribbean, Australia, and parts of South America. The causative agent is sexually transmitted, although there is a possibility that other modes of transmission may exist. Infectivity of this bacillus is presumed to be low, because sexual partners of infected patients often do not become infected or require repeated exposures to become infected.

Spectrum of Disease

Granuloma inguinale is characterized by the presence of enlarged subcutaneous nodules that evolve to form beefy, erythematous, granulomatous, painless lesions that bleed easily. The lesions, which usually occur on the genitalia, have been mistaken for neoplasms. Patients often have inguinal lymphadenopathy.

Laboratory Diagnosis

The organism can be visualized in scrapings of lesions stained with Wrights or Giemsa stain. Subsurface infected cells must be present; surface epithelium is not an adequate specimen. Groups of organisms can be seen within mononuclear endothelial cells and is referred to as a Donovan body. This pathognomonic characteristic of *K. granulomatis* is named after the physician who first visualized the organism in a lesion. The organism stains as a blue rod with prominent polar granules, giving rise to a "safety pin" appearance, surrounded by a large, pink capsule.

Cultivation *in vitro* is difficult, but it can be completed using media containing some of the growth factors found in egg yolk. More recently, this agent was cultured in human monocytes from biopsies of genital ulcers of patients with donovanosis.

Antibiotic Susceptibility Testing and Therapy

No antibiotic susceptibility testing is performed. Trimethoprim-sulfamethoxazole and doxycycline are the most effective drugs for the therapy of granuloma inguinale. Ciprofloxacin, azithromycin, or erythromycin (in pregnancy) also provide effective treatment for granuloma inguinale.

CASE STUDY 43.1

A generally healthy 13-year-old female presented to the emergency department complaining of a persistent headache, fever, and myalgias for the past 9 days. Her family physician had started her on amoxicillin therapy 4 days before admission. Over the next few days, the symptoms continued, and she developed abdominal pain and disorientation. Laboratory findings revealed neutropenia and elevated liver enzymes. On admission, she presented with photophobia, nuchal rigidity (stiff neck), and disseminated intravascular coagulation. She had recently traveled to Arkansas, where she stayed on a farm, rode horses, and removed multiple ticks from her legs. A bone marrow aspiration was performed yielding the diagnosis from the Wrights stain of the monocytes. After treatment with doxycycline, she had a complete recovery.

Questions

1. What is the etiologic agent of this disease, and how was it detected?
2. Why is this disease called a zoonosis?
3. Diagnosis of this disease is difficult. What laboratory methods are available to the physician to diagnose a patient with this disease?

CASE STUDY 43.2

A 20-year-old female was worried about a vaginal discharge and irritation she had for 3 days. The discharge was slight, clear, watery, and nonoffensive, and she had no abnormal vaginal bleeding. She changed her sexual partner 2 months earlier and soon after contracted genital thrush, which responded to topical clotrimazole. She used contraceptive pills and did not use condoms. She had no other sexual partners. She thought her partner had no other contacts, but she had little knowledge of his previous sexual history. The only noteworthy finding at vaginal examination was that her cervix bled easily when swabbed. A high vaginal swab was collected from the posterior fornix, and two swabs were collected from the endocervix and the urethra, a standard cotton swab and a second swab that is specific for chlamydia isolation, respectively. Her physician prescribed doxycycline and metronidazole. The next day, the laboratory report was received and indicated that chlamydia had been detected. The patient had a return visit to her physician and was upset that she had a sexually transmitted disease. She and her partner were referred to the local sexually transmitted disease clinic for further investigation and follow-up.

Questions

1. How is chlamydia presence in a patient sample identified by the laboratory?
2. Was the treatment prescribed for the infection appropriate, or should the prescription have been changed after receipt of the laboratory result indicating the presence of chlamydia?
3. What is the prevalence of chlamydia as a sexually transmitted disease?

From Hicks NR, Dawes M, Flemiger M, et al. Chlamydia infection in general practice. *BMJ*. 1999;318:790.

CASE STUDY 43.3

A female teenager displayed nonspecific symptoms of fever, headache, and malaise for 5 days before seeking medical assistance at the emergency department of a local hospital. Shortly after admission, she developed a petechial rash on her palms and forearms. Because of her classic triad of rickettsial symptoms, even though the presentation sequence was not concurrent, she was given the preliminary diagnosis of rickettsial disease, and appropriate testing was ordered. That day, she went into renal failure. Despite aggressive medical support, she developed disseminated intravascular coagulation that rapidly progressed to sepsis. She died a short time later. The fact that she lived in an area highly infested with Rocky Mountain spotted fever (RMSF)-carrying ticks was unknown to the medical staff until the moment she died. Laboratory results obtained later indicated that she had RMSF.

Questions

1. What is the etiologic agent of this disease?
2. How is this disease diagnosed by the laboratory?
3. What laboratory methods are available to the physician to diagnose a patient with this disease?

From Bacci MR, Namura JJ. Association between sepsis and Rocky Mountain spotted fever. *BMJ Case Reports.* 2012; https://doi.org/10.1136/bcr-2012-007024.

Chapter Review

1. Which organism causes Rocky Mountain spotted fever?
   a. *C. trachomatis*
   b. *Ehrlichia chaffeensis*
   c. *Rickettsia rickettsii*
   d. *Coxiella burnetii*

2. Which serovar of *C. trachomatis* causes lymphogranuloma venereum?
   a. A
   b. C
   c. H
   d. L1

3. Which organism is acquired via exposure to infected birds?
   a. *C. burnetii*
   b. *C. psittaci*
   c. *Anaplasma phagocytophilum*
   d. *T. whipplei*

4. A 24-year-old man presented to his physician in India because of a painless ulcer on his penis. Upon examination, the ulcer was erythematous, large, and "beefy." When the lesion was sampled with a swab, it readily started bleeding. In addition, inguinal lymph nodes were swollen. Wrights-Giemsa stain of material from the lesion revealed the presence of blue rods within the mononuclear cells that were stained more prominently on the ends than in the middle. What organism is most likely causing this lesion?
   a. *K. granulomatis*
   b. *C. trachomatis*
   c. *E. chaffeensis*
   d. *T. whipplei*

5. A physician calls the laboratory and asks the medical laboratory scientist which test to order to rule out *C. pneumoniae* as a cause of pneumonia in a 17-year-old patient. What does the medical laboratory scientist tell the physician?
   a. Sputum culture for routine bacterial pathogens
   b. Wright-Giemsa staining of bronchoalveolar lavage fluid
   c. Real-time PCR on a nasopharyngeal aspirate
   d. Serum testing for agglutination with *Proteus* OX-K, OX-19, and OX-2

6. Transmission of *Orientia tsutsugamushi* is associated with what vector?
   a. Ticks
   b. Fleas
   c. Lice
   d. Chiggers

7. Which triad of symptoms is associated with rickettsial infections?
   a. Urethral discharge, fever, and dysuria
   b. Coughing, production of sputum, and chest pain
   c. Fever, headache, and rash
   d. Genital lesion, swollen inguinal lymph nodes, and headache

8. **True or False**

_____ The phase II form (small-cell variant) of *C. burnetii* is like a spore and is not infectious.

_____ A woman presents to her nurse practitioner complaining of a vaginal discharge. The nurse practitioner suspects *C. trachomatis* and collects a specimen in the following manner: A large swab was used to remove all secretions from the cervix and then placed into the swab sheath and sent to the laboratory. This specimen was collected appropriately for *C. trachomatis.*

9. **Matching:** *Match each term with the appropriate definition.*

_____ bubo
_____ proctitis
_____ bartholinitis
_____ salpingitis
_____ morulae
_____ Donovan body

a. bacteria found in a lesion that are in the cytoplasm of mononuclear phagocytes or histiocytes
b. infection and inflammation of the fallopian tubes
c. inflammation of the anus and rectum
d. swollen lymph node
e. infection of the Bartholin gland or duct
f. intraphagosomal aggregates of replicating *Ehrlichia*

Match each disease with its causative agent (more than one may apply).

______ trachoma
______ scrub typhus
______ human monocytic ehrlichiosis
______ pneumonia
______ lymphogranuloma venereum
______ psittacosis
______ granuloma inguinale
______ human granulocytic anaplasmosis
______ Q fever
______ Whipple disease

a. *R. rickettsii*
b. *E. chaffeensis*
c. *C. trachomatis*
d. *O. tsutsugamushi*
e. *C. psittaci*
f. *C. burnetii*
g. *K. granulomatis*
h. *Rickettsia prowazekii*
i. *C. pneumoniae*
j. *T. whipplei*
k. *A. phagocytophilum*
l. *Rickettsia typhi*

Match each vector with the organism it transmits.

______ Lone Star tick *(Amblyomma americanum)*
______ flea
______ tick (*Ixodes* spp.)
______ chigger
______ louse
______ tick (*Dermacentor* spp.)

a. *A. phagocytophilum*
b. *O. tsutsugamushi*
c. *R. rickettsii*
d. *R. prowazekii*
e. *R. typhi*
f. *E. chaffeensis*

PROCEDURE 43.1

Weil-Felix Reaction

Purpose

The purpose of the Weil-Felix reaction is to detect the presence of antirickettsial antibodies in the blood of a patient with suspected rickettsial disease.

Principle

All *Rickettsia* spp., except *Rickettsia akari* and *Orientia tsutsugamushi,* express antigens that are similar to the somatic (O) antigens expressed on *Proteus* such that if a patient has an infection with a *Rickettsia* spp., the antibodies produced in response to the *Rickettsia* will also bind to *Proteus* cells. The suspension of *Proteus* will agglutinate when mixed with serum containing antirickettsial antibodies.

Method

Serial dilutions of sera from a patient with a suspected rickettsial infection are mixed with a suspension of three different *Proteus* antigens, *Proteus vulgaris* OX-19, *P. vulgaris* OX-2, and *Proteus mirabilis* OX-K. The mixture is observed for the presence of agglutination, which is positive.

Expected Results

Patients with *Rickettsia prowazekii* (epidemic typhus), *Rickettsia typhi* (murine typhus), and *Rickettsia rickettsii* (Rocky Mountain spotted fever) will be positive for OX-19 and negative for OX-2 and OX-K. Patients with *O. tsutsugamushi* (scrub typhus) will be positive for OX-K and negative for OX-19 and OX-2, and patients with *Rickettsia* spp. of the spotted fever group, but not *R. rickettsii,* will be positive for OX-2 and negative for OX-19 and OX-K.

Titers of 1:320 or greater or a four-fold rise in titer between an acute and convalescent sample are considered positive results.

Limitations

Sensitivity has been reported as low as 33%, specificity can be as low as 46%, and results need to be interpreted in the context of patient history (exposure to tick bites) and clinical symptoms.

Quality Control

Known sera that are positive and negative for anti-*Proteus* antibodies.

44

Cell Wall–Deficient Bacteria: *Mycoplasma* and *Ureaplasma*

OBJECTIVES

1. Describe the general characteristics of the *Mycoplasmataceae,* including microscopic and macroscopic appearance.
2. Identify key characteristic biochemical reactions for the differentiation of pathogenic *Mycoplasma* spp.
3. Explain the difficulties associated with isolation of these fastidious organisms, including nutritional requirements, immune response, cellular locations, and incubation requirements (length of time, temperature, and oxygenation requirements).
4. Compare the clinical presentation of *Mycoplasma pneumoniae* to *Streptococcus pneumoniae.*
5. Describe the proper processing, collection, transport, and storage of specimens for effective isolation of organisms discussed in this chapter.
6. State the site for colonization in the human host for *Mycoplasma genitalium, Mycoplasma hominis, M. pneumoniae,* and *Ureaplasma urealyticum.*
7. Describe the clinical manifestations associated with each of the major species considered in this chapter.
8. Describe the complications of serologic diagnosis of *M. pneumoniae.*
9. Explain the current limitations and recommendations for susceptibility testing related to the *Mycoplasmataceae.*
10. Correlate signs, symptoms, and laboratory findings that aid in the diagnosis of infections caused by the major pathogens discussed in this chapter.
11. Identify *M. genitalium* as an emerging cause of nongonococcal urethritis (NGU) in males and inflammatory syndromes in females, including cervicitis and pelvic inflammatory disease (PID).

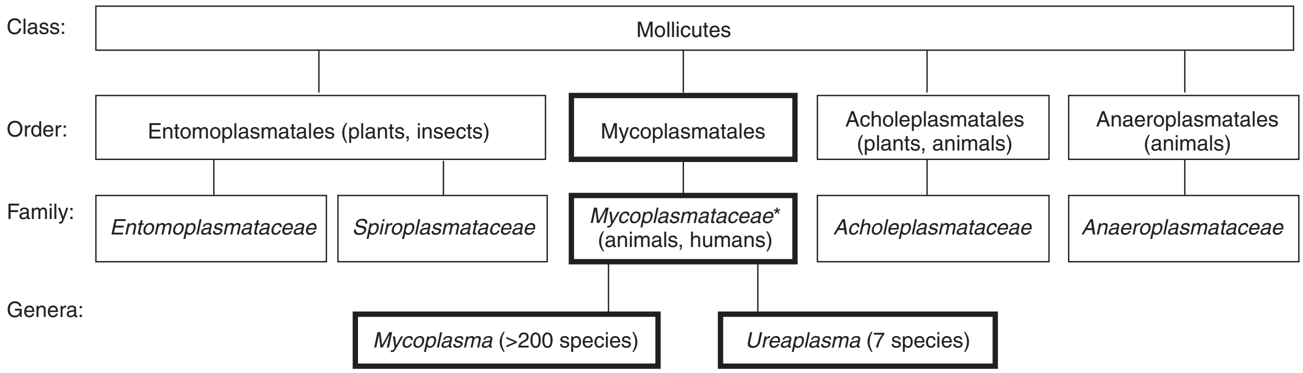
GENERA AND SPECIES TO BE CONSIDERED

Acholeplasma laidlawii
Mycoplasma amphoriforme
Mycoplasma buccale
Mycoplasma faucium
Mycoplasma fermentans
Mycoplasma genitalium
Mycoplasma hominis
Mycoplasma lipophilum
Mycoplasma orale
Mycoplasma penetrans
Mycoplasma phocicerebrale
Mycoplasma pirum
Mycoplasma pneumoniae
Mycoplasma primatum
Mycoplasma salivarium
Mycoplasma spermatophilum
Ureaplasma parvum
Ureaplasma urealyticum

This chapter addresses a group of bacteria, the mycoplasmas, which are the smallest known free-living forms; unlike all other bacteria, these prokaryotes do not have a cell wall. Although mycoplasmas are ubiquitous in the plant and animal kingdoms (more than 200 different species exist within this class), this chapter addresses the most prominent of the *Mycoplasma* spp. and *Ureaplasma* spp. that colonize or infect humans that are not of animal origin.

General Characteristics

Organisms in this chapter belong to the class Mollicutes (Latin, meaning "soft skin"). This class comprises four orders, which, in turn, contain five families and eight genera (Fig. 44.1). The mycoplasmas that colonize or infect humans belong to the family *Mycoplasmataceae*; this family comprises two genera, *Mycoplasma* and *Ureaplasma*. These organisms are highly fastidious and slow growing, and most are facultative anaerobes that require nucleic acid precursor molecules, fatty acids, and sterols such as cholesterol for growth. Morphologically, these bacteria have a very small cell size (approximately 0.3 to 1.0 µm in diameter). In addition, these organisms represent bacterial species that are highly reduced genetically; the *Mycoplasma* genus includes species with the smallest genomes



Class:
Mollicutes
Order:
Entomoplasmatales (plants, insects)
Mycoplasmatales
Acholeplasmatales (plants, animals)
Anaeroplasmatales (animals)
Family:
Entomoplasmataceae
Spiroplasmataceae
*Mycoplasmataceae** (animals, humans)
Acholeplasmataceae
Anaeroplasmataceae
Genera:
Mycoplasma (>200 species)
Ureaplasma (7 species)

*Mollicutes that have been detected in humans.

• **Fig. 44.1** Taxonomy of the class Mollicutes.

of all free-living bacteria. Mollicutes are descended from low G+C gram-positive bacteria (i.e., the *Firmicutes*), and their closest living relatives include bacilli, streptococci, and lactobacteria.

Epidemiology and Pathogenesis

Mycoplasmas are part of the human microbiota of the oropharynx and upper respiratory tract and can be part of the microbiota of the genitourinary tract. Besides those that are considered commensals, considerable evidence indicates the pathogenicity of some mycoplasmas; for others, a role in human disease is unclear.

Epidemiology

The mycoplasmas usually considered as commensals are listed in Table 44.1, along with their respective sites of colonization. These organisms are transmitted by direct sexual contact, by transplanted tissue from donor to recipient, or from mother to fetus during childbirth or *in utero*. *Mycoplasma pneumoniae* are transmitted by respiratory secretions. One species of *Acholeplasma* (organisms that are widely disseminated in animals), *Acholeplasma laidlawii*, has been isolated from the oral cavity of humans; however, the significance of these mycoplasmas and their colonization of humans remains uncertain.

Of the other mycoplasmas isolated from humans, the possible role that *Mycoplasma pirum, Mycoplasma amphoriforme, Mycoplasma fermentans,* and *Mycoplasma penetrans* might play in human disease is uncertain at this time. *M. pirum, M. fermentans,* and *M. penetrans* have been isolated from patients infected with human immunodeficiency virus (HIV); however, no clear link exists between acquisition or shedding of HIV and infections with these mycoplasmas. The potential for *M. penetrans* to play a role in the transition from HIV-positive patients to clinical acquired immune deficiency syndrome (AIDS) has been examined but no connection has been fully demonstrated. In contrast, the ability of *M. genitalium* to facilitate both the shedding and the acquisition of HIV following exposure has been determined. *M. fermentans* has been isolated from specimens such as bronchoalveolar lavage, bone marrow, peripheral blood, and the throats of children with pneumonia. *M. fermentans* has also been associated with infection in children and immunocompromised individuals. *M. amphoriforme* has been detected in the lower respiratory tract in patients with chronic respiratory disease and antibody deficiencies, and isolation from healthy asymptomatic carriers has never been reported. However, until recent advances in molecular diagnostic offering for *M. pneumoniae*, the serologic cross reactivity between *M. pneumoniae* and *M. amphoriforme* may have masked primary respiratory tract infections with *M. amphoriforme* in previously healthy patients by miscategorizing them as *M. pneumoniae* infections. Prospective studies evaluating culture-positive, *M. pneumoniae* DNA-negative respiratory specimens can be evaluated to determine the role of *M. amphoriforme* as a primary or opportunistic pathogen. The presence of various *Mycoplasma* spp. infections in immunocompromised patients has been demonstrated by genital or respiratory tract colonization associated with medical procedures such as renal transplantation or genitourinary manipulations or following trauma resulting in wound infections.

Finally, the remaining species that have been isolated from humans—*M. pneumoniae, M. genitalium, M. phocicerebrale, Ureaplasma urealyticum, Ureaplasma parvum*, and *Mycoplasma hominis*—have well-established roles in human infections. *M. genitalium*, *U. urealyticum, U. parvum,* and *M. hominis* have been isolated from the genitourinary tract of humans, and *M. pneumoniae* has been isolated from the respiratory tract. *M. genitalium* accounts for approximately 15% to 20% of nongonococcal urethritis (NGU), which

TABLE 44.1 Mycoplasmas Isolated From Humans

Organism	Source of Isolation	Clinical Presentations
Mycoplasma amphoriforme	Respiratory tract	• Chronic bronchopneumonia and relapsing airway infection in immunocompromised patients • Primary atypical pneumonia or secondary pneumonia (proposed/ suspected)
Mycoplasma buccale	Oropharynx	• Oral microbiome
Mycoplasma orale	Oropharynx	• Oral microbiome • Opportunistic pneumonia, infectious synovitis, osteomyelitis, or abscess in immunocompromised patients
Mycoplasma salivarium	Oropharynx, gingiva	• Oral microbiome • Opportunistic arthritis, submasseteric abscess,[a] gingivitis, or periodontitis in immunocompromised patients
Mycoplasma hominis	Genital tract, joints, respiratory tract (neonates), central nervous system (neonates)	• Vaginal microbiome • Bacterial vaginosis • Pelvic inflammatory disease • Pyelonephritis • Chorioamnionitis • Bronchopulmonary dysplasia (neonates) • Meningitis/meningoencephalitis (neonates) • Septic arthritis • Abscess (pelvic, brain, aortal) • Meningitis[a] • Osteomyelitis[a]
Mycoplasma pneumoniae		• Primary atypical pneumonia • Bronchitis • Pharyngitis • Meningoencephalitis • Pericarditis • Arthritis • Hemolytic anemia • Nephritis • Bell palsy • Stevens-Johnson syndrome
Mycoplasma faucium	Oropharynx	• Oral microbiome • Cerebral abscess[a]
Mycoplasma fermentans	Oropharynx, peripheral blood, respiratory tract, bone marrow, urine, genital tract	• Lipshütz ulcer[a] • Infectious rheumatoid arthritis • Malignant transformation (proposed) • Opportunistic pneumonia (proposed)
Mycoplasma lipophilum	Respiratory tract	• Pneumonia[a]
Mycoplasma penetrans	Urine, genital tract, blood, respiratory tract	• HIV disease progression (proposed) • Idiopathic nongonococcal urethritis
Mycoplasma phocicerebrale	Cutaneous lesions	• “Seal finger” (ulcerative keratitis secondary to seal bite)
Mycoplasma pirum	Rectum, peripheral blood, urine	• Gastrointestinal microbiome

TABLE 44.1 **Mycoplasmas Isolated From Humans—cont'd**

Organism	Source of Isolation	Clinical Presentations
Mycoplasma genitalium	Genital tract, urine	• Nongonococcal urethritis • Prostatitis • Pelvic inflammatory disease • Infertility • Cervicitis • Sexually acquired reactive arthritis • Enhanced HIV transmission
Mycoplasma primatum	Genital tract, oropharynx	• Oral microbiome • Opportunistic keratitis[a]
Mycoplasma spermatophilum	Genital tract, semen	• Impaired fertility (proposed)
Acholeplasma laidlawii	Cutaneous burns	• Complex burn infections[a,b]
Ureaplasma parvum	Genital tract, urine, semen, blood, neonatal respiratory tract, neonatal central nervous system	• Urogenital microbiome • Chorioamnionitis • Preterm labor • Bronchopulmonary dysplasia (neonates) • Meningitis/meningoencephalitis (neonates) • Nongonococcal urethritis
Ureaplasma urealyticum	Genital tract, urine, semen, blood, neonatal respiratory tract, neonatal central nervous system	• Urogenital microbiome • Chorioamnionitis • Fatal hyperammonemia syndrome in immunocompromised patients • Preterm labor • Bronchopulmonary dysplasia (neonates) • Meningitis/meningoencephalitis (neonates) • Nongonococcal urethritis

HIV, Human immunodeficiency virus.

[a] This presentation has been reported less than 5 times.

[b] This presentation is described in a single report, and all *Acholeplasma*-positive lesions were coinfected with Gram-positive bacilli. Evidence for an association between *A. laidlawii* and burn infections or carriage in humans is minimal.

is urethritis not attributable to *Neisseria gonorrhoeae,* the most common cause of urethritis in males. *M. genitalium* is not associated with the presence of other mycoplasmas or ureaplasmas in the urogenital tract. In females, this organism can cause cervicitis, pelvic inflammatory disease (PID), and postinfectious tubal factor infertility. Both *Ureaplasma* and *Mycoplasma* species have been isolated from the internal organs of stillborn, premature, and spontaneously aborted fetuses. Although *M. genitalium* and, to a lesser extent, *M. hominis* are associated but not yet definitely implicated in pregnancy-related complications, *U. urealyticum* and *U. parvum* are recognized as causes of chorioamnionitis, preterm labor, and premature rupture of the membranes both in clinical studies and prospective studies using animal (sheep) models. In addition, delivery following invasion of the chorioamnion and amniotic fluid by ureaplasmas is strongly associated with risk for bronchopulmonary dysplasia and meningitis/meningoencephalitis in preterm infants. Recently, *Ureaplasma* sp. and *M. hominis* have been identified as a cause of hyperammonemia in immunocompromised patients.

Risks associated with prenatal ureaplasmosis are highly strain dependent. Infants are commonly colonized with benign strains of *U. urealyticum* and *M. hominis*. Once an individual reaches puberty, colonization with these organisms occurs primarily as a result of sexual contact. *M. hominis* is associated with bacterial vaginosis (BV) and should be considered in clinical BV when other agents have been ruled out. The organism also has a commensal relationship with the protozoal parasite *Trichomonas vaginalis*, wherein it invades *T. vaginalis* cells and lives intracellularly. This relationship may play a role in elevated pathogenicity for *T. vaginalis* in the form of enhanced cytopathology and metronidazole resistance. The role of *T. vaginalis* in the improved survival and enhanced transmission for *M. hominis* has been confirmed during antibiotic treatment. *M. hominis* is rarely associated with infection at distal body sites, most notably cerebral abscess.

M. pneumoniae is a cause of community-acquired atypical pneumonia, often referred to as walking pneumonia (Chapter 68). The organism causes infections worldwide, with an estimated 2 million cases per year in the United States. *M. pneumoniae* infection may also result in bronchitis or pharyngitis. *M. pneumoniae* may be transmitted person to person by respiratory secretions or indirectly via inanimate objects contaminated with respiratory secretions (fomites). Infections can occur singly or as outbreaks in closed populations such as families and military recruit camps. Pneumonia caused by *M. pneumoniae* may present as asymptomatic to mild disease, with early nonspecific symptoms including malaise, fever, headache, sore throat, earache, and nonproductive cough. This differs significantly from the classic symptoms associated with pneumonia associated with a *Streptococcus pneumoniae* infection (Chapters 14 and 68). *M. pneumoniae* strongly attaches to the mucosal cells and may reside intracellularly within host cells, resulting in a chronic persistent infection that may last for months to years. The infections do not follow seasonal patterns as seen with influenza and other respiratory pathogens. Besides respiratory infection, *M. pneumoniae* can cause extrapulmonary manifestations such as pericarditis, hemolytic anemia, arthritis, nephritis, Bell palsy, and meningoencephalitis. Finally, *M. phocicerebrale*, an oropharyngeal commensal and occasional cause of wound infections of seals, is the only confirmed mycoplasmal zoonosis described to date. This organism is associated with ulcerative keratitis secondary to marine mammal contact colloquially known as “seal finger.”

Pathogenesis

In general, mycoplasmas colonize mucosal surfaces of the respiratory and urogenital tracts. Except for those mycoplasmas noted, most rarely produce invasive disease except in immunocompromised hosts or infections associated with medical device implants. Of the mycoplasmas that are established as causes of human infections, these agents predominantly reside extracellularly, attaching with great affinity to the surfaces of ciliated and nonciliated epithelial cells. Recently *M. fermentans, M. penetrans, M. genitalium, M. hominis*, and *M. pneumoniae* have been identified intracellularly. Intracellular invasion in bacterial infections is generally considered a means for immune evasion and may contribute to the persistent nature of infections, capacity for recrudescence after cessation of treatment, and difficulties in cultivation or isolation of *Mycoplasma* spp. *M. pneumoniae* has a complex and specialized attachment organelle that includes a P1 adhesin protein that primarily interacts with host cells. Similarly, *M. genitalium* uses a tip organelle to attach to host cells using the MgPa adhesion, which is homologous to the P1 adhesin of *M. pneumoniae*. With respect to the mycoplasmas that are clearly able to cause disease, many of the disease processes include a strong competent host immune response (inflammation), which leads to long-term inflammatory syndromes because of the chronic nature of these infections. In addition to adherence properties and host immune responses to infection, the ability to directly cause cell death may also contribute to their pathogenicity. *M. pneumoniae* produces a potent ADP-ribosylating toxin (“community-acquired respiratory distress syndrome” [CARDS] toxin) that is strongly associated with disease capacity.

Of interest, the mycoplasmas associated with HIV patients (*M. fermentans, M. penetrans,* and *M. pirum*) are all capable of invading human cells and modulating the immune system. Based on these findings, some investigators have proposed that these mycoplasmas might play a role in certain disease processes in these patients.

Spectrum of Disease

The clinical manifestations of mycoplasmosis in humans are summarized in Table 44.1.

Laboratory Diagnosis

The laboratory diagnosis of mycoplasma infections can be extremely challenging because of complex and time-consuming culture requirements; however, the recent availability of rapid, molecular diagnostic tests represents a major step forward in the diagnosis of mycoplasmosis and ureaplasmosis. Accurate, rapid diagnosis for *M. pneumoniae* and *M. genitalium* is highly desired because penicillin and other beta-lactam agents are ineffective treatments. The laboratory diagnosis of the cell wall deficient organisms implicated in human diseases (i.e., *M. pneumoniae, U. urealyticum, U. parvum, M. hominis,* and *M. genitalium*) is addressed.

Specimen Collection, Transport, and Processing

Consistent with the diverse spectrum of diseases, various specimens are appropriate for the diagnosis of mycoplasma infections by culture or other means of detection. Acceptable specimens include body fluids (e.g., blood, joint fluid, amniotic fluid, urine, prostatic secretions, semen, pleural secretions, sputum, and bronchoalveolar lavage specimens); tissues; wound aspirates; and swabs of wounds, the throat, nasopharynx, urethra, cervix, or vagina. Blood for culture of genital mycoplasmas should be collected without anticoagulants and immediately inoculated into an appropriate broth culture medium. Mycoplasmas are inhibited by sodium polyethyl sulfonate (SPS), the anticoagulant typically found in commercial blood culture media. This may be overcome by the addition of 1% wt/vol of gelatin. However, commercial blood culture media and automated instruments are not adequate for the detection of *Mycoplasma* spp. Swab specimens should be obtained without the application of any disinfectants, analgesics, or lubricant. Dacron or polyester swabs on aluminum or plastic shafts should be used. Care must be taken when collecting urine samples to prevent contamination with lubricants or antiseptics used during gynecologic examination.

Because mycoplasmas have no cell wall, they are highly susceptible to drying; therefore, transport media is necessary, particularly when specimens are collected on swabs. Liquid specimens such as body fluids do not require transport media if inoculated to appropriate media within 1 hour of collection. Tissues should be kept moist; if a delay in processing is anticipated, they should also be placed in transport media. Specific media for the isolation of *Mycoplasma* spp. include those containing 10% heat-inactivated calf serum containing 0.2 M sucrose in a 0.02 M phosphate buffer, pH 7.2, such as SP4 glucose broth, or Shepard 10B broth. Additional commercial media available for cultivation of these organisms include Stuart medium, trypticase soy broth supplemented with 0.5% bovine serum albumin, Mycotrans (Irvine Scientific, Irvine, CA), and A3B broth (Remel, Inc., Lenexa, KS). Excessive delays in processing can result in decreased viability and recovery of organisms from clinical specimens. If the storage time is expected to exceed 24 hours before cultivation, the samples should be placed in transport media and frozen at −80°C. Frozen samples should be thawed in a hot water bath at 37°C. Transport and storage conditions of various types of specimens are summarized in Table 44.2.

Direct Detection Methods

No direct methods for identifying *M. pneumoniae, Ureaplasma* spp., or other *Mycoplasma* spp. in clinical samples are recommended, although some methods have been described, such as immunoblotting and indirect immunofluorescence. Direct detection by Gram staining may rule out the presence of other infectious organisms, but does not informatively stain cell wall–deficient mycoplasmas and ureaplasmas. Acridine orange or a fluorochrome stain may be useful to visualize organisms. However, these are nonspecific stains that will stain nucleic acids in bacteria as well as human cells.

Nucleic Acid Detection

Several amplification methods, such as polymerase chain reaction (PCR), have been developed for the detection of the clinically relevant *Mycoplasma* and *Ureaplasma* species, including US Food and Drug Administration (FDA)-cleared or approved tests to detect *M. pneumoniae* and *M. genitalium*. Various targets including 16S ribosomal ribonucleic acid (rRNA) sequences, insertion sequences, and organism-specific genes have been used in the development of these assays. As a result of the fast turnaround time, specificity, and lack of need to cultivate fastidious organisms, PCR amplification for the diagnosis of these organisms is currently the "gold standard." The Illumigene (Meridian Biosciences, Inc., Cincinnati, OH) ab FDA cleared assay, is a single-target isothermal loop-mediated PCR test that may be used for detection. When considering the use of molecular amplification methods for the detection of infectious diseases, it is important to note that, although an organism is detectable, the patient's signs and symptoms must be correlated with the identified agent. It is possible to detect an organism by one method but not another—in other words, a patient may be PCR positive but culture negative or serologically negative for a *Mycoplasma* based on the patient's response to infection and current state of disease manifestation. Chapter 8 provides a more detailed description of the advantages, limitations, and methods used in the development of amplification assays. Multiplex real-time PCR assays that detect *M. pneumoniae* as well as other atypical respiratory tract pathogens such as *Chlamydia pneumoniae* and *Legionella pneumophila* are widely available in routine clinical laboratories. *M. genitalium* has been detected directly in urine and urethral swabs in males, using PCR methods targeting several unique genomic loci. In females, similar methods are used for detection from vaginal or cervical swabs. After successful implementation of commercial PCR-based diagnostics in Europe and Australia, a similar test for *M. genitalium* is also FDA cleared and available for use in the United States (Aptiva *M. genitalium* Assay by Hologic [Marlborough, MA]). Because macrolide resistance is increasing in *M. genitalium* at an alarming rate, the Australian company SpeeDx (Eveleigh, NSW, Australia) has developed ResistancePlus MG that detects the organism and the five distinct genotypes associated with macrolide resistance.

Cultivation

In general, the medium for mycoplasma isolation contains a beef or soybean protein with serum, fresh yeast extract, and other specific growth factors. As a result of the slow growth of these organisms, the medium must be highly selective to prevent overgrowth of faster-growing organisms that may be present in a clinical sample. Culture media and incubation conditions for these organisms are summarized in Table 44.3. Culture methods for *M. pneumoniae, U. urealyticum,* and *M. hominis* are provided in Evolve Procedures 44.1, 44.2, and 44.3, respectively. The quality control of the growth media with a fastidious isolate is of great importance.

For the most part, the different metabolic activity of the mycoplasmas for different substrates is used to detect their growth. Glucose (dextrose) is incorporated into media selective for *M. pneumoniae,* because this mycoplasma ferments glucose to lactic acid; the resulting pH change is then detected by a color change in a dye indicator. Similarly, urea or arginine can be incorporated into media to detect *U. urealyticum, U. parvum,* and *M. hominis,* respectively (Table 44.4). If a color change is observed (i.e., a change in pH detected by a chemical indicator added to the culture medium), a 0.1- to 0.2-mL aliquot is immediately subcultured to fresh broth and/or agar medium.

In some clinical situations, it may be necessary to provide quantitative information regarding the burden of

TABLE 44.2 Transport and Storage Conditions for *Mycoplasma* and Related Organisms

Specimen Type	Transport Conditions	Transport Media (Examples)[a]	Storage	Processing
Body fluid or liquid specimens[b]	Within 1 h of collection on ice or at 4°C	Not required	4°C up to 24 h[c]	Concentrate by high-speed centrifugation and dilute (1:10–1:1000) in broth culture media to remove inhibitory substances and contaminating bacteria; urine should be filtered through a 0.45-µm pore size filter
Swabs	Place immediately into transport media	0.5% albumin in trypticase soy broth modified Stuart 2SP (sugar-phosphate medium with 10% heat-inactivated fetal calf serum) Shepard 10B broth for ureaplasmas SP4 broth for other mycoplasmas and *M. pneumoniae*[d] *Mycoplasma* transport medium (trypticase phosphate broth, 10% bovine serum albumin, 100,000 U of penicillin/milliliter and universal transport media [Copan, Murrieta, CA])	4°C up to 24 h[c]	None
Tissue	Within 1 h of collection on ice or at 4°C	Not required as long as prevented from drying out	4°C up to 24 h[c]	Mince (not grind) and dilute (1:10 and 1:100) in transport media

[a] Not a complete list. A variety of commercial media is available.
[b] Except blood (see text).
[c] Can be stored indefinitely at −80°C if diluted in transport media after centrifugation.
[d] SP4 broth: sucrose phosphate buffer, 20% horse serum, *Mycoplasma* base, and neutral red.

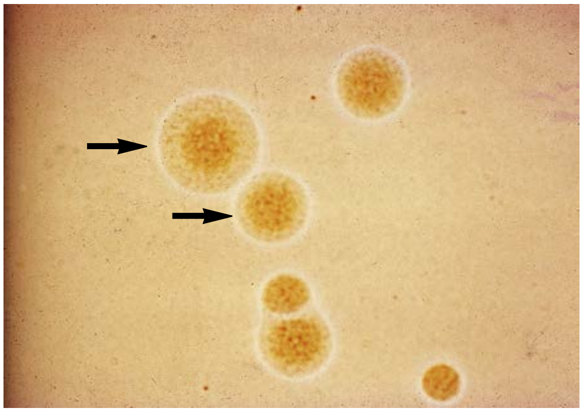
TABLE 44.3 Cultivation of *Mycoplasma pneumoniae, Ureaplasma* spp., and *Mycoplasma hominis*

Organism	Media (Examples)	Incubation Conditions
M. pneumoniae	Biphasic SP4 (pH 7.4) Triphasic system (Mycotrim RS, Irvine Scientific, Irvine, CA) PPLO[a] broth or agar with yeast extract and horse serum Modified New York City medium	Broths: 37°C, ambient air for up to 4 weeks Agars: 37°C, ambient air supplemented with 5%–10% CO_2 or anaerobically in 95% N_2 plus 5% CO_2 All cultures should be retained for 4 weeks before reporting as negative
U. urealyticum/U. parvum[b]*/M. hominis*[c]	A7 or A8 agar medium (Remel, Lenexa, KS); penicillin should be included to minimize bacterial overgrowth[a] New York City medium Modified New York City medium SP4 glucose broth with arginine[d] SP4 glucose broth with urea[e] Triphasic system (Mycotrim GU, Irvine Scientific) Shepard 10B broth (or *Ureaplasma* 10C broth)[e]	Broths: 37°C, ambient air for up to 7 days Agars: 37°C in 5%–10% CO_2 or anaerobically in 95% N_2 plus 5% CO_2 for 2–5 days Genital cultures should be retained for 7 days before reporting as negative

PPLO, pleuropneumonia-like organisms.
[a] Commercially available.
[b] Uses urea and requires acidic medium.
[c] Converts arginine to ornithine and grows over a broad pH range.
[d] For *M. hominis* isolation.
[e] For *U. urealyticum* isolation.

TABLE 44.4 **Basic Biochemical Differentiation of the Major *Mycoplasma* and *Ureaplasma* spp.**

Organism	Glucose Metabolism	Arginine Metabolism	Urease
M. fermentans	Positive	Positive	Negative
M. genitalium	Positive	Negative	Negative
M. hominis	Negative	Positive	Negative
M. pneumoniae	Positive	Negative	Negative
U. parvum	Negative	Negative	Positive
U. urealyticum	Negative	Negative	Positive

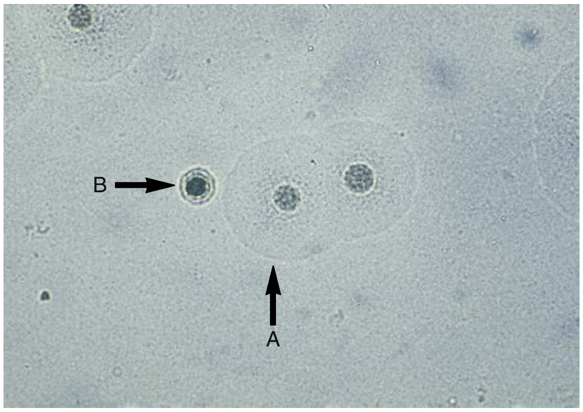


• **Fig. 44.2** Colonies of *Mycoplasma pneumoniae* visualized under 100× magnification. Note the variation in the size of the colonies *(arrows)*. (Courtesy Clinical Microbiology Laboratory, SUNY Upstate Medical University, Syracuse, NY.)

mycoplasmas in a clinical specimen. For example, quantitation of specimens taken at different stages during urination or after prostatic massage can help to determine the location of mycoplasmal infection in the genitourinary tract.

Approach to Identification

On agar, *M. pneumoniae* will appear as spherical, grainy, yellowish forms that are embedded in the agar, with a thin outer layer similar to those shown in Fig. 44.2. The agar surface is examined under 20× to 60× magnification using a stereomicroscope daily for *Ureaplasma* spp., at 24 to 72 hours for *M. hominis,* and every 3 to 5 days for *M. pneumoniae* and other slow-growing species. Because only *M. pneumoniae* and one serovar of *U. urealyticum* hemadsorb, *M. pneumoniae* is definitively identified by overlaying suspicious colonies with 0.5% guinea pig erythrocytes in phosphate-buffered saline. After 20 to 30 minutes at room temperature, colonies are observed for adherence of red blood cells.

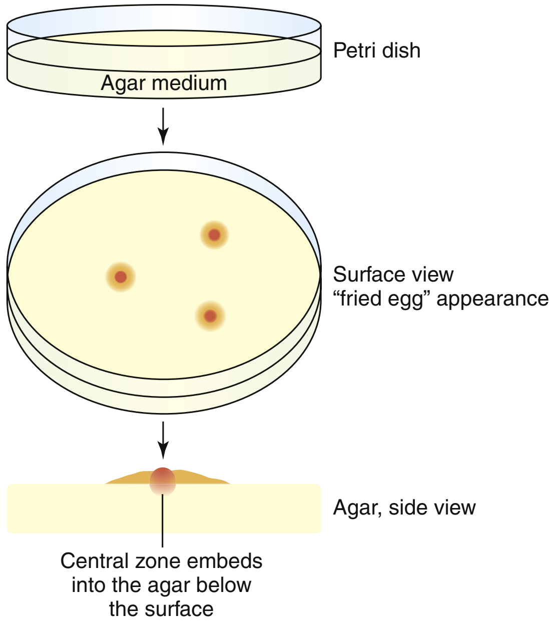


• **Fig. 44.3** Isolation of *Mycoplasma hominis* and *Ureaplasma urealyticum* (100× magnification). Note the "fried egg" appearance of the large *M. hominis* colony *(arrow A)* and the relatively small size of the *U. urealyticum* colony *(arrow B)*. (Courtesy Clinical Microbiology Laboratory, SUNY Upstate Medical University, Syracuse, NY.)

Cultures for the genital mycoplasmas are handled in a similar fashion, including culture examination and the requirement for subculturing. Colonies may be definitively identified on A8 agar (Hardy Diagnostics, Santa Maria CA.) as *U. urealyticum* by urease production in the presence of a calcium chloride indicator. *U. urealyticum* colonies (15 to 60 μm in diameter) will appear as dark brownish clumps. Colonies that are typical in appearance for *U. urealyticum* are shown in Fig. 44.3. *M. hominis* colonies are large (approximately 20 to 300 μm in diameter) and are urease negative (Fig. 44.3), with a characteristic "fried egg" appearance (Fig. 44.4). Similar fried egg colonies are produced by *M. genitalium* but typically take several weeks to develop and thus are not useful for diagnostic purposes. On conventional blood agar, strains of *M. hominis,* but not of *U. urealyticum,* produce nonhemolytic, pinpoint colonies that do not Gram stain. These colonies can be stained with the Dienes or acridine orange stains. Numerous transport and growth media systems for the detection, quantitation, identification, and antimicrobial susceptibility testing of the genital mycoplasmas are commercially available in the United States and Europe.

Serodiagnosis

Laboratory diagnosis of *M. pneumoniae* is usually made serologically. Nonspecific production of cold agglutinins occurs in approximately half of patients with atypical pneumonia caused by this organism. Antibodies to *M. pneumoniae* are typically detectable after approximately 1 week of illness, peaking between 3 to 6 weeks, followed by a gradual decline. The antibody response to *M. pneumoniae* varies greatly from patient to patient. Some patients fail to produce a detectable immunoglobulin M (IgM) level, whereas in others the IgM level will persist



• **Fig. 44.4** Colonial growth characteristics of *Mycoplasma* in agar medium.

for months. The variability associated with the antibody response necessitates the comparison of paired sera for proper diagnosis. In addition, cold agglutinins form in association with *M. pneumoniae* infection. The most widely used serologic tests are enzyme-linked immunosorbent assay (ELISA) tests, although indirect fluorescent antibody tests have been used with some success. IgM-specific tests such as the Immuno Card (Meridian Diagnostics, Cincinnati, OH) are commercially available, and a single positive result in children, adolescents, and young adults may be considered diagnostic in some cases. In addition, commercially available, membrane-based assay that simultaneously detects IgM and IgG against *M. pneumoniae* (Remel EIA, Lenexa, KS) has demonstrated good sensitivity and specificity compared with other tests. Several additional commercial assays are available that include enzyme immunoassay (EIA) microtiter assays.

Although serologic tests such as indirect hemagglutination and metabolism inhibition for genital mycoplasmas are available, they are rarely used. Because of the antigenic complexity of the mycoplasmas, and serologic cross reactivity among the outer membrane antigens, the development of a specific and useful serologic assay is a challenge.

Susceptibility Testing and Therapy

Although agar and broth dilution methods may be used to determine antibiotic susceptibilities, the complex growth requirements of mycoplasmas have restricted their performance to a few laboratories. The Human Mycoplasma Susceptibility Testing Subcommittee of the Clinical and Laboratory Standards Institute has formulated agar and broth dilution methods. Most mycoplasmal infections are treated empirically.

Most *M. pneumoniae* infections are self-limited and usually do not require treatment, but antibiotic treatment can markedly reduce or shorten the disease process. Because of the lack of a cell wall, *M. pneumoniae* and the other *Mollicutes* are innately resistant to all beta-lactam antibiotics, because this class of drugs interferes with cell wall synthesis. In addition, they are resistant to sulfonamides, trimethoprim, and rifampin. Susceptibility patterns vary by species to macrolides and lincosamides. *M. pneumoniae* and *M. genitalium* have historically been susceptible to the macrolides, tetracycline, ketolides, and fluoroquinolones. Although macrolides are still an appropriate first-line therapy for *M. pneumoniae*, they are rapidly becoming ineffective against predominant strains of *M. genitalium*. Single-dose macrolides (i.e., azithromycin) are beneficial for treating gonococcal and nongonococcal urethritis in sexually transmitted disease clinics, because the success of extended dosing regimens relies on patient compliance, which is often unreliable in high-risk clinical settings. Although this was initially a successful intervention against *M. genitalium* infection, the organism's facultative intracellular location affords it protection against macrolides during high-dose treatment, resulting in incomplete clearance, disease recrudescence, and increasing rates of macrolide resistance. Given the factors that single-dose macrolide treatment successfully addressed, it is predictable that outpatient treatment of *M. genitalium* will pose a unique challenge. Unfortunately, the susceptibility of *M. hominis* and *U. urealyticum* to various agents is not as predictable. For the most part, the tetracyclines are the drugs of choice for these agents, although resistance has been reported.

Multidrug-resistant mycoplasmas and ureaplasmas have been identified in genital and extragenital infections in immunocompromised patients. Treatment and clearance of these infections is extremely difficult and limited by the bacteriostatic concentrations of antimicrobials, as well as the slow growth and immune modulation associated with infections with these agents.

Prevention

No vaccines are available for the human mycoplasmas. Early studies both in human subjects and animal models have proven either ineffective or deleterious upon challenge, likely due to the inflammatory, immunomodulatory nature of the organisms. Urogenital transmission of mycoplasmas and ureaplasmas can be prevented through barrier protection, such as with the use of male condoms.

Chapter Review

1. Why are *Mycoplasmataceae* difficult to cultivate in the clinical laboratory?
   a. They lack cell walls.
   b. They require serum components including sterols in the growth medium.
   c. They are extremely sensitive to pH changes in the environment.
   d. All of the above

2. Mycoplasmas generally may be transmitted by all of the following *except:*
   a. Direct sexual contact
   b. Vertical transmission from mother to fetus
   c. Oral sexual practices
   d. A contaminated toothbrush

3. All of the following are considered commensal organisms capable of causing opportunistic infections *except:*
   a. *U. urealyticum*
   b. *M. fermentans*
   c. *M. genitalium*
   d. *M. hominis*
   e. *M. faucium*
   f. *U. parvum*

4. Which of the following would be the most reliable serologic diagnosis for *M. pneumoniae,* considering the pathogenesis and the immunologic response and based on the descriptions provided?
   a. A single acute immunoglobulin M (IgM) titer
   b. A single elevated acute IgM titer
   c. A negative IgM titer followed by two successive IgG titers demonstrating an increase in titer
   d. A classic paired sera with a definitive fourfold increase in titer

5. A genital swab was submitted for culture. *U. urealyticum* was isolated. The suspected biochemical profile to confirm identification would be:
   a. glucose +, arginine +, urease –
   b. glucose –, arginine +, urease +
   c. glucose –, arginine –, urease +
   d. glucose +, arginine –, urease –

6. A 21-year-old male presented to his family physician complaining of flulike symptoms, including a low-grade fever and body aches. A complete blood count was drawn, and the patient exhibited no elevation in the white blood cell count. Serology was negative for influenza. Chest x-ray indicated lobar consolidation representative of a respiratory infection. Based on the laboratory results and patient presentation, what is the most likely cause?
   a. Influenza A
   b. *Klebsiella pneumoniae*
   c. *Streptococcus pneumoniae*
   d. *Mycoplasma pneumoniae*
   e. *Pseudomonas aeruginosa*

7. A patient presented to his doctor around 1 p.m., complaining of frequent urination and abdominal pain. A urine sample was collected by the patient at 8 a.m. and submitted for culture. The routine urinalysis indicated a positive leukocyte esterase test. All other tests were normal. Polymerase chain reaction (PCR) was negative for *Ureaplasma* spp. After 24 hours of incubation, routine urine culture demonstrated the growth of three different organisms with no significant pathogens noted. What is the most likely cause for the conflicting laboratory results?
   a. The original urine sample was not inoculated onto proper growth media.
   b. The PCR test was likely contaminated.
   c. The sample delay in processing of the urine affected the viability of the organism.
   d. Both A and C
   e. All of the above

8. True or False

_____ All *Mycoplasma* spp. are capable of immune evasion through intracellular growth cycles.

_____ Sodium polyanethol sulfonate (SPS) in commercial blood culture media inhibits the growth of *Mycoplasma* spp.

_____ Specimens collected for the isolation of *Mycoplasma* or *Ureaplasma* should be placed in transport media and incubated at 37°C until processed.

_____ Current Clinical and Laboratory Standards Institute (CLSI) standards recommend broth or agar dilution methods for susceptibility testing for *Mycoplasma* and *Ureaplasma* species.

9. Matching: *Match each term with the appropriate description.*

____ *M. genitalium*
____ *M. fermentans*
____ *U. urealyticum*
____ *M. pneumoniae*
____ *M. hominis*

a. walking pneumonia
b. crosses placenta after colonization of the urogenital tract
c. nongonococcal urethritis, cervicitis, and pelvic inflammatory disease (PID)
d. arthritis associated with agammaglobulinemia
e. infections in immunocompromised patients

PROCEDURE 44.1

Isolation of *Mycoplasma pneumoniae*

Principle

Mycoplasma pneumoniae is primarily a respiratory tract pathogen that is extremely fastidious. Because this bacterial agent lacks a cell wall and has strict nutritional requirements, the recovery of this organism from clinical specimens requires special conditions in terms of both culture media and incubation conditions.

Method

1. Prepare biphasic SP4 culture media as follows:
   A. Combine the ingredients for the media base.
      Mycoplasma broth base (BD), 3.5 g
      Tryptone (Difco), 10 g
      Bacto-Peptone (Difco), 5 g
      (50% aqueous solution, filter sterilized), 10 mL
      Distilled water, 615 mL
   B. Stir the solids into boiling water to dissolve them and adjust the pH to 7.4 to 7.6. Autoclave according to the manufacturer's instructions. Cool to 56°C before adding the following supplements for each 625 mL of base to make a final volume of 1 L:
      CMRL 1066 tissue culture medium with glutamine, 10× (GIBCO), 50 mL
      Aqueous yeast extract (prepared as described in New York City Medium), 35 mL
      Yeastolate (Difco; 2% solution), 100 mL
      Fetal bovine serum (heat inactivated at 56°C for 30 min), 170 mL
      Penicillin G sodium, 1000 IU/mL
      Amphotericin B, 0.5 g
      Polymyxin B, 500,000 U
   C. To prepare the agar necessary for making biphasic media, add 8.5 g Noble agar (Difco) to the basal medium ingredients before adding the supplements.
   D. Dispense 1 mL of SP4 agar aseptically into the bottom of sterile 4-mL screw-capped vials. Allow the agar to set and dispense 2 mL of SP4 broth above the agar layer in each vial. Seal caps tightly and store at −20°C.
2. Place 0.1 to 0.2 mL of liquid specimen or dip and twirl a specimen received on a swab in a vial of biphasic SP4 culture medium. After expressing as much fluid as possible from the swab, remove the swab to prevent contamination.
3. Seal the vial tightly and incubate in air at 35°C for up to 3 weeks.
4. Inspect the vial daily. During the first 5 days, a change in pH, indicated by a color shift from orange to yellow or violet, or increased turbidity is a sign that the culture is contaminated and should be discarded.
5. If either a slight acid pH shift (yellow color) with no increase in turbidity or no change occurs after 7 days' incubation, subculture several drops of the broth culture to agar. Continue to incubate the original broth.
6. If broth that exhibited no changes at 7 days shows a slight acid pH shift at any time, subculture to agar as noted earlier. Broths that show no change at 3 weeks are subcultured to agar.
7. Incubate the agar plates in a very moist atmosphere with 5% to 10% CO_2 at 35°C for 7 days.
8. Observe the agar surface under 20× to 60× magnification using a stereomicroscope after 5 days for colonies, which appear as spherical, grainy, yellowish forms, embedded in the agar, with a thin outer layer (Fig. 44.2).
9. Definitive identification of *M. pneumoniae* is accomplished by overlaying agar plates showing suspicious colonies with 5% sheep or guinea pig erythrocytes in 1% agar prepared in physiologic saline (0.85% NaCl) instead of water. The 1% agar is melted and cooled to 50°C, the blood cells are added, and a thin layer is poured over the original agar surface.
10. Reincubate the plate for 24 h, and observe for beta hemolysis around colonies of *M. pneumoniae* caused by production of hydrogen peroxide. Additional incubation at room temperature overnight enhances the hemolysis. No other species of *Mycoplasma* produces this reaction.

PROCEDURE 44.2 ISOLATION OF *UREAPLASMA UREALYTICUM* AND *UREAPLASMA PARVUM*

Principle

Similar to other mycoplasmas, *Ureaplasma* spp. require special culture conditions to facilitate recovery of this bacterial agent from clinical specimens.

Method

1. Inoculate one *Ureaplasma* agar plate and one *Ureaplasma* broth each with a 0.1 mL specimen from transport medium.
2. Incubate broth in tightly sealed test tubes for 5 days. Observe twice daily for a color change in the broth to red, with no increase in turbidity. If color change occurs, immediately transfer one loopful to a *Ureaplasma* agar plate and streak for isolated colonies.
3. Agar plates are incubated in a candle jar or, optimally, in an anaerobic environment at 35°C. Colonies appear on agar within 48 h. Plates are inspected in the same way as described for *Mycoplasma pneumoniae* (Procedure 44.1). *Ureaplasma* colonies appear as small, granular, yellowish spheres.
4. To definitively identify colonies on *Ureaplasma* agar after 48 hours' incubation, pour a solution of 1% urea and 0.8% $MnCl_2$ in distilled water over the agar surface. *Ureaplasma urealyticum* stains dark brown because of production of urease (Fig. 44.3).

CASE STUDY 44.1

A 29-year-old previously healthy female presented with a productive cough, fever of 102°F, and severe headache. She had cervical adenopathy (swollen glands), although she had a nonerythematous throat with no exudate. Chest examination showed crackles bilaterally at the lung base with decreased breath sounds diffusely. This finding was confirmed by chest film that showed bilateral multifocal areas of patchy consolidation. Her neck was not stiff, but because of the severity of the headache, she was admitted to the neurologic service. Spinal fluid was obtained and was negative for bacteria upon Gram staining, *Cryptococcus* spp. negative using an India ink preparation and cryptococcal antigen, and negative for the presence of acid-fast organisms such as *Mycobacterium* spp. No pathogens were isolated from blood or sputum cultures. The patient did not improve on ceftriaxone. On day 3, she was prescribed ciprofloxacin. The patient gradually improved, although the headache, photophobia, and cough continued for some time.

Questions

1. What is the etiologic agent of disease in this case?
2. Can you explain why the bacterial cultures were negative?
3. Why is ciprofloxacin an effective therapy for *Mycoplasma pneumoniae* but ceftriaxone is not?

PROCEDURE 44.3 ISOLATION OF *MYCOPLASMA HOMINIS*

Principle

Similar to the other mycoplasmas, the successful recovery of *Mycoplasma hominis* by culture from clinical specimens requires special conditions.

Method A

1. Inoculate one *M. hominis* agar plate and two *M. hominis* broth tubes, one broth containing phenol red indicator and one without the possibly inhibitory phenol red, each with a 0.1-mL specimen from transport media.
2. Incubate broths in tightly sealed test tubes for 5 days. If the phenol red–containing broth changes color to red or violet, both broths are subcultured to *M. hominis* agar. After 48 h of incubation, transfer 0.1 mL or a loopful of broth from tubes that exhibited no change or only a slight increase in turbidity to *M. hominis* agar and streak for isolated colonies.
3. *M. hominis* agar plates are incubated in the same manner as *Ureaplasma* cultures. Plates should be observed daily for up to 5 days for colonies.

Method B (Alternative Method)

1. Inoculate specimen onto a prereduced colistin-nalidixic acid (CNA) sheep blood agar or anaerobic blood plate and incubate anaerobically for 48–72 h.
2. Examine for pinpoint colonies that show no bacteria on Gram stain.
3. Streak suspicious colonies to *M. hominis* agar and incubate as in step 3.

45

The Spirochetes

OBJECTIVES

1. Describe the bacterial agents discussed in this chapter in terms of morphology, taxonomy, and growth conditions.
2. Identify the four stages of syphilis (i.e., primary, secondary, latent, and tertiary), according to clinical symptoms, antibody production, transmission, infectivity, and treatment.
3. Explain congenital syphilis, including transmission and clinical manifestations.
4. Define reagin, cardiolipin, and biologic false positive.
5. Differentiate reagin and treponemal antibodies, including specificity and association with disease.
6. Identify the various serologic methods that use specific treponemal or nonspecific nontreponemal antigens.
7. Describe the basic principles for the RPR, VDRL, FTA-ABS, TP-PA, PaGIA, MHA-TP, EIA, CIA, and MBIA assays.
8. Compare *Borrelia* spp. to the other spirochetes discussed in this chapter, including morphology and growth conditions.
9. Describe the pathogenesis for and diagnosis of relapsing fever and Lyme disease, including the routes of transmission, vector, and disease presentation.
10. Explain the methodology and clinical significance for using a two-step diagnostic procedure for *Borrelia* spp. infections.
11. Compare and contrast the standard two-tier testing algorithm (STTT) with the modified two-tier testing algorithm (MTTT) for Lyme disease.
12. Describe the pathogenesis associated with leptospirosis, including the two major stages of the disease and the recommended clinical specimens.
13. Describe *Brachyspira* spp., including potential pathogenesis, appropriate specimen, transmission, and clinical significance.
14. Correlate patient signs and symptoms with laboratory data to identify the most likely etiologic agent.

GENERA AND SPECIES TO BE CONSIDERED

Treponema pallidum subsp. *pallidum*
Treponema pallidum subsp. *pertenue*
Treponema pallidum subsp. *endemicum*
Treponema carateum
Treponema denticola

Lyme Borreliosis

Borrelia afzelii
Borrelia bavariensis
Borrelia bissettiae
Borrelia burgdorferi sensu stricto
Borrelia garinii
Borrelia lusitaniae
Borrelia mayonii
Borrelia spielmanii
Borrelia valaisiana

Relapsing Fever

Borrelia caucasica
Borrelia crocidurae
Borrelia duttonii
Borrelia hermsii
Borrelia hispanica
Borrelia mazzottii
Borrelia miyamotoi (hard tick-borne relapsing fever)
Borrelia parkeri
Borrelia persica
Borrelia recurrentis
Borrelia turicatae
Borrelia venezuelensis
Brachyspira aalborgi
Brachyspira hominis (provisionally named)
Brachyspira pilosicoli

Pathogenic Species

Leptospira alexanderi
Leptospira alstonii
Leptospira borgpetersenii
Leptospira interrogans
Leptospira kirschneri
Leptospira mayottensis
Leptospira noguchii
Leptospira santarosai
Leptospira weilii

Intermediate Species

Leptospira broomii
Leptospira fainei
Leptospira inadai
Leptospira licerasiae
Leptospira venezuelensis
Leptospira wolffii

Saprophytic Species

Leptospira biflexa
Leptospira idonii
Leptospira meyeri
Leptospira terpstrae
Leptospira vanthielii
Leptospira wolbachii
Leptospira yanagawae

This chapter discusses the bacteria that belong to the phylum Spirochaetes. The phylum includes three orders, which include four medically relevant genera: the order Brachyspirales (*Brachyspira* spp.), the order Leptospirales (*Leptospira* spp.), and the order Spirochaetales. Within the order Spirochaetales, there are two families: *Borreliaceae* (*Borrelia* spp.) and *Spirochaetaceae* (*Treponema* spp.).

The spirochetes are all long, slender, helically curved organisms, with the unusual morphologic features of **axial fibrils** and an outer sheath. These fibrils, or **axial filaments,** are flagella-like organelles that wrap around the bacteria's cell walls, are enclosed within the outer sheath, and facilitate motility of the organisms. The fibrils are attached in the cell wall by platelike structures, called **insertion disks,** located near the ends of the cells. The protoplasmic cylinder gyrates around the fibrils, causing bacterial movement to appear as a corkscrewlike winding. Differentiation of genera *(Treponema)* within the family *Spirochaetaceae* is based on the number of axial fibrils **(endoflagella)**, the number of insertion disks present (Table 45.1), and biochemical and metabolic features. The spirochetes also fall into genera based loosely on their morphology (Fig. 45.1): *Treponema* appear as slender with tight coils; *Borrelia* (family *Borreliaceae*) are somewhat thicker with fewer and looser coils; and *Leptospira* (family *Leptospiraceae*) resemble *Borrelia*, except for their hooked ends. *Brachyspira* (family *Brachyspiraceae*) are comma-shaped or helical, with tapered ends with four flagella at each end.

Treponema

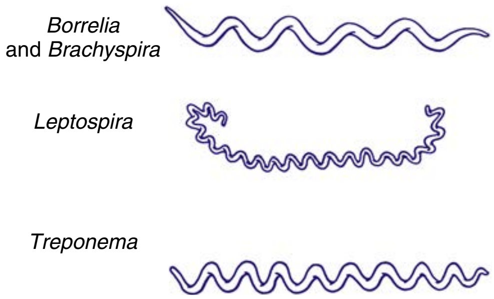
General Characteristics

The major pathogens in the genus *Treponema*—*Treponema pallidum* subsp. *pallidum*, *Treponema pallidum* subsp. *pertenue*, *Treponema pallidum* subsp. *endemicum*, and *Treponema carateum*—infect humans and have not been cultivated for more than one passage *in vitro.* Most species stain poorly with Gram staining or Giemsa methods and are best observed with the use of dark-field or phase-contrast microscopy. The organisms are microaerophilic.

Other treponemes such as *Treponema vincentii*, *T. denticola*, *T. refringens*, *T. socranskii*, *T. parvum*, *T. pectinovorum*, *T. putidum*, *T. lecithinolyticum*, *T. amylovorum*, *T. medium*, and *T. maltophilum* are normal microbiota of the oral cavity or the human genital tract. These organisms are cultivable anaerobically on artificial media. Acute necrotizing ulcerative gingivitis, also known as **Vincent disease,** is a destructive lesion of the gums. Methylene blue–stained material from the lesions of patients with Vincent disease shows certain morphologic types of bacteria. Observed morphologies include spirochetes and fusiform; oral spirochetes, particularly unusually large ones, may be important in this disease, along with other anaerobes.

Epidemiology and Pathogenesis

Key features of the epidemiology of diseases caused by the pathogenic treponemes are summarized in Table 45.2. In general, these organisms enter the host by either penetrating intact mucous membranes (as is the case for *T. pallidum* subsp. *pallidum*—hereafter referred to as *T. pallidum*) or entering through breaks in the skin. *T. pallidum* is transmitted by sexual contact and vertically from mother to the unborn fetus. Neonates can also become infected from contact with contaminated lesions or infected maternal blood during the birthing process. Although rare in the United States, the transmission of *T. pallidum* in blood products still occurs in underdeveloped countries that do not have routine donor screening and processing facilities. After *T. pallidum* penetrates the host, the organism subsequently invades the bloodstream and spreads to other body sites. The mechanisms associated with disease pathology to the host are unclear. Molecular studies have not identified a *T. pallidum* protein that binds to host fibronectin and laminin receptors on various human cells. Binding to different host cells is apparent in cells that produce fibronectin. The organism has an inherent ability to cross the endothelial, blood-brain, and placental barriers. *T. pallidum* has been shown to activate platelets to aid in movement and dissemination throughout the host. As a result, *T. pallidum* has a remarkable **tropism** (attraction) to arterioles; infection ultimately leads to **endarteritis** (inflammation of the lining of arteries) and subsequent progressive tissue destruction.



• **Fig. 45.1** Species designation of spirochetes based on morphology.

TABLE 45.1 **Spirochetes Pathogenic for Humans**

Genus	Axial Filaments	Insertion Disks
Treponema	6–10	1
Borrelia	30–40	2
Leptospira	2	3–5

TABLE 45.2 Epidemiology and Spectrum of Disease of the Treponemes Pathogenic for Humans

Agent	Transmission	Geographic Location	Disease	Clinical Manifestations[a]	Age Group
Treponema pallidum subsp. *pallidum*	Sexual contact or congenital (mother to fetus).	Worldwide	Venereal syphilis[b]	Refer to text in this chapter	All ages
Treponema pallidum subsp. *pertenue*	Traumatized skin contact with an infected lesion (person-to-person contact).	Humid, warm climates: Africa, South and Central America, Pacific Islands	Yaws	Skin—papules,[b] nodules, ulcers Primary lesion (mother yaw), disseminated lesions (frambesia) May progress to a latent stage and late infection involving destructive lesions to bone and cartilage	Children
Treponema pallidum subsp. *endemicum*	Mouth to mouth by utensils (person-to-person contact).	Arid, warm climates: North Africa, Southeast Asia, Middle East	Endemic nonvenereal syphilis	Skin/mucous membrane patches, papules, macules, ulcers, scars[b] May progress to disseminated oropharyngeal with generalized lymphadenopathy May demonstrate a latent stage, and late syphilis destructive to skin, bone, and cartilage	Children or adults; rarely congenital
Treponema carateum	Traumatized skin contact with an infected lesion (person-to-person contact).	Semiarid, warm climates: Central and South America, Mexico	Pinta	Skin papules, macules. Hyperkeratotic pigmented may lead to disseminated skin lesions and lymphadenopathy; late stage may result in pigmentary changes in skin (hyper- or hypopigmentation)	All ages but primarily children and adolescents

[a] All diseases have a relapsing clinical course and prominent cutaneous manifestations.
[b] If untreated, organisms can disseminate to other parts of the body, such as bone.

Spectrum of Disease

In recent years, there has been a resurgence of primary and secondary syphilis cases in the United States, with a 10.5% increase in the number of reported cases between 2016 and 2017.

T. pallidum causes **venereal** (transmitted through sexual contact) **syphilis.** The clinical presentation of venereal syphilis is varied and complex, often mimicking many other diseases. The disease is divided into stages: incubating, primary, secondary, early nonprimary nonsecondary syphilis, unknown duration or late syphilis, and tertiary.

Primary syphilis is characterized by the appearance of one or more hard **chancres** (painless ulcers) that develop(s) at the site of inoculation, most commonly the genitalia. The primary stage is extremely infectious because the lesion contains a large number of organisms. Disease at this stage may be undetectable in the vagina or rectum. Within 3 to 6 weeks, the chancre heals spontaneously (without treatment). Dissemination of the organism occurs during this primary stage; once the organism has reached a sufficient number (usually within 4 to 10 weeks), clinical manifestations of **secondary syphilis** become apparent.

During secondary syphilis, the patient usually seeks medical attention. Systemic symptoms such as fever, weight loss, malaise, and loss of appetite are present in about half of patients. Common symptoms are flulike (fever, sore throat, and lymphadenopathy). The skin is the organ most commonly affected in secondary syphilis, with patients having a widespread rash (generally on the face, scalp, palms of hands, and soles of the feet) and generalized lymphadenopathy. Patchy hair loss may occur, such as a loss of eyebrows ("moth-eaten" area). This stage is a highly infectious state, again because large numbers of spirochetes are present. Aseptic meningitis may also occur. This stage may be mild and go unnoticed by the patient, or symptoms may disappear without treatment. This is when the disease becomes **subclinical** (asymptomatic) but not necessarily dormant (inactive). During this period, diagnosis can be made using serologic methods. Relapses are common during **early, nonprimary, nonsecondary** (≤1 year) **syphilis**. **Unknown duration or late latent syphilis** (≥1 year) is usually asymptomatic and noninfectious. Many untreated cases develop into tertiary syphilis.

Tertiary syphilis is the tissue-destructive phase that appears 10 to 25 years after the initial infection in up to 35% of untreated patients. Complications of syphilis at this stage include central nervous system disease (**neurosyphilis**) and cardiovascular abnormalities (**cardiovascular syphilis**), such as aortic valve insufficiency associated with the presence of cardiovascular lesions, eye disease (**ocular syphilis**), and granuloma-like lesions (**gummas**) that are soft, painless, and noninfectious, and found on the skin or in the bones or visceral organs. Neurosyphilis has been categorized into five major clinical presentations: asymptomatic, meningeal, meningovascular, parenchymatous, and gummatous.

As seen with primary and secondary syphilis, there has also been an increase in the number of reported congenital syphilis cases in recent years; cases of congenital syphilis have increased every year in the United States since 2013. **Congenital syphilis** is transmitted from a mother to an unborn fetus during any stage of infection but is most often associated with early syphilis. The unborn fetus may develop an asymptomatic infection or symptomatic infection. Clinical signs known as **Hutchinson's triad** (deafness, blindness, notched peg-shaped teeth) may occur. Additionally, poor bone formation may result, such as "saber shin" bowing of the tibia and the "bulldog" appearance of a deformed maxilla. Finally, neurosyphilis or neonatal death can occur.

The additional pathogenic treponemes are major health concerns in developing countries. Although morphologically and antigenically similar, these agents differ epidemiologically and with respect to their clinical presentation from *T. pallidum.* The diseases caused by these treponemes are summarized in Table 45.2.

Laboratory Diagnosis

Specimen Collection

Samples collected from ulcers and lesions should not be contaminated with blood, microorganisms, or tissue debris. The site should be cleansed with sterile gauze moistened with saline. The sample should be placed on a clean glass slide and cover slipped. Polymerase chain reaction (PCR) samples should be collected on a sterile Dacron or cotton swab and placed in a cryotube containing nucleic acid transport medium or universal transport medium. Tissue or needle aspirates of lymph nodes should be placed in 10% buffered formalin at room temperature. To test for congenital syphilis, a small section of the umbilical cord is collected and fixed in 10% buffered formalin at room temperature until processed. A 3 to 4 cm section of umbilical cord distal from the placenta for the detection of congenital syphilis should be collected immediately following delivery and processed as a tissue. Serum is the specimen of choice for serology; however, plasma may be used in some assays. Plasma should be tested within 24 hours to avoid false-positive results. Capillary draws of whole blood, serum, or plasma may be used for rapid syphilis tests. Maternal serum may also be used to screen for congenital syphilis. Infants' serum should be used for immunoglobulin (Ig)M specific tests because cord blood specimens may be contaminated with maternal blood.

Serum, plasma, and cerebrospinal fluid (CSF) should be stored at 4°C if testing is delayed more than 4 hours and at –20°C if delayed more than 5 days. Samples collected for PCR, such as unfixed tissue, ulcer exudate, mucosal and skin lesions, CSF or amniotic fluid, and whole blood in EDTA, should be stored at –80°C if testing is delayed.

Direct Detection

Treponemes can be detected in material taken from skin lesions by dark-field examination or fluorescent antibody staining and microscopic examination. Material for microscopic examination is collected from suspicious lesions. The area around the lesion must first be cleansed with a sterile gauze pad moistened in saline. The surface of the ulcer is then abraded until some blood is expressed. After blotting the lesion until there is no further bleeding, the area is squeezed until serous fluid is expressed. Dark-field microscopy should be completed within 20 minutes of collection in order to identify motile treponemes. For other microscopic techniques, the surface of a clean glass slide is touched to the exudate, allowed to air dry, and transported in a dust-free container for fluorescent antibody staining. A *T. pallidum* fluorescein-labeled antibody is commercially available for staining. For dark-field examination, the expressed fluid is aspirated using a sterile pipette, dropped onto a clean glass slide, and cover slipped. The slide containing material for dark-field examination must be transported to the laboratory immediately. Because positive lesions may be teeming with viable spirochetes that are highly infectious, all supplies and patient specimens must be handled with extreme caution and carefully discarded as required for contaminated materials. Gloves should always be worn.

Material for dark-field examination is examined under 400× high-dry magnification for the presence of motile spirochetes. Treponemes are long (8 to 10 µm, slightly larger than a red blood cell) and consist of 8 to 14 tightly coiled, even spirals (Fig. 45.2). Once seen, characteristic forms should be verified by examination under oil immersion magnification (1000×). Although the dark-field examination depends greatly on technical expertise and the numbers of organisms in the lesion, it can be highly specific when performed on genital lesions. Dark-field methods cannot be used to evaluate oral or rectal lesions.

Lesion exudates or tissue samples may be used for direct fluorescent antibody detection for *T. pallidum* (DFA-TP). DFA-TP visualizes specimens on slides with fluorescein isothiocyanate (FITC) labeled antibodies. Polyclonal and monoclonal antibodies may be used; however, the US Food and Drug Administration (FDA) has not approved this test. Dark-field microscopy and fluorescent antibody methods are insensitive. Dark-field microscopy is no longer performed in most clinical laboratories.

Nucleic Acid Detection

Although nucleic acid–based assays are not currently available within many clinical laboratories, several methods have been developed using PCR for the detection of *T. pallidum*. These methods are primarily useful in the identification of organisms within exudate or lesions, and are sensitive and specific when used to analyze genital lesions. Commercially available extraction kits can be used, such as the QIAamp DNA mini kit (Qiagen, Inc., Valencia, CA).

Although there are currently no FDA-approved nucleic acid tests available for the detection of *T. pallidum*, the Center for Disease Control Laboratory Reference and Research Branch, Division of Sexually Transmitted Disease Prevention, has developed a multiplex PCR assay. The TaqMan-based assay simultaneously detects *T. pallidum*, *Haemophilus ducreyi*, and herpes simplex viruses (HSV1 and HSV2). In addition, laboratory-developed tests have been shown to detect atypical cases of syphilis in tonsillar, vertebral, and ocular syphilis. However, a major limitation of PCR is that the sensitivity of the test begins to decrease during secondary syphilis.

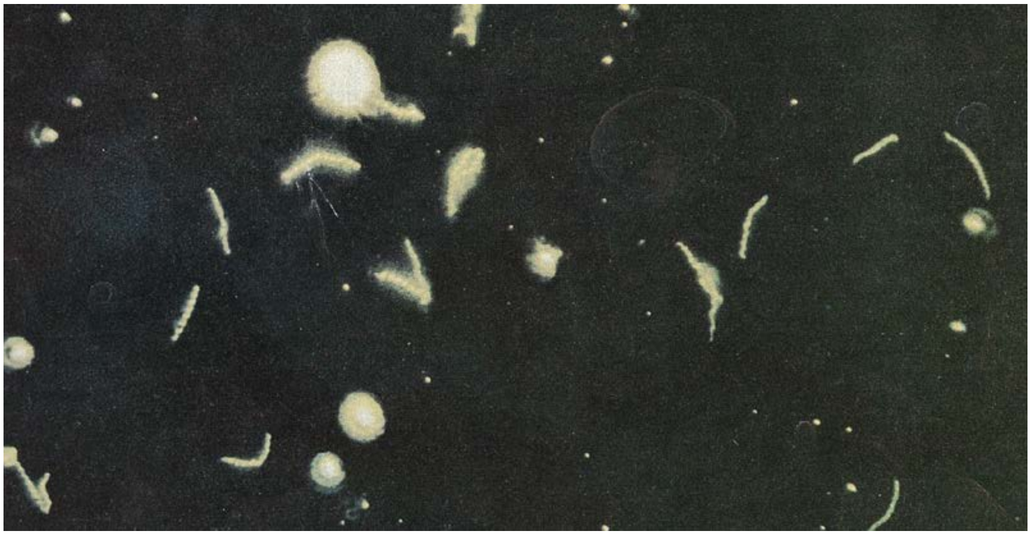
Serodiagnosis

Serologic tests for treponematosis measure the presence of two types of antibodies: treponemal and nontreponemal. Treponemal antibodies are produced against antigens of the organisms themselves, whereas nontreponemal antibodies, often referred to as **reagin antibodies,** are produced in infected patients against components of mammalian cells. Reaginic antibodies, although almost always produced in patients with syphilis, are also produced in patients with other infectious diseases such as leprosy, tuberculosis, chancroid, leptospirosis, malaria, rickettsial disease, trypanosomiasis, lymphogranuloma venereum (LGV), measles, chickenpox, hepatitis, and infectious mononucleosis; noninfectious conditions such as drug addiction; autoimmune disorders, including rheumatoid disease and systemic lupus erythematosus; and in conjunction with increasing age, pregnancy, and recent immunization. Nontreponemal serologic tests are useful in monitoring treatment, whereas treponemal tests are not, as titers tend to remain elevated, even after successful treatment. Serologic testing may be negative during the early course of infection.

Rapid Syphilis Tests

Rapid point-of-care immunochromatographic strip assays have been developed that detect treponemal antibodies from whole blood, serum, or plasma. These rapid tests are capable of detecting IgM and IgG antibodies with antigens bound to a solid phase membrane. The tests provide results within 20 to 25 minutes and are useful for screening in the clinical setting. Although the rapid tests demonstrate similar sensitivities and specificities in comparison to laboratory-based methods, follow-up nontreponemal antibody titers are required for further evaluation.

The Chembio DPP Syphilis Screen & Confirm Assay (Chembio Diagnostic Systems, Inc., Medford, NY) utilizes an immunochromatographic test strip and is able to detect both treponemal and nontreponemal antibodies by utilizing two test lines on the same strip. There are other rapid



• **Fig. 45.2** Appearance of *Treponema pallidum* in dark-field preparation.

point-of-care immunochromatographic strip assays that qualitatively detect antibodies to both *T. pallidum* and HIV-1/2 (SD Bioline HIV/Syphilis Duo, Abbott, Lake Forest, IL; Chembio DPP HIV-Syphilis Assay, Chembio Diagnostic Systems, Inc., Medford, NY).

Nontreponemal Antibody Tests

The three nontreponemal serologic tests are the Venereal Disease Research Laboratory (VDRL), the TRUST assay, and the rapid plasma reagin (RPR) tests, which measure IgM and IgG antibodies. Each of these tests is a flocculation (or agglutination) test, in which soluble antigen particles are coalesced to form larger particles that are visible as clumps when they are aggregated in the presence of an antibody. The VDRL is used as a quantitative test and may be performed on serum or CSF in suspected cases of neurosyphilis. The RPR uses charcoal particles to detect antibodies in serum or plasma. There are numerous RPR kits commercially available that vary in methodology and procedures. Automated RPR tests use latex agglutination or immunoassay methods to increase the ability to screen multiple samples simultaneously. The TRUST assay is similar to the RPR but utilizes toluidine red in place of charcoal particles and is considered a macroflocculation. See Evolve Procedures 45.1 and 45.2 for details and limitations for the VDRL and RPR. Nontreponemal serologic tests for syphilis can be used to determine antibody quantitative titers, which are useful to follow the patient's response to therapy. The relative sensitivity of each test is shown in Table 45.3 to confirm that a positive nontreponemal test result is from syphilis rather than from one of the other infections or biologic false-positive conditions noted previously. For syphilis, traditional diagnosis is useful in active infections. However, early or treated infections may be incorrectly diagnosed. In addition, primary testing using RPR or VDRL may result in a high rate of false positives. The CDC has recommended a **reverse algorithm** to detect early primary or treated infections that may be missed using traditional nonspecific screening methods. Reverse testing suggests the use of specific antibody testing for syphilis, using EIA for IgM and IgG or a similar technique. *T. pallidum* antibodies persist for many years after infection. Specific tests may then be followed by nonspecific screening tests, which become less reactive over time. However, reverse testing is not currently widely accepted, and more data are needed to resolve clinical diagnostic discrepancies (Fig. 45.3).

Treponemal Serologic Tests

Specific treponemal serologic tests are typically positive within 1 to 2 weeks after the appearance of the primary lesion and include automated enzyme immunoassays (EIAs) and agglutination tests, such as the *T. pallidum* particle agglutination (TP-PA) test, the microhemagglutination assay (MHA-TP), *T. pallidum* indirect hemagglutination (TPHA), particle gel immunoassay (PaGIA), the fluorescent treponemal antibody absorption (FTA-ABS) test, chemiluminescence immunoassays (CIAs), and microbead immunoassays (MBIA). Once positive, their usefulness is limited because these tests tend to yield positive results throughout the patient's life. The specificity of these tests is around 99%.

The FTA-ABS test is performed by overlaying whole treponemes fixed to a slide with serum from patients suspected of having syphilis. This test is typically performed after a positive VDRL or RPR screening test. The patient's serum is first absorbed with non–*T. pallidum* treponemal antigens (sorbent) to reduce nonspecific cross-reactivity.

TABLE 45.3 **Sensitivity of Commonly Used Serologic Tests for Syphilis**

Method	Stage		
	Primary	Secondary	Late
Nontreponemal (Reaginic Tests)—Screening			
Venereal Disease Research Laboratory (reaginic) test (VDRL)	78%	100%	96%
Rapid plasma-reagin (RPR) card test and automated reagin test (ART)	86%	100%	98%
Specific Treponemal Tests—Confirmatory			
FTA-ABS	78%	93%	93%
TP-PA	95%	100%	87%
Trep-Sure EIA	95%	100%	99%
Centaur CIA	95%	100%	94%
Liason CIA	96%	100%	93%
Bioplex MBIA	96%	100%	94%

FTA-ABS, Fluorescent treponemal antibody absorption; *TP-PA, Treponema pallidum* particle agglutination; *EIA,* enzyme immunoassay; *CIA*, chemiluminescence immunoassay; *MBIA*, microbead immunoassay.

Fluorescein-conjugated antihuman antibody reagent is applied as a marker for specific antitreponemal antibodies in the patient's serum. This test should not be used as a primary screening procedure. It has been demonstrated that FTA-ABS is less sensitive than TP-PA and other immunoassays (CIA, EIA, MBIA) at all stages of syphilis, especially primary syphilis.

TP-PA (Fujirebio America, Fairfield, NJ) tests use gelatin particles sensitized with *T. pallidum* subsp. *pallidum* antigens. Serum samples are diluted in a microtiter plate, and sensitized gelatin particles are added. The presence of specific antibodies causes the gelatin particles to agglutinate and form a flat mat across the bottom of the microdilution well in which the test is performed. The MHA-TP is a passive hemagglutination assay of sensitized erythrocytes that are tested against the patient's serum. Agglutination indicates the presence of IgG or IgM antitreponemal antibodies in the patient's serum. TPHA is an indirect hemagglutination assay that uses sensitized red blood cells, which aggregate when exposed to positive patient serum. This test is similar to the MHA-TP. The PaGIA test, which uses gel immunoassay technology, is an established method in blood group serology. The assay contains recombinant antigens for the detection of *T. pallidum* antibodies in the patient's serum or plasma. The results are available in approximately 15 minutes.

Several EIAs are available that use direct, antibody class capture, indirect sandwich or competitive assay methodology. EIAs use recombinant antigens to detect IgM, IgG, or both. Trep-Sure EIA (Phoenix Biotech, Mississauga, Ontario, Canada) is a qualitative EIA that measures IgG and IgM treponemal antibodies. It utilizes microplates that are coated with treponemal antigens. Patient antibodies bind to these antigens, and horseradish peroxidase conjugated to treponemal antigens is added, which binds to the antigen-antibody complexes. A chromogenic reaction occurs when the substrate for horseradish peroxidase, tetramethylbenzidine is added. The reaction is detected with a spectrophotometer at 450 nm.

Several automated multiplex flow or MBIA systems exist that use bead-capture technology. These assays use a capture antibody attached to a suspension of small micropolystyrene beads. The beads are tagged with fluorophores of differing intensity, giving each a unique fingerprint. The sandwich immunoassay uses a flow cytometry dual-laser system for detection. There are currently three Luminex commercial platforms that use this technology: Abbott Architect (Abbott Laboratories, Abbott Park, IL), Bio-Rad Bioplex (Bio-Rad Laboratories, Hercules, CA), and Zeus AtheNA (Zeus Scientific, Branchburg, NJ).

CIA also utilize bead technology and are automated. This type of assay utilizes a luminescent molecule as the antigen conjugate. The Liaison Treponema screen (DiaSorin, Stillwater, MN) uses magnetic beads to capture patient antibodies with an isoluminol-antigen conjugate. Positive samples are detected using a flash-chemiluminescent signal. The ADVIA Centaur syphilis assay (Siemens Healthcare Diagnostics, Inc., Newark, DE) is a direct sandwich immunoassay utilizing acridinium ester-labeled *T. pallidum* recombinant antigens, which bind to patient antibodies present in the specimen. Streptavidin-coated magnetic latex particles with biotinylated *T. pallidum* antigens bind to the antigen-antibody complexes. A light signal is produced during the reaction.

Antimicrobial Susceptibility Testing and Therapy

Because the treponemes cannot be cultivated, susceptibility testing is not performed. For all treponemal infections, penicillin G is the drug of choice. Ceftriaxone is also highly effective in most cases of syphilis, other than early syphilis. Tetracycline or doxycycline is often the treatment of choice when patients are allergic to penicillin. Treatment varies depending on the stage of disease and the host (e.g., children or adults, HIV-infected, or infected with congenital syphilis).

Prevention

No vaccines are available for the treponematoses. Prevention begins with early and appropriate treatment, thereby preventing person-to-person spread.

Borrelia

General Characteristics

Borreliosis is considered a **relapsing fever** transmitted by a human-specific body louse or the soft-body tick of the genus *Ornithodoros*. Organisms belonging to the genus *Borrelia* are helical shaped and composed of 3 to 10 loose coils (Fig. 45.1) without hooked ends. They contain endoflagella located beneath the outer membrane that enables the organism to actively demonstrate a characteristic corkscrew motility. The cells contain a protoplasmic cylinder that is composed of a peptidoglycan layer and an inner membrane. In contrast to the treponemes, *Borrelia* spp. stain well with a Giemsa stain. Species that have been grown *in vitro* are microaerophilic or anaerobic.

Epidemiology and Pathogenesis

Although pathogens for mammals and birds, *Borrelia* are the causative agents of tick-borne and louse-borne relapsing fever and tick-borne Lyme disease in humans (Table 45.4).

Relapsing Fever

Human relapsing fever is caused by more than 20 species of *Borrelia* and is transmitted to humans by the bite of a louse or tick. *Borrelia recurrentis* is responsible for louse-borne or epidemic relapsing fever. This spirochete is transmitted from the louse *Pediculus humanus* subsp. *humanus*, and disease is found worldwide; humans are the only reservoir for *B. recurrentis*. All other borreliae that cause disease in the United States are transmitted via tick bites and are named after the species of tick, usually of

TABLE 45.4 Epidemiology and Spectrum of Disease of *Borrelia* spp. Pathogenic for Humans

Disease	Agent	Primary Arthropod Vector	Geographic Location	Clinical Manifestations
Lyme disease (Lyme borreliosis)	*Borrelia burgdorferi sensu lato* (*B. burgdorferi sensu stricto*, *B. mayonii*, *B. afzelii*,[a] *B. garinii*,[b] *B. valaisiana*, *B. lusitaniae*, *B. bavariensis*, *B. spielmanii*, *B. finlandensis*, *B. bissettiae*, *B. carolinensis*)	*Ixodes scapularis* and *I. pacificus* in the United States, *I. ricinus* in Europe, and *I. persulcatus* in Asia	Northeast, Mid-Atlantic, Upper Midwest, West Coast United States, Europe, and Asia	Refer to text in this chapter

[b] Neuroborreliosis is strongly associated.
[c] Neurological involvement is common.

the genus *Ornithodoros* (soft tick), from which they are recovered. Common species in the United States include *Borrelia hermsii*, *Borrelia turicatae*, *Borrelia parkeri*, and *Borrelia mazzottii*. Depending on the organisms and the disease, their reservoir is either humans or rodents, in most cases. Although their pathogenic mechanisms are unclear, these spirochetes exhibit antigenic variability that may account for the cyclic fever patterns associated with this disease.

Lyme Disease

Although there are currently more than 20 different *Borrelia* genospecies within the *B. burgdorferi sensu lato* complex, only *Borrelia burgdorferi sensu stricto* (strict sense of *B. burgdorferi*), as well as *Borrelia garinii*, *Borrelia afzelii*, *Borrelia spielmanii*, *Borrelia lusitaniae*, and *Borrelia valaisiana,* and the recently discovered *Borrelia mayonii,* are agents of Lyme disease and are transmitted by the bite of *Ixodes* ticks. *B. burgdorferi* and *B. mayonii* (less commonly) cause Lyme disease in North America. Currently, *B. mayonii* has been detected in ticks in the Upper Midwest. **Lyme disease** is the most common vector-borne disease in North America and Europe and is an emerging problem in northern Asia. Hard ticks, belonging primarily to the genus *Ixodes*, act as vectors in the United States, including *Ixodes pacificus* in California and *Ixodes scapularis* in other areas. The ticks' natural hosts are deer and rodents. However, the adult ticks feed on a variety of mammals, including raccoons, domestic and wild carnivores, and birds. The ticks will attach to pets as well as to humans; all stages of ticks—larva, nymph, and adult—can harbor the spirochete and transmit disease. The nymphal form of the tick is most likely to transmit disease because it is active in the spring and summer, when people are dressed lightly and participate in outdoor activities in wooded areas. At this stage, the tick is the size of a pinhead and the initial tick bite may be overlooked. Ticks generally require a period of attachment of at least 24 hours before they transmit disease; however, other common diseases associated with *Ixodes* ticks, such as **anaplasmosis**, may be transmitted earlier on in the attachment period. Endemic areas of disease have been identified in many states, including Massachusetts, Connecticut, Maryland, Minnesota, Oregon, and California, as well as in Europe, Russia, Japan, and Australia. Direct invasion of tissues by the organism is responsible for the clinical manifestations. However, IgM antibodies are produced continually months to years after initial infection as the spirochete changes its antigens. *B. burgdorferi*'s potential ability to induce an autoimmune process in the host because of cross-reactive antigens may contribute to the pathology associated with Lyme disease. Moreover, by virtue of its ability to vary its surface antigens (e.g., outer surface protein [Osp] A to G), as well as avoid complement, *B. burgdorferi* is able to avoid the human host response. The pathologic findings associated with Lyme disease are also believed to result from the release of host cytokines initiated by the presence of the organism.

Spectrum of Disease

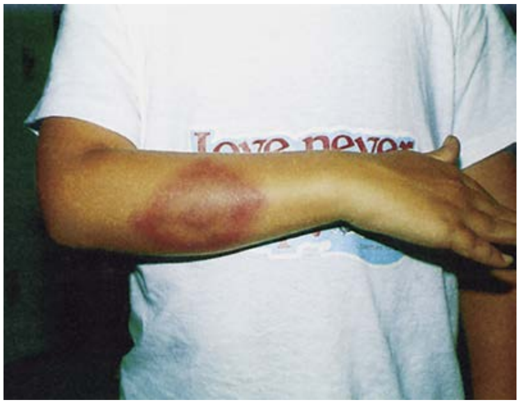
Relapsing Fever

Between 2 and 15 days after infection, patients have an abrupt onset of fever, headache, and myalgia that lasts for 4 to 10 days. Physical findings often include petechiae, diffuse abdominal tenderness, and conjunctival effusion. As the host produces specific antibodies in response to the agent, organisms disappear from the bloodstream, becoming sequestered (hidden) in different organs during the afebrile period. Subsequently, organisms reemerge with newly modified antigens and multiply, resulting in another febrile period. Subsequent relapses are usually milder and of shorter duration. In general, more relapses are associated with cases of untreated tick-borne relapsing fever, but louse-borne relapsing fevers tend to be more severe. *B. miyamotoi* can manifest as meningoencephalitis in immunocompromised patients.

Treatment of relapsing fever with antibiotics may result in the formation of the **Jarisch-Herxheimer reaction.** This reaction is associated with the clearance of the organisms from the bloodstream and the release of cytokines within hours of antibiotic treatment. The patient experiences tachycardia, chills, rigors, hypotension, fever, and diaphoresis. Death may be associated with the reaction. An acute respiratory distress syndrome has also been recognized in cases associated with tick-borne relapsing fever.

Lyme Disease

Lyme disease is characterized by three stages, not all of which occur in any given patient. The first stage, **early localized,** is characterized by **erythema migrans (EM),** a red, ring-shaped skin lesion sometimes with a central clearing ("bull's-eye" appearance) that first appears at the site of the tick bite but may develop at distant sites as well (Fig. 45.4). Patients may experience headache, fever, muscle and joint pain, and malaise during this stage. The **second stage, early disseminated,** beginning weeks to months after infection, may include arthritis, but the most important features are neurologic disorders (i.e., meningitis, neurologic deficits) and carditis. This is a result of the hematogenous spread of



• **Fig. 45.4** Appearance of the classic erythema migrans lesion of acute Lyme disease.

spirochetes to organs and tissues. In addition, neurologic symptoms and infection may occur in the meninges, spinal cord, peripheral nerves, and brain (neuroborreliosis). The **third stage, late disseminated,** is usually characterized by chronic arthritis or **acrodermatitis chronica atrophicans (ACA),** a diffuse skin rash, and may continue for years. There is an association between *Borrelia* species and distinct clinical manifestations. For example, *B. garinii* has been associated with up to 72% of European cases of neuroborreliosis. Infection with *B. mayonii* has been associated with nausea and vomiting, as well as the presence of a diffuse skin rash and higher levels of spirochetemia, distinguishing it from *B. burgdorferi*.

Laboratory Diagnosis

Specimen Collection, Transport, and Processing

Peripheral blood in EDTA is the specimen of choice for direct detection of borreliae that cause relapsing fever. *B. burgdorferi* can be visualized, cultured, and identified using PCR; CSF samples may be used for nucleic acid detection in the diagnosis of *B. miyamotoi*–associated meningoencephalitis or in patients with neurological symptoms associated with *B. burgdorferi*. Serum should be collected for serology during acute and convalescent phases, separated by at least 2 weeks. Specimens submitted for stain or culture include blood, biopsy specimens, and body fluids, including joint and CSFs. Body fluids should be transported without any preservatives. Tissue biopsy specimens should be placed in sterile saline to prevent drying. Skin biopsies of the EM lesion can be used for culture and nucleic acid detection. Whole blood in EDTA can also be used for culture or nucleic acid detection during early disseminated infection. Synovial fluid and tissue may also be tested using nucleic acid tests to monitor treatment in Lyme arthritis.

Direct Detection Methods

Relapsing Fever

Clinical laboratories rely on direct observation of the organism in peripheral blood from patients for diagnosis. Organisms can be found in 70% of cases when blood specimens from febrile patients are examined. The organisms can be seen directly in wet preparations of peripheral blood (mixed with equal parts of sterile, nonbacteriostatic saline) under dark- or bright-field illumination, in which the spirochetes move rapidly, often pushing the red blood cells around. The organisms may be visualized by staining thick and thin films with Wright or Giemsa stains or the quantitative buffy coat (QBC) method, using procedures similar to those used to detect malaria. *B. miyamotoi* may be detected microscopically in CSF in patients experiencing meningoencephalitis. *B. burgdorferi* may be visualized in tissue sections stained with Warthin-Starry silver stain. In general, the number of spirochetes in the blood of patients with Lyme borreliosis is below the lower limits of microscopic detection, although *B. mayonii* may be seen on a blood smear due to high spirochetemia.

Nucleic Acid Detection

PCR has become important in diagnosing Lyme disease. PCR has detected *B. burgdorferi* DNA in clinical specimens from patients with early and late clinical manifestations; optimal specimens include synovial tissue, CSF, synovial fluid, and skin biopsies from patients with EM. PCR amplification of *B. burgdorferi* nucleic acid sequences has been successful from urine but is not recommended. Laboratories have used a variety of nucleic acid–based methods to increase sensitivity and specificity and decrease turnaround time for diagnosing Lyme borreliosis. PCR has confirmed EM with an overall sensitivity and specificity of 68% and 100%, respectively. The ability to detect spirochetes in blood or plasma by PCR is dependent on the stage of illness (from 40% of patients with secondary EM to only 9.5% of patients with primary EM); PCR also does relatively well in detecting *B. burgdorferi sensu lato* in synovial fluids. In contrast, variable results using PCR occur in CSF specimens obtained from patients with peripheral or central nervous system involvement with Lyme borreliosis. PCR testing can be used to diagnose Lyme borreliosis caused by *B. mayonii*. PCR has also been used for the detection of organisms within the relapsing fever *Borrelia* group. However, 16SrRNA gene sequences do not provide good discrimination between species. Other sequences have been used for speciation, including the chromosomally encoded flagellin sequence *(flaB)*, the 16-23S ribosomal RNA intergenic spacer gene, and the glycerophosphodiester *(glpQ)* gene unique to relapsing fever *Borrelia* species.

Serodiagnosis

Relapsing Fever

Serologic tests for relapsing fever have not demonstrated reproducible or reliable data for diagnosis because of the many antigenic shifts *Borrelia* organisms undergo during the course of disease. Protein heterogeneity in strains of different species is quite variable. For example, the OspC protein has 21 major recognized antigenic types. In addition, patients may exhibit increased titers to *Proteus* OX K antigens (up to 1:80), but other cross-reacting antibodies are rare. EIA using recombinant GlpQ antigen has been successful in the relapsing fever *Borrelia* group. Patients infected with relapsing fever *Borrelia* can demonstrate reactivity in *B. burgdorferi* EIA antibody assays, including the C6 antibody assay. References laboratories and the CDC perform Western blot testing for relapsing fever. Infection is confirmed by Western blot when the organisms GlpQ and 22-kDa antigens are positive with IgG and IgM.

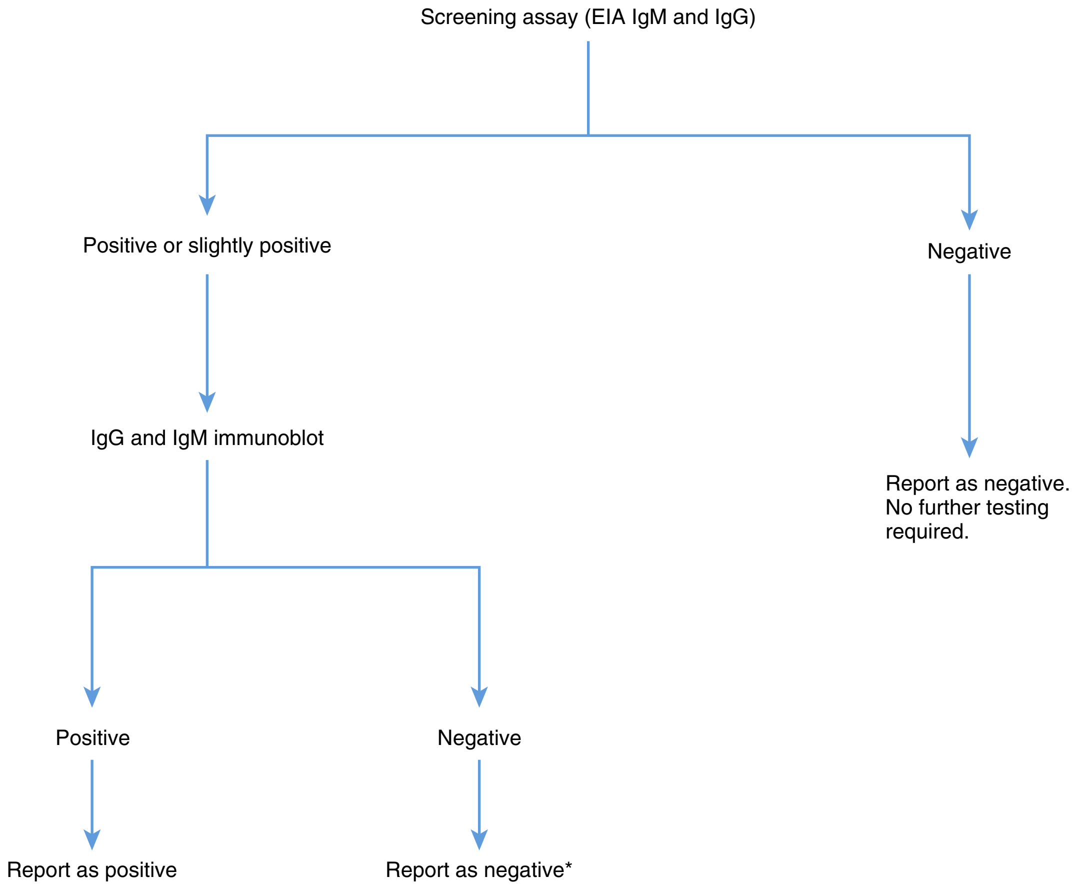
Lyme Disease

Despite its inadequacies, serology continues to be the standard for the diagnosis of Lyme disease. *B. burgdorferi* has numerous immunogenic lipids, proteins, lipoproteins, and carbohydrate antigens on its surface and outer membrane. The earliest antibody response and development of IgM are in response to the OspC membrane protein, the flagellar antigens (FlaA and FlaB), or the fibronectin-binding protein (BBK32). The IgM levels peak within several weeks but may be detectable for several months. The IgG response develops slowly during the first several weeks of disease and increases with antibody responses to Osp17 (decorin-binding protein) and additional proteins, including p39 (BmpA) and p58. The late-stage infection demonstrates IgG antibodies to numerous antigens.

Numerous serologic tests are commercially available. These include indirect immunofluorescence assays (IFA), which are being used less frequently, EIA, CIA, Immunoblots, and Western blots. The CDC recommends using validated and FDA approved IFA, CIA, or EIA as a first step, followed by an immunoblot, when performing serologic testing using the STTT. Measuring antibody by EIA or CIA are the most common screening methods used because they are quick, reproducible, and relatively inexpensive. However, false-positive rates are high, mainly as a result of cross-reactivity. In addition, there is a lack of standardization between assays regarding the antigenic composition and antibodies detected from different manufacturers. The specificity of IFA may be improved by the adsorption of serum with the Reiter *Treponema*, *Treponema phagedenis* sonicate, or egg yolk (IFA-ABS). Patients with syphilis, HIV infection, leptospirosis, mononucleosis, parvovirus infection, rheumatoid arthritis, and other autoimmune diseases commonly show positive results. Capture EIAs have been developed to prevent false-positive reactions with rheumatoid factor. In addition, this may be overcome by pretreatment of the patient's sera with anti-IgG.

For the United States, the CDC recommends a two-step approach to the serologic diagnosis of Lyme disease. In the STTT, the first step is a sensitive screening test such as an EIA, IFA, or CIA; if this test is positive for IgM or IgG or equivocal, the result must be confirmed by separate IgM and IgG immunoblotting (Fig. 45.5). Western blots should not be performed without a previously positive CIA, IFA, or EIA result, as this decreases the specificity of the test and can lead to false-positive results. IgM immunoblot requires reactivity in at least two of the three antigens tested: 23 kDaOspC, 39, and 41 kDa antigens. An IgM immunoblot requires reactivity in at least 5 of 10 antigens included in the assay: 18, 23, 28, 30, 39, 41, 45, 58, 66, and 93 kDa. IgM should only be used during the first 30 days of the infection, whereas IgG may be used at any stage during the disease process. As with *B. burgdorferi*, Lyme borreliosis caused by *B. mayonii* can also be detected with two-tier serologic testing.

Recently, the CDC changed its recommendations for Lyme disease testing to include an MTTT. In this algorithm,



Screening assay (EIA IgM and IgG)
Positive or slightly positive
Negative
IgG and IgM immunoblot
Report as negative. No further testing required.
Positive
Negative
Report as positive
Report as negative*

• **Fig. 45.5** Two-step serodiagnostic procedure. *Note: If neuroborreliosis is suspected, a paired sera and cerebrospinal fluid (CSF) specimen is recommended for testing. Any disease of short duration. For Lyme disease, it is recommended that a follow-up serologic test be performed at a later date. *EIA*, Enzyme immunoassays.

two EIAs are used: one as the primary screening test and the other as the second confirmatory test, which is performed if the first EIA is positive or equivocal. The FDA cleared ZEUS Scientific's EIAs (ZEUS ELISA) for use in the MTTT. The first-tier test, ZEUS ELISA *Borrelia* VlsE1/pepC10 IgG/IgM Test System, measures IgM and IgG antibodies to the *Borrelia burgdorferi* antigens VlsE1 and pepC10. Positive or equivocal results are followed by the second-tier test, either the ZEUS ELISA *Borrelia burgdorferi* IgG/IgM Test System, ZEUS ELISA *Borrelia burgdorferi* IgM Test System, or ZEUS ELISA *Borrelia burgdorferi* IgG Test System, which measure antibodies to *Borrelia burgdorferi* whole-cell antigen. All of the assays are horseradish peroxidase based. The MTTT allows for a greater ease of performance and interpretation as compared with the STTT by eliminating the need to perform a Western blot and decreases turnaround time.

In certain clinical situations, results of serologic tests must be interpreted with caution. For example, patients with Lyme arthritis commonly remain antibody-positive despite treatment but do not necessarily have a persistent infection. Conversely, patients with a localized EM may be seronegative. Because of these limitations and others, the FDA and the American College of Physicians have published guidelines regarding the use of laboratory tests for Lyme disease diagnosis. Of paramount importance is the clinician's determination before ordering serologic tests of the pretest probability of Lyme disease based on clinical symptoms and the incidence of Lyme disease in the population represented by the patient.

Cultivation

Although the organisms that cause relapsing fever can be cultured in nutritionally rich media under microaerobic conditions, the procedures are cumbersome and unreliable and are used primarily as research tools. Similarly, the culture of *B. burgdorferi* may be attempted, although the yield is low. The best specimens for culture in untreated patients include the peripheral area of the EM ring lesion or synovial tissue. CSF and blood or plasma (greater than 9 mL), in general, are of low diagnostic yield by culture. This seems to correlate with the duration of the neurologic disease—in other words, positive results decrease as the duration of the disease increases. To cultivate the organism, the plasma, spinal fluid sediment, or macerated tissue biopsy is inoculated into a tube of modified Kelly's medium (BSK II, BSK-H, or Preac-Mursic) and incubated at 30°C to 34°C for up to 12 weeks under microaerophilic conditions. Likewise, *B. mayonii* can be cultivated under these conditions in BSK II medium. Blind subcultures (0.1 mL) are performed weekly from the lower portion of the broth to fresh media, and the cultures are examined by dark-field microscopy or by fluorescence microscopy after staining with acridine orange for the presence of spirochetes. Because of the long incubation time and low sensitivity associated with cultivation, cultivation is often confined to reference or research laboratories.

Antimicrobial Susceptibility Testing and Therapy

Currently there are no standardized methods, and borreliae are difficult to culture; therefore, antimicrobial susceptibility testing is not routinely performed.

Several antibiotics, including tetracycline, are effective in treating relapsing fever, although it is associated with a higher rate of **Jarisch-Herxheimer reaction,** which can be life threatening. Doxycycline, amoxicillin, or cefuroxime and parenteral cephalosporins are drugs of choice during the first stage of Lyme disease. Broad-spectrum cephalosporins, particularly ceftriaxone or cefotaxime, have been used successfully with patients who either fail initial treatment or present in later stages of the disease, such as neuroborreliosis. Oral regimens are typically successful; however, patients with atrioventricular block may require intravenous (IV) therapy. Symptomatic treatment failures have been reported.

Prevention

Avoiding tick-infested areas; wearing protective clothing; checking the clothing, body, and pets for ticks; and removing them promptly also assist in the prevention of infection. There are no vaccines against infections caused by other *Borrelia* spp.

Brachyspira

General Characteristics

Brachyspira spp. are comma or helical shaped, with tapered ends containing four flagella. *Brachyspira aalborgi* requires anaerobic incubation and has not been isolated from animals, whereas *Brachyspira pilosicoli* colonizes the intestine of a variety of animal species. The organisms reside in the brush border within the intestine and appear as a basophilic fringe, referred to as a "false brush border," upon histologic staining with hematoxylin and eosin.

Epidemiology and Pathogenesis

B. aalborgi is most likely transmitted via fecal-oral contamination. *B. pilosicoli* infection results from ingesting water contaminated with feces from infected animals. *Brachyspira* spp. cause intestinal spirochetosis, which may manifest as chronic diarrhea. The organisms have been associated with crypt abscesses, ulceration, necrosis, and multiple organ failure. Pathogenic mechanisms are not well understood. Clinical significance must be carefully correlated with patient signs and symptoms.

Laboratory Diagnosis

Specimen Collection and Direct Detection

Fresh stool or rectal swabs may be collected and examined by dark-field microscopy. In addition, tissue biopsy specimens may be submitted for culture, PCR and histologic examination using periodic acid-Schiff (PAS) or hematoxylin and eosin staining. PCR amplification methods have been developed but are not available within the clinical laboratory.

Cultivation

Brachyspira spp. can be grown in the laboratory on brain-heart infusion (BHI) or tryptic soy agar containing 10% fetal bovine blood, 400 µg/mL of spectinomycin, and 5 µg/mL polymyxin in anaerobic conditions at 37°C. Increased growth can be seen at 41°C. Confluent growth patterns typically occur. *B. aalborgi* is weakly beta-hemolytic on BHI containing 10% fetal bovine blood.

Approach to Identification

B. aalborgi can be differentiated from *B. pilosicoli* by a strong positive hippurate hydrolysis reaction and a weak indole reaction. *B. pilosicoli* is indole-negative and has a weak hippurate hydrolysis reaction. Matrix-assisted laser desorption ionization and time-of-flight mass spectrometry have been successfully used for the identification of *Brachyspira* species.

Antimicrobial Susceptibility Testing and Therapy

Isolates of *B. pilosicoli* have demonstrated susceptibility to Augmentin (amoxicillin-clavulanic acid), ceftriaxone, chloramphenicol, meropenem, tetracycline, and metronidazole.

Leptospira

General Characteristics

The leptospires include both free-living and parasitic forms. The organisms are spiral-shaped, right-handed helices with hooked ends. The organisms contain two axial filaments and exhibit either a spinning motility or a rapid back-and-forth movement. *Leptospira* spp. are typically classified into three major groups, with *Leptospira interrogans sensu stricto* being the main species associated with human leptospirosis; in France, this organism is responsible for about 60% of human cases.

Molecular classification using 16S ribosomal ribonucleic acid (rRNA) sequencing currently separates the genus into three distinct groups of pathogens, intermediate pathogens, and environmental saprophytes.

The pathogens include more than 200 serologically defined types that were formerly designated as species and are now referred to as serovars, or serotypes, of *L. interrogans sensu stricto* and more than 60 serovars of *L. biflexa sensu lato*. Each serovar is usually associated with a particular animal host, and therefore serovar identification is important for epidemiology studies and prevention strategies. The genotypic classification scheme now includes approximately 23 genomospecies, which incorporates all current serovars of *Leptospira*. Serovars cross species lines as a result of the horizontal transfer of genetic elements, making it difficult to fully classify species phenotypically.

Epidemiology and Pathogenesis

Leptospirosis, a zoonosis, has a worldwide distribution but is most common in developing countries and warm climates via contact with infected animals or contaminated water. *L. interrogans* can infect most mammals throughout the world, as well as reptiles, amphibians, fish, birds, and invertebrates. The organism is maintained in nature by virtue of persistent colonization of renal tubules of carrier animals. Humans become infected through direct or indirect contact with the urine of infected animals. Humans and animals can be classified as a maintenance (infection is endemic) host or accidental host for leptospires. Leptospires enter the human host through breaks in the skin, mucous membranes, or conjunctivae. Infection can be acquired in home and recreational settings (e.g., swimming, hunting, canoeing) or in people who work in certain occupational settings (e.g., farmers, ranchers, abattoir workers, trappers, veterinarians).

Pathogenic leptospires rapidly invade the bloodstream after entry, and spread throughout all sites in the body, such as the central nervous system and kidneys. Virulent strains show chemotaxis toward hemoglobin as well, as the ability to migrate through host tissues. A number of potential virulence factors that might facilitate this process are shown in Box 45.1. How *L. interrogans* causes disease is not completely understood, but it appears that the presence of endotoxin and other toxins may play a role in activation of the hemostasis pathways as an autoimmune response in the human host.

Spectrum of Disease

Symptoms begin abruptly 2 to 30 days after infection and include fever, headache, and myalgia. The most common clinical syndrome is **anicteric leptospirosis,** which is a self-limiting illness consisting of a septicemic stage, with high fever and severe headache that lasts 3 to 7 days, followed by the immune stage. Symptoms associated with the immune stage (onset coincides with the appearance of IgM) are varied but are generally milder than those associated with the septicemic stage. The hallmark of the immune stage is aseptic meningitis. **Weil disease,** or **icteric leptospirosis,** is generally the most severe illness, with symptoms caused by liver, kidney, or vascular dysfunction with lethal pulmonary hemorrhage; death can occur in up to 10% of cases.

• BOX 45.1 Potential Virulence Factors of *Leptospira*

Hemolysins
Sphingomyelinases C and H
Proteolytic enzymes (thermolysin, collagenase)
Catalase
Cobalamin biosynthesis
Sialic acids
Fibronectin-binding protein for adhesion and invasion
Lipopolysaccharide and outer membrane proteins

Unfortunately, the clinical presentations of leptospirosis mimic those of many other diseases.

Laboratory Diagnosis

Specimen Collection, Transport, and Processing

During the first 10 days of illness, leptospires are present in the blood, CSF, and peritoneal dialysate. Urine specimens can be collected beginning in the second week of illness and up to 30 days after the onset of symptoms. Specimens may be collected in citrate, heparin, or oxalate anticoagulants. There are no other special requirements for specimen collection, transport, or processing. Citrate or ethylenediaminetetraacetic acid (EDTA) is the preferred anticoagulant for nucleic acid–based testing. Urine specimens should not be placed in preservatives and should be processed within 1 hour for optimal results. Urine specimens collected for nucleic acid testing can be placed in several commercial products and transported over long periods. Specimens should be transported at room temperature and inoculated for culture within 24 hours.

Direct Detection

Blood, CSF, and urine may be examined directly by dark-field microscopy. The detection of motile leptospires in these specimens is optimized after centrifuging at 1500× *g* for 30 minutes; sodium oxalate or heparin-treated blood is initially spun at 500× *g* for 15 minutes to remove blood cells. Other techniques, such as fluorescent antibody staining and hybridization techniques using leptospira-specific DNA probes, have also detected leptospires in clinical specimens.

Nucleic Acid Detection

Conventional and real-time PCR assays have been used to detect leptospires in blood, plasma, serum, urine, aqueous humor, CSF, autopsy tissue, and environmental samples. Nucleic acid detection is at least comparable to culture and useful in confirming diagnosis during the acute stages of the infection.

Cultivation

Albeit insensitive, the definitive method for laboratory diagnosis of leptospirosis is to culture the organisms from blood, CSF, or urine. A few drops of heparinized or sodium oxalate–anticoagulated blood are inoculated into tubes of semisolid media enriched with rabbit serum (Fletcher's or Stuart's) or bovine serum albumin. Urine should be inoculated soon after collection, because acidity (diluted out in the broth medium) may harm the spirochetes. One or two drops of undiluted urine and a 1:10 dilution of urine are added to 5 mL of medium. The addition of 200 μg/mL of 5-fluorouracil (an anticancer drug) may prevent contamination by other bacteria without harming the leptospires. Commercial media such as the Ellinghausen-McCullough-Johnson-Harris (EMJH) or Fletcher's medium (Difco EMJH or Difco Fletcher's medium; BD Diagnostic Systems, Sparks, MD) are available, which contain 5-fluorouracil for use at the patient's bedside. Tissue specimens, especially from the liver and kidney, may be aseptically macerated and inoculated in dilutions of 1:1, 1:10, and 1:100 as for urine cultures.

All cultures are incubated at room temperature or 30°C in the dark for up to 6 to 8 weeks. Because organisms grow below the surface, material collected from a few centimeters below the surface of broth cultures should be examined weekly for the presence of growth, using a direct wet preparation under dark-field illumination. Leptospires exhibit corkscrewlike motility.

Approach to Identification

Based on the number of coils and hooked ends, leptospires can be distinguished from other spirochetes. Physiologically, the saprophytes can be differentiated from pathogens by their ability to grow at 10°C and lower, or at least 5°C lower than the growth temperature of pathogenic leptospires. Leptospires may also be visualized using dark-field microscopy or immunofluorescence.

Serodiagnosis

Serodiagnosis of leptospirosis requires a fourfold or greater rise in titer of agglutinating antibodies. The microscopic agglutination test (MAT) using live cells is the standard serologic procedure. Serologic diagnosis of leptospirosis is performed using pools of bacterial antigens containing many serotypes in each pool. Positive results are indicated by the presence of agglutination using dark-field microscopy. However, a macroscopic agglutination procedure is more readily accessible to routine clinical laboratories. Reagents are available commercially. Indirect hemagglutination and an ELISA test for IgM antibody are also available; IgM-detection assays are primarily used because IgM antibodies become detectable during the first week of illness. Rapid immunochromatographic assays are now available for the detection of IgM and/or IgG antibodies to *Leptospira interrogans* (Abbott, Chicago, IL).

Molecular Typing Methods

Several nucleic acid–based amplification methods have been developed. However, PCR methodologies are not useful for the differentiation of serovars and therefore are of limited use in epidemiologic studies. Highly complex and labor-intensive techniques such as pulsed-field gel electrophoresis (PFGE) and restriction-fragment-length polymorphism (RFLP) and ribotyping are more useful for the identification of serovars. Nucleic acid sequencing has been used to successfully identify *Leptospira* directly in clinical specimens when the bacterial load was high.

Antimicrobial Susceptibility Testing and Therapy

Treatment of leptospirosis is supportive management and the use of appropriate antibiotics. Ceftriaxone, penicillin, amoxicillin, doxycycline, and tetracycline are recommended for the treatment of leptospirosis. Standardized procedures for antibiotic susceptibility are limited by the slow growth of the organisms and the need for serum during cultivation.

Prevention

General preventive measures include the vaccination of domestic livestock and pet dogs. In addition, protective clothing, rodent control measures, and preventing recreational exposures, such as avoiding freshwater ponds, are indicated in preventing leptospirosis.

Chapter Review

1. Primary syphilis is characterized by what clinical sign:
- **a.** Chancre
- **b.** Rash
- **c.** Lymphadenopathy
- **d.** Gummas

2. Rapid point-of-care tests for syphilis utilize which of the following methods:
- **a.** Horseradish peroxidase–conjugated antigens
- **b.** Fluorescent-tagged antihuman antibodies
- **c.** Chemiluminescent molecules
- **d.** Antigens bound to a solid-phase membrane

3. The reverse testing algorithm for syphilis includes:
- **a.** Testing first for nonspecific antibodies and, if positive, testing for treponemal specific antibodies
- **b.** Testing first for specific treponemal antibodies and, if positive, testing for nonspecific antibodies
- **c.** Testing for nonspecific antibodies and, if positive, no further testing is required
- **d.** Testing for specific treponemal antibodies and, if positive, no further testing is required

4. In addition to syphilis, reaginic antibodies can also be produced in patients with which of the following conditions?
- **a.** Leptospirosis
- **b.** Measles
- **c.** Autoimmune disorders
- **d.** All of the above

5. Which spirochete resides in the brush border of the intestine?
- **a.** *Treponema pallidum*
- **b.** *Brachyspira pilosicoli*
- **c.** *Borrelia burgdorferi*
- **d.** *Leptospira interrogans*

6. The standard serologic procedure for the diagnosis of leptospirosis is:
- **a.** PaGIA
- **b.** MBIA
- **c.** MA
- **d.** EIA followed by Western blot

7. A patient presents with a red skin lesion that has central clearing and flulike symptoms. She reports spending a lot of time outdoors hiking in wooded areas. What laboratory test should be ordered?
- **a.** Tissue biopsy of the skin lesion to stain and visualize spirochetes
- **b.** Whole blood specimen for culture of spirochetes
- **c.** Urine specimen for PCR
- **d.** Serum specimen for serologic testing

8. True or False

_____ Treponemal serologic tests are useful in monitoring treatment for syphilis.

_____ Infection with *Borrelia mayonii* can be detected using the two-tiered serologic test algorithm for Lyme disease.

9. Matching: *Match each term with the appropriate definition.*

_____ *Borrelia burgdorferi*	a. Renal involvement
_____ *Brachyspira* spp.	b. Erythema migrans
_____ MBIA	c. Direct detection method
_____ TP-PA	d. Antigen-coated beads
_____ Leptospirosis	e. Congenital syphilis
_____ Prozone reaction	f. Intestinal spirochetosis
_____ Dark-field microscopy	g. Nontreponemal test
_____ VDRL	h. False negative
_____ Hutchinson's triad	i. Agglutination of gelatin particles sensitized with *T. pallium* antigens

CASE STUDY 45.1

A 43-year-old female was referred to the infectious disease clinic for recurrent symptoms beginning about 4 months after she noticed a painful, swollen spot on her leg after removal of a tick. She had been treated with doxycycline for 14 days for presumed Lyme disease, documented by a positive IFA titer and presentation with migratory arthralgias, which were worse in the small joints of the hands. She also complained of fatigue, poor mentation, and occasional headaches. Because her symptoms recurred 2 months after treatment, she was unable to continue employment. Six months after a course of amoxicillin and later two courses of ceftriaxone, she again became symptomatic. A Western blot and PCR of her serum were ordered. The Western blot result was equivocal, but the PCR was positive for the agent of Lyme disease.

Questions

1. How did this patient acquire Lyme disease?
2. Why did the physician order further testing to diagnose Lyme disease in this patient?
3. The patient did not respond to therapy for *B. burgdorferi*. Can you explain why this can happen?

PROCEDURE 45.1

Rapid Plasma Reagin Test

Purpose

The rapid plasma reagin (RPR) test is a presumptive serologic screening test for syphilis.

Principle

The test is based on the presence of reagin, a nonspecific antilipid antibody found in the serum of patients infected with *Treponema pallidum*. Syphilis infection results in the breakdown of human tissue, releasing fatty substances that combine with *T. pallidum* protein to form an antigen, resulting in the formation of nonspecific and specific *T. pallidum* antibodies. The RPR antigen consists of cardiolipin, lecithin, and cholesterol bound to charcoal particles. The nonspecific antibody reacts with the test antigen, resulting in flocculation. The flocculation is visible on a white test card by incorporating charcoal particles in the antigen preparation.

Specimen

Patient serum or plasma is tested at room temperature, 20°C–25°C.

Method

1. Place a 50 μL sample of patient serum or plasma and positive and negative controls into three separate circles on the test card.
2. Mix the RPR-carbon reagent gently before applying to each circle.
3. Add exactly one drop (20 μL) of reagent to each sample.
4. Mix the specimen and reagent with a stirrer, carefully spreading each sample over the entire surface of the circle. Use a clean stirrer for each sample.
5. Place the test card on a mechanical rotator or shaker at 80–100 rpm for 8 min.
6. Read the results before drying.

Expected Results

Reactive: samples that demonstrate small to large clumps; a weak positive may show fine granulation or partial clumping.

Nonreactive: samples that demonstrate no clumping or very slight roughness.

Limitations

1. Slide flocculation tests are affected by room temperature. All test reagents and specimens should be warmed to room temperature before testing.
2. Failure to read results within 8 min may lead to drying and the appearance of false-positive results.
3. Patient samples that are hemolyzed, lipemic, or contain a high concentration of bilirubin may interfere with test results.
4. The RPR test cannot be used to test CSF specimens.
5. Biologic false positives occur as a result of other physiologic or pathologic conditions.
6. False negatives may be seen in specimens with high titers (prozone reaction).

Quality Control

Positive controls should demonstrate readily visible flocculation.

Negative controls will appear uniformly turbid.

PROCEDURE 45.2

Venereal Disease Research Laboratory Test

Purpose

The Venereal Disease Research Laboratory (VDRL) test is a slide flocculation test used for screening patients for infection with *Treponema pallidum*.

Principle

Patients infected with *T. pallidum* produce nonspecific antibodies capable of reacting with the cardiolipin test antigen. Cardiolipin is a lipid antigen extracted from beef heart that contains cardiolipin, lecithin, and cholesterol. The VDRL test is typically positive within 1–2 weeks after the appearance of the primary lesion. The test becomes reactive in late phase primary syphilis and highly reactive in secondary syphilis. The results will slowly decrease and become less reactive in late or tertiary syphilis. The VDRL test is also useful in the diagnosis of congenital syphilis and neurosyphilis. Maternal antibodies are capable of crossing the placenta; a positive VDRL immediately after birth may be solely a result of the presence of maternal antibodies. A quantitative titer is thus required at birth, followed by a second titer approximately 1 month after birth. No increase in titer will assist in ruling out the possibility of congenital syphilis.

Specimen

Patient serum or cerebrospinal fluid (CSF) samples. The serum must be inactivated before testing. The sample is heated at 56°C for 30 min. This inactivates serum proteins, such as complement within the patient specimen. CSF samples should not be heated before testing.

Method

1. Place 50 μL of the patient sample, a positive reactive, and a negative nonreactive control into separate circles on the test card.
2. Place 20 μL of reagent next to the sample and stir each, making sure to completely cover the circle on the test card. Use a separate stirrer for each sample to prevent contamination.
3. Place the test card on a rotator or shaker at 180 rpm for 4 min.

Expected Results

Strongly reactive results will demonstrate large visible clumps.

Weakly reactive results will appear as small clumps.

Nonreactive results will appear as a diffuse, evenly turbid, reaction.

Limitations

1. Results should be read immediately to prevent drying of the sample and the appearance of clumping caused by evaporation.
2. Biologic false positives occur as a result of other physiologic or pathologic conditions. Various conditions including pregnancy, menstruation, vaccination, trauma, and a variety of infectious diseases and immunologic disorders may cause biologic false positives.
3. False negatives may be seen in specimens with high titers (prozone reaction).

Quality Control

A reactive and nonreactive control should be included in each assay, demonstrating results as indicated in expected outcomes.

46

Overview of the Methods and Strategies in Parasitology

OBJECTIVES

This chapter provides an overview of the general epidemiology, pathogenesis, spectrum of disease, and approach to the identification of parasites. The detailed technical procedures should be used in conjunction with additional organism-specific chapters in this section to provide a clear description of the process, from specimen collection to identification. However, students should consider the following general objectives for the methods provided:

1. State the specific diagnostic purpose for each test methodology as well as its advantages and disadvantages.
2. Briefly describe the principle associated with the test method.
3. Determine specimen acceptability for parasite identification, including collection method, collection time/receipt time, number or quantity of specimen, and presence of interfering and contaminating substances.
4. Select appropriate preservatives for parasite specimens and explain the chemical principle and rationale for the preservative, including polyvinyl alcohol (PVA), universal fixative, formalin, and sodium acetate acetic acid formalin (SAF).
5. Select the appropriate method of detection and identification of parasites based on the type of specimen.
6. Discuss the effectiveness of antibody serology, antigen detection, molecular methods, and the traditional processing of ova and parasites (O&Ps) for the diagnosis of various parasite infections.

Parasitic diseases are often associated with the earth's tropical zones; however, many parasitic organisms that infect humans are worldwide in distribution and occur with some frequency in the temperate zones. In addition, people who travel to and from areas where parasites are endemic may contract one of these infections and then seek medical attention in their home country, far distant from the expected geographic area. An increase in the number of compromised patients, particularly those who are immunodeficient or immunosuppressed, has also led to increased interest in the field of parasitology. These individuals are greatly at risk for certain parasitic infections. Parasites that infect humans are classified into six major divisions:

- Protozoa (amebae, flagellates, ciliates, sporozoans, coccidia, microsporidia)
- Nematoda, or roundworms
- Platyhelminthes, or flatworms (cestodes, trematodes)
- Pentastomids, or tongue worms
- Acanthocephala, or thorny-headed worms
- Arthropoda (e.g., insects, spiders, mites, ticks)

The identification of parasitic organisms traditionally depends on the observation of characteristic morphologic criteria; accurate depiction of these criteria, in turn, depends on correct specimen collection, processing, and adequate fixation. Improperly submitted specimens may result in failure to detect the organisms or their misidentification. Tables 46.1 to 46.3 present information on the various groups of parasites, those that may be recovered from various body sites, the most frequently used specimen collection approaches, and appropriate processing methods.

Epidemiology

Parasites are usually restricted to specialized environments inside and outside of their hosts. The **host specificity** of any individual parasite greatly influences factors associated with transmission and control. A disease of wild or domestic animals, **zoonotic disease,** also occurs in humans**.** Animals that are potential sources of a parasitic infection for humans are **reservoir hosts.** Some parasitic organisms are free living during specific stages of their life cycles and do not depend on human or other living hosts for survival. In some cases, humans become an **accidental** or unintended **host.** When humans are the only host for a parasite or a stage of its development, control and prevention options are relatively easy to define. However, if an infection is zoonotic or has an

TABLE 46.1 Description of the More Common Groups of Human Parasites

Parasite Group	Description
Protozoa, Intestinal	
Amebae	Single-celled organisms; pseudopodia (motility), trophozoite, and cyst stages in the life cycle. Exceptions: Some have no identified cyst. Fecal-oral transmission of the infective cyst. *Entamoeba histolytica* causes amebiasis and is the most significant organism in this group.
Flagellates	Protozoa with characteristic flagella. Fecal-oral transmission. Exceptions: *Trichomonas* has a trophozoite and no cyst stage. Reproduction by longitudinal binary fission. Examples: *Giardia duodenalis* and *Dientamoeba fragilis.*
Ciliates	Single-celled protozoa; cilia (motility), which beat in a coordinated, rhythmic pattern, moving the trophozoite in a spiral path. Trophozoite and cyst stages in the life cycle; both stages show a large macronucleus and a micronucleus. Fecal-oral transmission. *Neobalantidium coli* is the single human pathogen in the group.
Coccidia	Protozoa; asexual and sexual life cycles. Fecal-oral transmission via contaminated food and/or water. Infective stage (oocyst) containing sporocysts and/or sporozoites. Examples: *Cryptosporidium* spp., *Cyclospora cayetanensis*, *Cystoisospora belli*, and *Sarcocystis* spp.
Microsporidia	Small (1–2.5 μm) intestinal protozoa. Transmission by ingestion, inhalation, or direct inoculation of spores. Nine genera cause disease in humans; the two most important are *Encephalitozoon* and *Enterocytozoon*.
Protozoa, Other Sites	
Amebae	Pathogenic free-living organisms associated with warm freshwater environments. Except for *Entamoeba gingivalis* (found in the mouth), they have been isolated from the central nervous system (CNS), eye, and other body sites. Examples: *Naegleria fowleri*—acute CNS infection and death. Chronic CNS disease (*Acanthamoeba* spp., *Balamuthia mandrillaris*), and *Acanthamoeba* spp. can also cause keratitis.
Flagellates	Have flagella (long, proteinaceous organelles used for motility). Sexual transmission. Examples: *Trichomonas vaginalis* is located in the genitourinary system. *Trichomonas tenax* can be identified in the mouth and is considered nonpathogenic.
Coccidia	Obligate intracellular, spore forming. Transmission is typically fecal-oral through ingestion of contaminated materials or food. Examples: *Cryptosporidium* spp. and *Toxoplasma gondii*.
Microsporidia	Small (1–2.5 μm) spore-forming protozoa. Transmission is typically by ingestion of spores. Life cycles vary considerably; some have an asexual life cycle, whereas others are complex and have both asexual and sexual life cycles and multiple hosts. Examples: *Encephalitozoon, Pleistophora, Trachipleistophora,* and *Anncaliia* spp.
Protozoa, Blood and Tissue	
Malaria, babesiosis	Arthropod vector–borne protozoa. Transmission via insect bite. Examples: *Plasmodium* spp. includes parasites that undergo exoerythrocytic and pigment-producing erythrocytic schizogony in vertebrates and a sexual stage followed by sporogony in mosquitoes. *Babesia* spp. are tick-borne and can cause severe disease in patients who have been splenectomized or otherwise immunologically compromised.
Flagellates (leishmaniae)	Trypanosomatid protozoa; two morphologic forms—promastigotes (anterior flagellum) in the insect host and amastigote (no flagella) in the vertebrate host. Transmission is through an insect vector. Recovery and identification of the organisms are related to body site. Recovery of leishmanial amastigotes is limited to the site of the lesion in infections other than those caused by the *Leishmania donovani* complex (visceral leishmaniasis).

TABLE 46.1 **Description of the More Common Groups of Human Parasites—cont'd**

Parasite Group	Description
Flagellates (trypanosomes)	Trypanosomatid protozoa; morphologic forms are identified based on the position, length, and attachment site of the flagella. At some time in their life cycle, these protozoa have the trypomastigote form with the typical undulating membrane and free flagellum at the anterior end. Transmission is typically through an insect vector. Some organisms cause African sleeping sickness (e.g., *Trypanosoma brucei gambiense, T. brucei rhodesiense*). The etiologic agent of American trypanosomiasis is *Trypanosoma cruzi,* which has amastigote and trypomastigote stages in the mammalian host and an epimastigote form in the arthropod host.
Nematodes, intestinal	Helminthic parasites; roundworms. Nematodes have separate sexes, are elongate-cylindrical and bilaterally symmetric with a triradiate symmetry at the anterior end. Nematodes have an outer cuticle layer, no circular muscles, and a pseudocele that contains all systems (digestive, excretory, nervous, and reproductive). Transmission is by ingestion of eggs or by skin penetration of larval forms from the soil. Examples: *Ascaris, Enterobius, Trichuris,* and *Strongyloides* spp. and hookworm.
Nematodes, tissue	Helminthic parasites; roundworms. Many of these organisms are rarely seen in the United States; however, some are important and are found worldwide. Diagnosis may be difficult if the only specimens are biopsy and/or autopsy, and interpretation must be based on examination of histologic preparations. Examples: *Trichinella* spp., visceral larva migrans (VLM), ocular larva migrans (OLM), cutaneous larva migrans (CLM).
Nematodes, filarial	Helminthic parasites; roundworms. Transmission is via arthropods. Adult worms tend to live in the tissues or lymphatics of the vertebrate host. The diagnosis is made based on recovery and identification of the larval worms (microfilariae) in the blood, other body fluids, or skin. Examples: *Wuchereria, Brugia, Loa,* and *Onchocerca* spp.
Cestodes, intestinal	Helminthic parasites; tapeworms. Adult tapeworm consists of a chain of egg-producing units called proglottids, which develop from the neck region of the attachment organ (scolex). Food is absorbed through the worm's integument. The intermediate host contains the larval forms acquired through ingestion of the adult tapeworm eggs. Transmission is through the ingestion of larval forms in poorly cooked or raw meat or freshwater fish. Examples: *Dipylidium caninum* (infection is acquired by accidental ingestion of dog fleas). *Hymenolepis nana* and *Hymenolepis diminuta* are transmitted via ingestion of certain arthropods (fleas, beetles). In addition, *H. nana* can be transmitted through egg ingestion (life cycle can bypass the intermediate beetle host). Humans can serve as both the intermediate and definitive hosts in *H. nana* and *Taenia solium* infections.
Cestodes, tissue	Tissue tapeworms. Transmission is through ingestion of certain tapeworm eggs or accidental contact with certain larval forms, leading to tissue infection. Humans serve as the accidental intermediate host. Examples: *T. solium, Echinococcus granulosus,* and several other species.
Trematodes, intestinal	Flatworms that are exclusively parasitic. Except for the schistosomes (blood flukes), flukes are hermaphroditic. They may be flattened; most have oral and ventral suckers. Transmission: Intestinal trematodes require a freshwater snail to serve as an intermediate host; these infections are food-borne (freshwater fish, mollusks, or plants). Example: *Fasciolopsis buski,* the giant intestinal fluke.
Trematodes, liver, lung	Transmission: Liver and lung trematodes require a freshwater snail to serve as an intermediate host; these infections are food-borne (freshwater fish, crayfish or crabs, or plants). Examples: Public health concerns include cholangiocarcinoma associated with *Clonorchis* and *Opisthorchis* infections, severe liver disease associated with *Fasciola* infections, and misdiagnosis of tuberculosis in individuals infected with *Paragonimus* spp.
Trematodes, blood	Schistosomes; sexes are separate. Males are characterized by an infolded body that forms the gynecophoral canal in which the female worm is held during copulation and oviposition. Transmission: Infection is acquired by skin penetration by the cercarial forms that are released from freshwater snails. The adult worms reside in the blood vessels over the small intestine, large intestine, or bladder. Examples: *Schistosoma mansoni, Schistosoma haematobium,* and *Schistosoma japonicum*.

TABLE 46.2 **Body Sites and Parasite Recovery (Trophozoites, Cysts, Oocysts, Spores, Adults, Larvae, Eggs, Amastigotes, Trypomastigotes)**

Site	Parasites
Blood	
Red cells	*Plasmodium* spp. *Babesia* spp.
White cells	*Leishmania* spp. *Toxoplasma gondii*
Whole blood/plasma	*Trypanosoma* spp. Microfilariae
Bone marrow	*Leishmania* spp. *Trypanosoma cruzi* *Plasmodium* spp.
Central Nervous System	
Cutaneous ulcers	*Taenia solium* (cysticerci) *Echinococcus* spp. *Naegleria fowleri* *Acanthamoeba* spp. *Balamuthia mandrillaris* *Sappinia diploidea* *Toxoplasma gondii* Microsporidia *Trypanosoma* spp. *Leishmania* spp.
Intestinal tract	*Entamoeba bangladeshi* *Entamoeba histolytica* *Entamoeba dispar* *Entamoeba coli* *Entamoeba hartmanni* *Entamoeba polecki* *Endolimax nana* *Iodamoeba bütschlii* *Blastocystis hominis* *Giardia duodenalis* *Chilomastix mesnili* *Dientamoeba fragilis* *Pentatrichomonas hominis* *Neobalantidium coli* *Cryptosporidium* spp. *Cyclospora cayetanensis* *Cystoisospora belli* *Sarcocystis* spp. Microsporidia *Ascaris lumbricoides* *Anisakis* spp. *Enterobius vermicularis* Hookworm *Strongyloides stercoralis* *Angiostrongylus* spp. *Trichostrongylus* spp. *Trichuris trichiura* *Hymenolepis nana* *Hymenolepis diminuta* *Taenia saginata* *Taenia solium* *Diphyllobothrium latum* *Clonorchis sinensis (Opisthorchis)* *Paragonimus* spp. *Schistosoma* spp. *Fasciolopsis buski* *Fasciola hepatica* *Metagonimus yokogawai* *Heterophyes heterophyes*
Liver, spleen	*Capillaria hepatica* *Clonorchis/Opisthorchis* *Echinococcus* spp. *Entamoeba histolytica* *Fasciola hepatica* *Leishmania donovani* *Toxocara* spp. Microsporidia
Lung	*Cryptosporidium* spp.[a] *Dirofilaria immitis* *Echinococcus* spp. Hookworm larvae *Paragonimus* spp. Microsporidia
Muscle	*Gnathostoma spinigerum* *Taenia solium* (cysticerci) *Taenia/Multiceps* spp. *Trichinella* spp. *Onchocerca volvulus* (nodules) *Spirometra/Diphyllobothrium* spp. *Trypanosoma cruzi* Microsporidia
Skin	*Ancylostoma* spp. *Dracunculus medinensis* *Gnathostoma spinigerum* *Leishmania* spp. *Onchocerca* spp. Microfilariae *Taenia* spp. *Demodex* spp. *Sarcoptes scabiei*
Urogenital system	*Trichomonas vaginalis* *Schistosoma* spp. *Baylisascaris procyonis* Microsporidia Microfilariae
Eye	*Acanthamoeba* spp. *Dirofilaria* spp. *Toxoplasma gondii* *Toxocara* spp. *Loa loa* Microsporidia

Note: This table does not include every possible parasite that can be identified in each body site; the most likely organisms have been listed.

[a] Disseminated in severely immunosuppressed individuals.

TABLE 46.3 **Specimens and Body Site: Specimen Options, Collection and Transport Methods, and Processing**

Specimens and/or Body Site	Specimen Options	Collection and Transport Methods	Specimen Processing	Comments
Stool for ova and parasites (O&Ps) examination	Fresh stool	½ pint waxed container; 30 min if liquid, 60 min if semi formed, 24 h if formed; delivery to laboratory	Direct wet smear (not on formed specimen), concentration, permanent stained smear	Stool specimens containing barium are unacceptable; intestinal protozoa may be undetectable for 5–10 days after barium use. Certain substances and medications also impede detection of intestinal protozoa: mineral oil, bismuth, antibiotics, antimalarial agents, and nonabsorbable antidiarrheal preparations. After administration of any of these compounds, parasitic organisms may not be recovered for a week to several weeks. Specimen collection should be delayed after barium or antibiotics are administered for 5–10 days or at least 2 weeks, respectively.
	Preserved stool[a]	5% or 10% formalin, MIF, SAF, Schaudinn's, PVA, modified PVA, single vial systems, universal fixative	Concentration, permanent stained smear Depending on specimen (fresh or preserved) and patient's clinical history, immunoassays may also be performed.	
Stool for culture of nematodes	Fresh stool, entire stool specimen	½ pint waxed container; immediate delivery to laboratory	Filter paper strip, Petri dish, and agar plate, charcoal cultures are all available.	Fresh stool (do not refrigerate) is required for these procedures.
Stool for recovery of tapeworm scolex	Preserved stool, entire stool specimen	5% or 10% formalin (10% recommended)	The stool is filtered with a series of mesh screens and examined for the very small tapeworm scolex (proof of therapy efficacy) and/or proglottids.	After treatment for tapeworm removal, the patient should be instructed to take a saline cathartic and to collect all stool material passed for the next 24 h. The stool should be immediately placed in 10% formalin and thoroughly broken up and mixed with the preservative (1-gallon [3.8-L] plastic jars are recommended, half-full of 10% formalin).
	Adult worms, worm segments	Saline, 70% alcohol		
Cellophane tape preparation for pinworms	Surface sample from perianal skin; anal impression smear	Cellophane (Scotch) tape preparation or commercial sampling paddle or swab	Tape is lifted from a slide, a drop of xylene substitute is added, the tape is replaced, and the specimen is ready for examination under the microscope.	Specimens should be collected late at night after the person has been asleep for several hours or first thing in the morning before going to the bathroom or taking a shower. At least 4–6 consecutive negative tapes are required to rule out the infection.
Sigmoid colon	Sigmoidoscopy material, prepared as smears	Fresh or PVA or Schaudinn's smears; specimen is taken with a spatula rather than cotton-tipped swabs; transported as smears in preservative	Direct wet smear, permanent stained smears	Material from the mucosal surface should be aspirated or scraped; it should not be collected with cotton-tipped swabs. At least 6 representative areas of the mucosa should be sampled and examined (6 samples, 6 slides). A parasitology specimen tray (containing Schaudinn's fixative, PVA, and 5% or 10% formalin) should be provided, or a trained technologist should be available at the time of sigmoidoscopy to prepare the slides. Examination of sigmoidoscopy specimens does not take the place of routine O&Ps examinations. If the amount of material is limited, use of a fixative containing PVA is highly recommended.

Continued

TABLE 46.3 **Specimens and Body Site: Specimen Options, Collection and Transport Methods, and Processing—cont'd**

Specimens and/or Body Site	Specimen Options	Collection and Transport Methods	Specimen Processing	Comments
Duodenum	Duodenal contents	Entero-Test or aspirates; string in Petri dish or tube; immediate transport to laboratory	The specimen may be centrifuged (10 min at 500×) and should be examined immediately as a wet mount for motile organisms. Iodine also can be used. Direct wet smear of mucus; permanent stained smears can also be prepared.	A fresh specimen is required; the amount may vary from <0.5 mL to several milliliters of fluid. If the specimen cannot be completely examined within 2 h after collection, any remaining material should be preserved in 5%–10% formalin.
Entero-Test capsule (string)	Duodenal contents	Entero-Test (string test) in Petri dish (fresh) or preserved in PVA	Bile-stained mucus clinging to the yarn should be scraped off (mucus can also be removed by pulling the yarn between the thumb and finger) and collected in a small Petri dish; disposable gloves are recommended. Usually 4 or 5 drops of material are collected. The specimen should be examined immediately as a wet mount for motile organisms (iodine may be added later to facilitate identification of any organisms present). The pH of the terminal end of the yarn should be checked to ensure adequate passage into the duodenum (a very low pH means that it never left the stomach). The terminal end of the yarn should be yellow-green, indicating that it was in the duodenum (the bile duct drains into the intestine at this point). Permanent stained smears can also be prepared.	If the specimen cannot be completely examined within 1 h after removal of the yarn, the material should be preserved in 5%–10% formalin, or PVA-mucus smears should be prepared.
Urogenital tract	Vaginal discharge Urethral discharge Prostatic secretions	Saline swab, transport swab (no charcoal), culture medium, plastic envelope culture, air-dried smear for FA	Direct wet smear; fluorescence; urine must be centrifuged before examination.	Fresh specimens are required; an air-dried smear may be an option for fluorescence. Do not refrigerate swabs and/or culture containers at any time, because motility and/or ability to grow will probably be lost.
	Urine	Single unpreserved specimen, 24-h unpreserved specimen, early morning Nucleic acid–based testing media according to manufacturer's instructions	Examination of urinary sediment may be indicated in certain filarial infections. Administration of the drug diethylcarbamazine (Hetrazan) has been reported to enhance the recovery of microfilariae from the urine. The triple-concentration technique is recommended for the recovery of microfilariae. The membrane filtration technique can be used with urine for the recovery of microfilariae. A membrane filter technique for the recovery of *Schistosoma haematobium* eggs has also been useful.	

TABLE 46.3 **Specimens and Body Site: Specimen Options, Collection and Transport Methods, and Processing—cont'd**

Specimens and/or Body Site	Specimen Options	Collection and Transport Methods	Specimen Processing	Comments
Sputum	Sputum	True sputum (not saliva)	Direct wet smear; permanent stained smears; fluorescence also available (Calcofluor for microsporidia). Sputum is usually examined as a wet mount (saline or iodine), using low and high dry power (10× and 400×). The specimen is not concentrated before preparation of the wet mount. If the sputum is thick, an equal amount of 3% sodium hydroxide (NaOH) (or undiluted chlorine bleach) can be added; the specimen is thoroughly mixed and then centrifuged. NaOH should not be used if the examiner is looking for *Entamoeba* spp. or *Trichomonas tenax.* After centrifugation, the supernatant is discarded, and the sediment can be examined as a wet mount with saline or iodine. If examination is delayed, the sputum should be fixed in 5% or 10% formalin to preserve helminth eggs or larvae or in PVA.	True sputum is required; all specimens, especially induced specimens and BAL, should be delivered immediately to the laboratory (do not refrigerate).
	Induced sputum	No preservative (10% formalin if time delay)		
	Bronchoalveolar lavage (BAL)	Sterile; immediate delivery to laboratory		
Aspirates	Bone marrow	Sterile; immediate delivery to laboratory	Permanent stained smears; cultures can also be set (specifically designed for the recovery of blood parasites).	All aspirates for culture must be collected using sterile conditions and containers; this is mandatory for culture isolation of leishmania and trypanosomes.
	Cutaneous ulcers	Sterile plus air-dried smears		
	Liver, spleen	Sterile, collected in 4 separate aliquots (liver)		
	Lung			
	Transbronchial aspirate	Air-dried smears		
	Tracheobronchial aspirate	Air-dried smears		
Central nervous system	Cerebrospinal fluid (CSF)	Sterile	Direct wet smear, permanent stained smears; culture for free-living amebae (*Naegleria, Acanthamoeba* spp.).	All specimens must be transported immediately to the laboratory (STAT procedure).

Continued

TABLE 46.3 Specimens and Body Site: Specimen Options, Collection and Transport Methods, and Processing—cont'd

Specimens and/or Body Site	Specimen Options	Collection and Transport Methods	Specimen Processing	Comments
Biopsy	Intestinal tract	Routine histology	Direct wet smears, permanent stained smears; specimens to histology for routine processing.	The more material that is collected and tested, the more likely the organism is to be isolated and subsequently identified. Sterile collection is required for all specimens that will be cultured; bacterial and/or fungal contamination prevents isolation of parasites in culture.
	Cutaneous ulcers	Sterile, nonsterile to histopathology (formalin acceptable)		
	Eye	Sterile (in saline), nonsterile to histopathology		
	Scrapings	Sterile (in saline)		
	Cornea (scrapings)	Collected by physician, placed directly on microscope slide	Fixed using methyl alcohol and stained using Calcofluor white.	Helpful in diagnosis of *Acanthamoeba* keratitis.
	Liver, spleen	Sterile, nonsterile to histopathology		
	Lung			
	Brush biopsy	Air-dried smears		
	Open lung biopsy	Air-dried smears		
	Muscle	Fresh, squash preparation, nonsterile to histopathology		
	Skin biopsy	Nonsterile to histopathology (formalin acceptable)		
	Scrapings	Sterile (in saline), nonsterile to histopathology		
	Skin snip	Aseptic, smear or vial No preservative		
Blood	Smears of whole blood	Fresh (first choice) Thick and thin films; immediate delivery to laboratory	Thick and thin films, specialized concentrations and/or screening methods	Examination of blood films (particularly for malaria) is considered a STAT procedure; immediate delivery to the laboratory is mandatory.
	Anticoagulated blood	Anticoagulant (second choice) EDTA (first choice) Heparin (second choice)	Thick and thin films, specialized concentrations and/or rapid methods Quantitative Buffy Coat (QBC) Microhematocrit Centrifugation Method (Becton Dickinson, Tropical Disease Diagnostics, Sparks, MD)	Delivery to the laboratory within 30 min or less. If delayed, typical parasite morphology may not be seen in blood collected using anticoagulants. Knott concentration procedure: Used primarily to detect microfilariae in the blood, especially when a light infection is suspected. The disadvantage of the procedure is that the microfilariae are killed by the formalin and are no longer motile. Membrane filtration technique: This technique, using Nuclepore filters, has proved highly efficient in demonstrating filarial infections when microfilaria are of low density. It has also been successfully used in field surveys.

EDTA, Ethylenediaminetetraacetic acid; *FA,* fluorescent antibody; *MIF,* merthiolate-iodine-formalin; *PVA,* polyvinyl alcohol; *SAF,* sodium acetate–acetic acid–formalin.

[a] A number of new stool fixatives are available; some use a zinc sulfate base rather than mercuric chloride. Some collection vials can be used as a single-vial system; both the concentration and permanent stained smear can be performed from the preserved stool. However, not all single-vial systems (proprietary formulas) provide material that can be used for fecal immunoassay procedures. A universal fixative is now available (TOTAL-FIX) that contains no formalin, mercury, or PVA.

Modified from Garcia LS. *Diagnostic Medical Parasitology*. 6th ed. Washington, DC: ASM Press; 2016.

environmental phase, these measures can be complex, especially if more than one reservoir species or environmental resource is involved.

A human parasitic infection can be initiated through a variety of mechanisms and pathways depending on the species of microorganism. Many parasites of the intestinal tract are transmitted through ingestion of the infective form of the parasite in contaminated food or water (e.g., *Giardia duodenalis, Cryptosporidium* spp., *Ascaris lumbricoides*). Other parasites can be transmitted from host to host through sexual means (venereal transmission) (e.g., *Trichomonas vaginalis*), through skin penetration of infective larvae (e.g., *Strongyloides stercoralis,* hookworm), or through the bites of various arthropods (e.g., *Plasmodium, Trypanosoma, Leishmania*) (Table 46.4).

Pathogenesis and Spectrum of Disease

Although a number of parasites can cause serious and life-threatening disease, particularly in compromised patients, many organisms reach a "status quo" with the host and cause no significant damage. Obvious disease symptoms may not be the ultimate outcome of infection. Depending on the parasite, one or multiple body sites may be infected. Some parasitic infections can result in few or no symptoms, whereas infection with other parasites can result in devastating permanent damage and eventual death of the host. Some parasites multiply in the human body, whereas others mature but do not increase in number inside the body. These life-cycle differences play important roles in pathogenicity and disease outcome. It is also important to remember that a patient who is debilitated or immunocompromised (including the very young and the very old) may react differently to a parasitic infection than a healthy adult.

Certainly, it is not to the parasite's advantage to damage the host to the extent that severe illness or death results; this makes survival of the parasite difficult at best. When this occurs, long-term survival of the parasite may depend on rapid and efficient transmission from host to host or the parasite's ability to survive within the environment without a live host.

It is important to understand the life cycle of parasites in terms of potential prevention and control as well as mechanisms of infectivity and disease outcome (Table 46.5). Table 46.6 lists mechanisms of pathogenesis and the spectrum of parasitic diseases. Specific guidelines for physician requests are presented in Table 46.7.

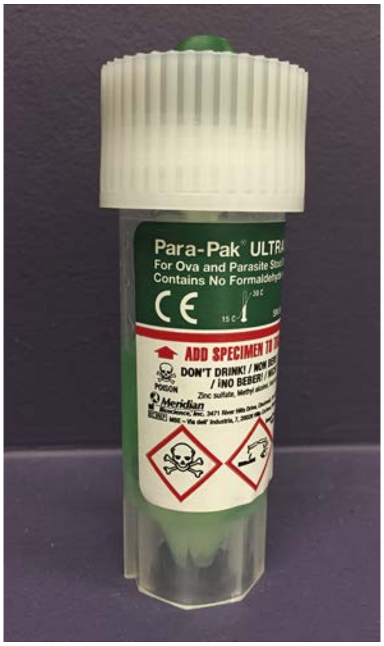
Laboratory Diagnosis

As with all laboratory testing, the ability to detect and correctly identify human parasites is directly linked to the quality of the clinical specimen, submission of the appropriate specimen or specimens, appropriate processing and handling before analysis, relevant diagnostic test orders, and the experience and training of laboratory personnel (Table 46.8). A summary of human parasites and applicable collection fixatives, clinical specimens, diagnostic tests, the elements of a positive finding, and comments are presented in Tables 46.9 and 46.10.

Specimen Collection and Transport

Depending on its stage of development in the clinical specimen (adult, larvae, eggs, trophozoites, cysts, oocysts, spores), a particular parasite may not be able to survive outside the host. For this reason, clinical specimens should be transported to the laboratory immediately to increase the likelihood of finding intact organisms. Because a lag time often occurs between collection of the specimen and its arrival in the laboratory, most facilities routinely use preservatives for collection and transport (Fig. 46.1). This approach ensures that any parasites present maintain their morphology and can be identified after processing.

Correct processing depends on the use of appropriate fixatives, immediate fixation upon collection of the specimen, and adequate mixing between the fixative and specimen (Table 46.9). It is mandatory that specimen collection guidelines be available in plain and direct language for health care personnel or patients performing specimen collection and that all clients recognize the importance of following such guidelines. In areas with non-native English speakers, alternate language versions should be readily available to provide clear directions for specimen collection. Specimen rejection criteria must be included as a part of the guidelines; guidelines must be followed and enforced to limit the possibility of reporting misleading or incorrect results. Detailed specimen descriptions and body sites, in addition to collection and transport information, are included in Table 46.3.



• **Fig. 46.1** Stool collection vial. Most laboratories recommend immediate placement of stool samples into a preservative such as this to preserve morphology.

TABLE 46.4 **Epidemiology of the More Common Groups of Human Parasites**

Parasite Group	Habitat (Reservoir)	Mode of Transmission	Prevention
Protozoa, Intestinal			
Amebae	Single-celled organisms generally found in humans. Although certain animals harbor some of these organisms, they are not considered important reservoir hosts.	Humans acquire infections by ingesting food and water contaminated with fecal material containing the resistant infective cyst stage of the protozoa. Various sexual practices have been documented in transmission.	Preventive measures include increased attention to personal hygiene, sanitation measures, and elimination of sexual activities that may involve fecal-oral contact.
Flagellates	The flagellates are generally found in humans. Although certain animals harbor some of these organisms, they are not considered important reservoir hosts; one exception may be animals such as the beaver that harbor *Giardia duodenalis*. Contaminated water supplies are also a source.	Humans acquire infections by ingesting food and water contaminated with fecal material containing the resistant infective cyst stage of the protozoa; the trophozoite forms may be transmitted from person to person in helminth eggs.	Preventive measures include increased attention to personal hygiene and sanitation measures, elimination of sexual activities that may involve fecal-oral contact, adequate water treatment (including filtration), and awareness of environmental sources of infection.
Ciliates	*Neobalantidium coli* is generally found in humans and pigs. In some areas of the world, pigs are considered important reservoir hosts.	Humans acquire infections by ingesting food and water contaminated with fecal material containing the resistant infective cyst stage of the protozoa.	Preventive measures include increased attention to personal hygiene and sanitation measures as well as the elimination of sexual activities that may involve fecal-oral contact.
Coccidia	Coccidia are found in humans. In some cases (e.g., cryptosporidiosis) animal reservoirs (cattle) can serve as important hosts. The muscle of various animals may contain sarcocysts that are infective for humans through the consumption of raw or poorly cooked meat. Numerous water-borne outbreaks with *Cryptosporidium* spp. have been reported throughout the world. Coccidian oocysts are extremely resistant to environmental conditions, particularly if kept moist.	These protozoa are acquired through ingestion of various meats or by fecal-oral transmission through contaminated food and/or water. The infective forms are called *oocysts* (*Cryptosporidium* spp.*, Cystoisospora belli, Cyclospora cayetanensis*) or *sarcocysts* (*Sarcocystis* spp.), which are contained in infected meat. Cryptosporidia have also been implicated in nosocomial infections.	Preventive measures include increased attention to personal hygiene and sanitation measures and elimination of sexual activities that may involve fecal-oral contact. Adequate water treatment (including filtration) is mandatory; awareness of environmental sources of infection is also important.
Microsporidia	Microsporidia can infect every living animal, some of which probably serve as reservoir hosts for human infection. However, host specificity has not been well defined. The spores are environmentally resistant and can survive for years if kept moist.	Infection with microsporidial spores usually occurs through ingestion; however, inhalation of spores and direct inoculation from the environment almost certainly occur.	Preventive measures include increased attention to personal hygiene and sanitation measures, increased awareness of environmental exposure possibilities, and adequate water treatment.
Protozoa, Other Sites			
Amebae	Free-living amebae are associated with warm, freshwater environments; they are also found in soil. Although humans can harbor these organisms, person-to-person transfer is rare. Environmental sources are the primary link to human infection. Contaminated eye care solutions have been linked to organisms that cause keratitis.	Infection occurs through contact with contaminated water; organisms enter through the nasal mucosa and may travel via the olfactory nerve to the brain. Disease can be very severe and life-threatening; keratitis is also caused by these organisms, and infection can be linked to blindness or severe corneal damage. Eye infections can be linked to contaminated lens solutions or direct accidental inoculation of the eye from environmental water and/or soil sources.	Prevention includes avoidance of contaminated environmental water and soil sources and adequate care of contact lens systems.

TABLE 46.4 Epidemiology of the More Common Groups of Human Parasites—cont'd

Parasite Group	Habitat (Reservoir)	Mode of Transmission	Prevention
Flagellates	*Trichomonas vaginalis* infection is found in a large percentage of humans; humans may present as symptomatic or asymptomatic. Person-to-person transfer is very common; reinfection is also common, particularly if sexual partners are not treated.	*T. vaginalis* is found in the genitourinary system and is usually acquired by sexual transmission.	Prevention involves awareness of sexual transmission; treatment of all partners is necessary when infection is diagnosed in an individual patient.
Protozoa, Blood and Tissue			
Malaria, babesiosis	Humans harbor the five species of malaria (*Plasmodium vivax, P. ovale, P. malariae, P. knowlesi,* and *P. falciparum*). Other animals can carry *Babesia* spp., and animal reservoir hosts play a large role in human transmission.	These organisms are borne by arthropods, *Plasmodium* spp. by the female anopheline mosquito and *Babesia* spp. by one or more genera of ticks. Infections can be transmitted transplacentally, via shared needles, through blood transfusions, and from organ transplants.	Prevention involves vector control and awareness of transmission through blood transfusions, shared drug needles, congenital infections, and organ transplants. Careful monitoring of the blood supply is necessary. Malaria prophylaxis is recommended for persons traveling to endemic areas.
Flagellates (leishmaniae)	Some strains of leishmaniae have reservoir hosts (e.g., dogs for the Mediterranean strain of *Leishmania donovani* and wild rodents for the African strains of *L. donovani*). *Leishmania tropica* has been linked to the same animal reservoirs.	Transmission is through the bite of infected sandflies. Infection can be spread person-to-person contact (cutaneous lesions), blood transfusions, shared needles, and organ transplants.	Prevention includes vector control, avoiding environmental sources (e.g., dogs, wild rodents), and careful handling of all clinical specimens from infected patients.
Flagellates (trypanosomes)	Humans are the only known hosts for *Trypanosoma brucei gambiense* (West African trypanosomiasis); *Trypanosoma brucei rhodesiense* (East African trypanosomiasis) infections are found in a number of antelope and other ungulates that act as reservoir hosts. Rodents and some mammals are reservoir hosts for *Trypanosoma cruzi*.	Transmission is through the bite of the infected tsetse fly and through blood transfusion, shared needles, and organ transplants. Transmission of *T. cruzi* is through the infected feces of the triatomid bug; the bug takes a blood meal, immediately defecates, and the human host scratches the infected feces into the bite site; bug saliva contains an irritant that stimulates scratching.	Prevention relies on vector control and awareness of potential exposure/infection from blood sources (transfusions, shared needles, organ transplants). Laboratory accidents while handling infected blood have been reported.
Nematodes, intestinal	These roundworms generally do not have animal reservoirs relevant to human infection. One exception is the pig ascarid; human infections have been reported. These worms are found worldwide; *Ascaris lumbricoides* is probably the most common parasite in humans. *Strongyloides stercoralis* is particularly important as the causative agent of severe disease in the compromised host.	*A. lumbricoides* and *Trichuris trichiura* eggs must undergo development in the soil before they are infective; thus, children who play in the dirt are a particularly high-risk group. Ingestion of food and water contaminated with infective eggs is the primary route of infection. Hookworm and *S. stercoralis* infections are initiated by larval penetration of the skin from contaminated soil. Pinworm infection *(E. vermicularis)* is acquired through ingestion of infective eggs from the environment (hand-to-mouth).	Prevention includes avoiding ingestion of contaminated soil and/or avoiding frequenting soil contaminated with hookworm eggs (pets, soil, water, warmth, warm weather); treatment for pinworm is recommended, but reinfection is common.

Continued

TABLE 46.4 **Epidemiology of the More Common Groups of Human Parasites—cont'd**

Parasite Group	Habitat (Reservoir)	Mode of Transmission	Prevention
Nematodes, tissue	*Trichinella* spp. have a number of animal reservoir hosts, including bears, walruses, pigs, rodents, and other animals. Dog and cat hookworms cause cutaneous larva migrans (CLM), and the dog and cat ascarid, *Toxocara* spp., causes visceral and ocular larva migrans (VLM, OLM). These infections can be serious and cause severe disease if not treated.	*Trichinella* organisms are acquired by ingestion of raw or poorly cooked infected meat. CLM is caused by skin penetration of infective larvae from the soil; children should avoid sandboxes where dogs and cats are known to defecate. Larval migration is limited to the skin. VLM and OLM are caused by accidental ingestion of *Toxocara* spp. eggs from contaminated soil; larval migration occurs throughout the body, including the eyes.	Preventive measures include adequate cooking of infected meat; awareness of possibility of contaminated soils for dog and cat hookworms and/or ascarids; and covering of all sandboxes where pets have access to defecate and children play.
Nematodes, filarial	*Wuchereria bancrofti, Loa loa*, and *Onchocerca volvulus* have no animal reservoirs and are found only in humans, whereas *Brugia* spp. can be found in cats and monkeys. *Dracunculus medinensis* can infect dogs, cats, monkeys, and humans.	Filarial nematodes are transmitted through the bite of a blood-sucking arthropod (midges, mosquitoes, and flies). *Dracunculus* infections are acquired through ingestion of water contaminated with small crustaceans, *Cyclops* spp., which contain infective larvae.	Prevention involves vector control and protection of well-water sources.
Cestodes, intestinal	The human serves as the definitive host for beef *(Taenia saginata)* and pork *(Taenia solium)* tapeworms; cows/camels and pigs serve as intermediate hosts, respectively. Humans also serve as the intermediate host for *T. solium* (cysticercosis). *Diphyllobothrium latum* adult tapeworms can be found in a number of wild animals, the most important being dogs, bears, seals, and walruses, which serve as reservoir hosts; humans are the definitive host. *Hymenolepis nana* (dwarf tapeworm) can occur in rodents; humans can serve as both intermediate and definitive hosts, with development from the egg to adult worm occurring in the human intestine.	Human infection with the adult worm occurs through ingestion of raw or poorly cooked meat (beef, camel, pork) containing the intermediate forms, the cysticerci. Humans become the accidental intermediate host when eggs from an adult *T. solium* tapeworm are ingested. The cysticerci develop in the muscle and tissues of the human rather than the pig. Infection with the adult *D. latum* tapeworm occurs through ingestion of poorly cooked freshwater fish containing the sparganum or plerocercoid larval form. Infection with *H. nana* is primarily acquired through accidental ingestion of eggs from an adult tapeworm.	Preventive measures involve adequate cooking of infected meat and treatment of patients harboring adult tapeworms (accidental ingestion of eggs can lead to infection).
Cestodes, tissue	Adult worms are found in a variety of animals; the human becomes the accidental intermediate host after ingestion of eggs from the adult worms. Reservoir hosts include dogs, cats, and rodents.	Ingestion of certain tapeworm eggs or accidental contact with certain larval forms can lead to tissue infection with *Taenia solium, Echinococcus* spp., and several others.	Preventive measures involve increased attention to personal hygiene and sanitation measures.
Trematodes, intestinal	Fish-eating wild and domestic animals serve as reservoir hosts. The definitive host of *Fasciolopsis buski* is the pig.	Ingestion of water chestnut and caltrop (raw, peeled with the teeth) is the source of infection; metacercariae are encysted on the plant material. Pig feces are used to fertilize various water plant crops.	Preventive measures include avoiding eating raw water plants that may contain encysted larval forms of the flukes and adequate waste disposal of farm animal feces (pigs).

TABLE 46.4 Epidemiology of the More Common Groups of Human Parasites—cont'd

Parasite Group	Habitat (Reservoir)	Mode of Transmission	Prevention
Trematodes, liver, lung	Cats, dogs, and wild fish-eating mammals can serve as reservoir hosts for *Opisthorchis* spp., *Clonorchis sinensis*, and *Paragonimus* spp. *Fasciola hepatica* is normally a parasite of sheep, and *Fasciola gigantica* is a parasite of cattle; humans are accidental hosts.	Infection occurs through ingestion of encysted metacercariae in raw or poorly cooked fish, crabs, crayfish, and on plants. Infection with *Fasciola* spp. is not easily acquired (the parasite is not that well adapted to the human host).	Prevention requires thorough cooking of potentially infected fish, crabs, crayfish and avoiding eating raw water plants that may contain encysted metacercariae.
Trematodes, blood	*Schistosoma mansoni* and *S. haematobium* appear to be restricted to the human host; *S. japonicum* can be found in cattle, deer, dogs, and rodents; *S. mekongi* is found in dogs and rodents. The worms mature in the blood vessels, and eggs make their way outside the body in stool and/or urine. The freshwater snail is a mandatory part of the life cycle (contains developmental forms of schistosome).	Infection occurs through skin penetration by infected cercariae released from a freshwater snail containing the intermediate stages of the schistosome life cycle. Cercariae can be released from the snail intermediate host singly or in groups.	Prevention involves protection from potentially contaminated water sources; awareness of mode of transmission; and proper handling of human waste containing eggs (continued infection of snail intermediate hosts).

TABLE 46.5 Parasitic Infections: Clinical Findings in Normal and Compromised Hosts

Organism	Normal Host	Compromised Host
Entamoeba histolytica	Asymptomatic to chronic-acute colitis, extraintestinal disease may also occur (primary site: right upper lobe of liver).	Diminished immune capacity may lead to extraintestinal disease.
Free-living amebae *Naegleria fowleri* *Acanthamoeba* spp. *Balamuthia mandrillaris* *Sappinia* spp.	Patients tend to have eye infections with *Acanthamoeba* spp. linked to poor lens care.	Primary amoebic meningoencephalitis (PAM); granulomatous amebic encephalitis (GAE).
Giardia duodenalis	Asymptomatic to malabsorption syndrome.	Certain immunodeficiencies tend to predispose an individual to infection.
Toxoplasma gondii	Approximately 50% of individuals have antibody and organisms in tissue but are asymptomatic. It is important to note that a developing fetus may be severally affected if the mother is infected; this is highly dependent on the time (trimester) when the infection occurs.	Disease in compromised hosts tends to involve the central nervous system (CNS), with various neurologic symptoms; it can mimic neurologic symptoms of infection with the human immunodeficiency virus (HIV).
Cryptosporidium spp. *Cryptosporidium hominis* (humans) *Cryptosporidium parvum* (humans and animals)	Self-limiting infection with diarrhea and abdominal pain.	Because of the autoinfective nature of the life cycle, infection is not self-limiting and may produce fluid loss of more than 10 L/day; multisystem involvement may occur. No effective therapy is available.
Cyclospora cayetanensis	Self-limiting infection with diarrhea (3–4 days); relapses common.	Diarrhea may persist for 12 weeks or longer; biliary disease has also been reported in this group, particularly those with acquired immunodeficiency syndrome (AIDS).

Continued

TABLE 46.5 Parasitic Infections: Clinical Findings in Normal and Compromised Host—cont'd

Organism	Normal Host	Compromised Host
Cystoisospora belli	Self-limiting infection with mild diarrhea or no symptoms.	May lead to severe diarrhea, abdominal pain, and possibly death (rare case reports); diagnosis occasionally may be missed because of failure to recognize the oocyst stage; is not seen when concentrated from polyvinyl alcohol (PVA) fixative.
Sarcocystis spp.	Self-limiting infection with diarrhea or mild symptoms.	Symptoms may be more severe and last for a longer period.
Microsporidia *Anncaliia* *Nosema* *Vittaforma* *Encephalitozoon* *Enterocytozoon* *Pleistophora* *Trachipleistophora* *"Microsporidium"*	Little is known about these infections in the normal host. Most infections have been identified as causing intestinal symptoms *(Enterocytozoon, Encephalitozoon)* or eye infections *(Vittaforma, Encephalitozoon).*	Organisms infect various parts of the body; diagnosis often depends on histologic examination of tissues; routine examination of clinical specimens (e.g., stool, urine) is becoming more common; infection can probably cause death.
Leishmania spp.	Asymptomatic to mild disease. Depending on species, infection can result in cutaneous, diffuse cutaneous, or mucocutaneous disease.	More serious manifestations of visceral leishmaniasis; some cutaneous species manifest visceral disease; infection is difficult to treat and manage; definite coinfection with AIDS.
Strongyloides stercoralis	Asymptomatic to mild abdominal complaints; can remain latent for many years because of low-level infection maintained by internal autoinfective life cycle.	Can result in disseminated disease (hyperinfection syndrome resulting from autoinfective nature of life cycle); abdominal pain, pneumonitis, sepsis-meningitis with gram-negative bacilli, eosinophilia; distinct link to certain leukemias or lymphomas; can be fatal.
Crusted (Norwegian) scabies	Infections can range from asymptomatic to moderate itching.	Severe infection with reduced itching response; hundreds of thousands of mites on the body; infection is very easily transferred to others; secondary infection is common.

TABLE 46.6 Pathogenesis and Spectrum of Parasitic Diseases

Parasite Group	Pathogenesis	Spectrum of Disease
Protozoa, Intestinal		
Amebae	Pathogens can cause severe disease; however, exposure does not always lead to disease; infection may be self-limiting; disease more likely in the compromised host.	Nonpathogens cause no disease, patients are asymptomatic; *Entamoeba histolytica* causes intestinal symptoms (bloody diarrhea) and the potential for amoebic liver abscess; other tissues may be involved, especially in the immunocompromised patient. "*Blastocystis hominis*" comprises a number of strains, some considered pathogenic; patients' conditions range from asymptomatic to severe diarrhea.
Flagellates	Not all patients are infected upon exposure; disease spectrum varies; some patients may remain asymptomatic; if nonexposed patients become infected, symptoms are much more likely to occur.	Nonpathogens cause no disease, patients are asymptomatic; *Giardia duodenalis* (malabsorption syndrome) and *Dientamoeba fragilis* cause intestinal symptoms ranging from "indigestion" to nonbloody diarrhea, cramping, gas, and so on.
Ciliates	*Neobalantidium coli* infection is rare in the United States; people who have regular contact with pigs are much more likely to become infected; wide range of symptoms.	*N. coli* causes intestinal symptoms, including severe watery diarrhea, similar to coccidial and microsporidial infections.

TABLE 46.6 **Pathogenesis and Spectrum of Parasitic Diseases—cont'd**

Parasite Group	Pathogenesis	Spectrum of Disease
Coccidia	All coccidia infective to humans can cause severe disease, particularly in the immunocompromised patient; infections in the immunocompetent patient tend to be self-limiting; *Cryptosporidium* spp. can maintain the infective cycle in the patient as a result of the autoinfective portion of the life cycle (the immunocompromised patient cannot produce antibody to limit this autoinfective cycle); huge water-borne outbreaks have been documented for *Cryptosporidium* spp.; infecting dose is low for *Cryptosporidium* spp.	*Cryptosporidium* spp., *Cyclospora cayetanensis,* and *Cystoisospora belli* cause intestinal symptoms, including severe watery diarrhea; infections are more severe in immunocompromised patients. Life-threatening infections can be seen with *Cryptosporidium* spp.; the organisms can disseminate to other tissues, primarily the lung. *Sarcocystis* can cause intestinal symptoms and/or muscle pain, depending on the mode of infection (ingestion of oocysts or infected meat).
Microsporidia	A number of genera are pathogenic for humans and for animals; wide range of body sites; disease varies, depending on patient's immune status; disease outcome is complicated by lack of treatment for some genera; albendazole is effective for *Encephalitozoon* spp.	Every human tissue may be infected; *Enterocytozoon bieneusi* and *Encephalitozoon intestinalis* are the most common and are found in the intestinal tract; the latter can also disseminate to other tissues, including the kidneys. Eye infections have been seen in both healthy and compromised patients; severe corneal infections seen.
Protozoa, Other Sites		
Amebae	Pathogenic for humans; disease ranging from acute meningoencephalitis to chronic encephalitis, cutaneous infections to keratitis, and the potential for other body sites; disease spectrum depends on patient's immune capacity and the organism involved; disease can be mild (*Acanthamoeba* spp.) to fatal *(Naegleria fowleri)*.	Infection occurs through contact with contaminated water; organisms enter through the nasal mucosa and may travel via the olfactory nerve to the brain. Disease caused by *N. fowleri* can be severe and life-threatening (primary amoebic meningoencephalitis [PAM)]; chronic granulomatous amoebic encephalitis (GAE) can be caused by *Acanthamoeba* spp. and *Balamuthia mandrillaris;* keratitis is also caused by these organisms, and infection can be linked to blindness or severe corneal damage. Eye infections can be linked to contaminated lens solutions or to direct, accidental inoculation of the eye from environmental water and/or soil sources.
Flagellates	*Trichomonas vaginalis* causes genitourinary disease, depending on vaginal pH, presence or absence of other organisms, sexual practices, and other factors. Disease can vary from mild to severe.	*T. vaginalis* is found in the genitourinary system and is usually acquired by sexual transmission. Disease can be asymptomatic in the male but can cause pain, itching, and discharge in females; some strains of drug-resistant *Trichomonas* have been documented.
Protozoa, Blood and Tissue		
Malaria, babesiosis	*Plasmodium vivax, Plasmodium falciparum, Plasmodium ovale, Plasmodium knowlesi,* and *Plasmodium malariae* are pathogenic for humans; *P. falciparum* malaria is the leading cause of death in endemic areas; although the host can develop antibody, protection is strain specific and short-lived.	Malaria can cause a range of symptoms, with life-threatening illness caused by *P. falciparum/P. knowlesi;* symptoms include fever, chills, nausea, and central nervous system (CNS) symptoms; *Babesia* infections often mimic those seen with malaria but without the fever periodicity.
Flagellates (leishmaniae)	*Leishmania donovani* invades the spleen, liver, and bone marrow and can cause serious disease, particularly in compromised hosts.	Leishmaniasis can infect the skin and mucous membranes and the organs of the reticuloendothelial system; symptoms can be mild to life threatening.
Flagellates (trypanosomes)	Humans are the only known hosts for *Trypanosoma brucei gambiense* (West African trypanosomiasis); *Trypanosoma brucei rhodesiense* (East African trypanosomiasis) infections are found in a number of antelope and other hoofed mammals that serve as reservoir hosts. *Trypanosoma cruzi* (American trypanosomiasis) can be found in rodents and chickens.	*T. brucei gambiense* and *T. brucei rhodesiense* cause African sleeping sickness, with eventual invasion of the CNS, leading to coma and death; Chagas disease (*T. cruzi*) causes acute to chronic problems, primarily linked to cardiac disease and diminished cardiac capacity; the muscles of the gastrointestinal (GI) tract are also infected, leading to loss of function in terms of movement of food through the GI tract.

Continued

TABLE 46.6 **Pathogenesis and Spectrum of Parasitic Diseases—cont'd**

Parasite Group	Pathogenesis	Spectrum of Disease
Nematodes, intestinal	These worms can cause mild to severe disease, depending on the worm burden (original number of eggs ingested or infective larvae penetrating the skin); young children and debilitated patients are more likely to be symptomatic; severe infections are seen in hyperinfections caused by *Strongyloides stercoralis* (autoinfective life cycle and immunocompromised patients); outcome varies tremendously from patient to patient and depends on the original infective dose.	*Ascaris lumbricoides, Trichuris trichiura*, and hookworm symptoms range from none to diarrhea, pain, and so on, depending on the worm burden; anemia may be seen with severe hookworm infection; *S. stercoralis* infections can involve many body tissues (disseminated disease) in the immunocompromised patient and can cause death; pinworm infection *(Enterobius vermicularis)* symptoms range from none to anal itching, irritability, loss of sleep, and so on.
Nematodes, tissue	Depending on the infective dose, *Trichinella* spp. can cause mild to severe disease; both cutaneous larva migrans (CLM) (dog/cat hookworm larvae) and toxocariasis (visceral larva migrans [VLM], ocular larva migrans [OLM]) through ingestion of dog/cat ascarid eggs cause serious disease if not treated; CLM, VLM, and OLM are seen in children more than adults.	*Trichinella* spp. can cause eosinophilia, muscle aches and pains, and death, depending on the worm burden; CLM can cause severe itching and eosinophilia as a result of larval migration in the skin; VLM and OLM are caused by larval migration throughout the body, including the eyes (mimics retinoblastoma).
Nematodes, filarial	*Wuchereria bancrofti, Loa loa*, and *Onchocerca volvulus* cause human disease; however, some filarial infections are not well adapted to humans and require many years of exposure before disease is evident; some infections are not evident, some cause multiple disease manifestations.	Symptoms range from asymptomatic to elephantiasis, blindness, skin changes, lymphadenitis, and lymphangitis; in some cases, Loeffler syndrome may also be seen.
Cestodes, intestinal	The beef *(Taenia saginata)*, pork *(Taenia solium)*, and freshwater fish *(Diphyllobothrium latum)* tapeworms infect humans and are generally found in the intestine as a single worm. In the case of cysticercosis, ingestion of *T. solium* eggs can cause mild to severe disease, depending on the infecting dose and body site (muscle, CNS). *Hymenolepis nana* (dwarf tapeworm) infection can lead to many worms in the intestinal tract (autoinfective cycle; the organism can go from egg to larval form to adult in the human host).	Human infection with the adult tapeworm can cause no symptoms, or mild intestinal symptoms may occur. When the human becomes the accidental intermediate host for *T. solium*, CNS symptoms may occur, including epileptic seizures. Infection with the adult *D. latum* tapeworm can cause intestinal symptoms, such as pain, diarrhea, and so on, but the patient may also be asymptomatic; a vitamin B_{12} deficiency may be seen. Infection with *H. nana* is primarily acquired from accidental ingestion of eggs from an adult tapeworm; symptoms may be absent, or diarrhea may be present.
Cestodes, tissue	*Echinococcus* spp. can cause severe disease, depending on the original infecting dose of tapeworm eggs; multiple organs can be involved, including brain, liver, lung, and bone; some cysts grow like a metastatic tumor; surgical removal can be very difficult if not impossible.	Depending on the body site, hydatid cysts can cause pain, anaphylactic shock (fluid leakage), or CNS symptoms. The patient may be unaware of infection until a cyst begins to press on other body organs or a large fluid leak occurs.
Trematodes, intestinal	Many genera and species are pathogenic for humans; disease severity depends on the infective dose of metacercariae; some patients may be unaware of the infection.	Intestinal trematodes can cause pain and diarrhea; intestinal toxicity can sometimes be seen in heavy infections with *Fasciolopsis buski*.
Trematodes, liver and lung	Many genera and species are pathogenic for humans; disease severity depends on the infective dose of metacercariae; some patients may be unaware of the infection.	*Paragonimus* spp. infection in the lungs can be severe, resulting in coughing, shortness of breath, and other symptoms; liver fluke infection can involve the bile ducts and gallbladder; symptoms depend on worm burden.
Trematodes, blood	Schistosomes are pathogenic for humans; however, the loading dose of cercariae from infected water sources determines the outcome of disease; very light infections may not produce symptoms; heavy infections can lead to death.	Symptoms may range from asymptomatic in light infections to severe organ failure resulting from deposition of eggs and subsequent granuloma formation in the tissues; "pipe-stem" fibrosis is seen in blood vessels; collateral circulation may develop; severe disease can cause death.

TABLE 46.7 Recommendations for Stool Testing

Patient and/or Situation	Test Ordered[a]	Follow-Up Test
Patient with diarrhea and acquired immunodeficiency syndrome (AIDS) or other cause of immune deficiency. Potential water-borne outbreak (municipal/city water supply).	*Cryptosporidium* or *Giardia/Cryptosporidium* immunoassay.	If immunoassays are negative and symptoms continue, special tests for microsporidia (modified trichrome stain) and other coccidia (modified acid-fast stain), in addition to ova and parasites (O&Ps) examination, should be performed.
Patient with diarrhea (nursery school, day care center, camper, backpacker). Patient with diarrhea and potential water-borne outbreak (resort setting). Patient with diarrhea from areas where *Giardia* sp. is the most common parasite found.	*Giardia* or *Giardia/Cryptosporidium* immunoassay (perform testing on two stools before reporting as negative). Particularly relevant for areas of the United States where *Giardia* sp. is the most common organism found.	If immunoassays are negative and symptoms continue, special tests for microsporidia and other coccidia (see previous entry) and O&P examination should be performed.
Patient with diarrhea and relevant travel history. Patient with diarrhea who is a past or present resident of a developing country. Patient in an area of the United States where parasites other than *Giardia* sp. are found.	O&P examination, *Entamoeba histolytica* immunoassay; various tests for *Strongyloides* spp. may be relevant (even in the absence of eosinophilia).	If examinations are negative and symptoms continue, special tests for coccidia and microsporidia should be performed.
Patient with unexplained eosinophilia and possible diarrhea; if chronic, patient may also have history of respiratory problems (larval migration) and/or sepsis or meningitis (hyperinfection).	Although the O&P examination is a possibility, the agar plate culture for *Strongyloides stercoralis* is recommended (it is more sensitive than the O&P examination).	If tests are negative and symptoms continue, additional O&P examinations and special tests for microsporidia and other coccidia should be performed.
Patient with diarrhea (suspected food-borne outbreak).	Test for *Cyclospora cayetanensis* (modified acid-fast stain, autofluorescence).	If tests are negative and symptoms continue, special procedures for microsporidia and other coccidia and O&P examination should be performed.

[a] Depending on the particular immunoassay kit used, various single or multiple organisms may be included. Selection of a particular kit depends on many variables, such as clinical relevance, cost, ease of performance, training, personnel availability, number of test orders, training of physician clients, sensitivity, specificity, equipment, and time to result. Very few laboratories handle this type of testing in exactly the same way. Many options are clinically relevant and acceptable for good patient care. It is critical that the laboratory report indicate specifically which organisms could be identified using the kit; a negative report should list the organisms relevant to that particular kit.

Note: Two ordering/collection/processing/examination situations are considered STAT orders (i.e., they require immediate attention for potentially life-threatening situations): central nervous system (CNS) specimens to be examined for free-living amebae and blood films in potential malaria or other cases involving blood parasites.

Specimen Processing

Diagnostic parasitology procedures designed to detect organisms in clinical specimens typically depend on morphologic criteria and visual identification (Evolve Procedures 46.1 to 46.10). Many clinical specimens, such as those from the intestinal tract, contain numerous artifacts that complicate the differentiation of parasites from surrounding debris. Specimen preparation may require concentration methods designed to increase the chance of finding the organism(s) by removing some fecal debris. Microscopic examination requires review of the prepared clinical specimen using multiple magnifications; organism identification also depends on the skill of the microbiologist. Final identification is based on microscopic examination of stained preparations to identify key characteristics of the parasite form. (Table 46.3 includes specific details on specimen processing.)

Approach to Identification

Protozoa are small, ranging from 1.5 µm (microsporidia) to approximately 80 µm (*Neobalantidium coli,* a ciliate) in size. Some are intracellular and require multiple detection and staining methods for identification. Helminth infections are usually diagnosed by finding eggs, larvae, and/or adult worms in various clinical specimens, primarily from the intestinal tract (Fig. 46.2). Identification to the species level may require microscopic examination of the specimen. Recovery and identification of blood parasites can require concentration, culture, and microscopy. Confirmation of suspected parasitic infections depends on the proper collection, processing, and examination of clinical specimens; often multiple specimens may be necessary to find and confirm the existence of a parasitic infection and the identity of the suspected organism or organisms (Table 46.10).

TABLE 46.8 **Stool Specimen Collection and Testing Options**

Option	Pros	Cons
Rejection of stools from inpatients who have been in house for longer than 3 days.	Data suggest that patients who begin to have diarrhea after they have been inpatients for a few days are not symptomatic from parasitic infections but generally from other causes.	The chance always exists that the problem is related to a health care–associated (nosocomial) parasitic infection (rare); *Cryptosporidium* spp. and microsporidia may be possible considerations.
Examination of a single stool (ova and parasites [O&Ps]). Data suggest that 40%–50% of organisms present are found with only a single stool examination. Two O&Ps examinations (concentration, permanent stained smear) are acceptable but not always as good as three specimens (may be a relatively cost-effective approach); any patient remaining symptomatic requires additional testing.	Some believe that most intestinal parasitic infections can be diagnosed from examination of a single stool. If the patient becomes asymptomatic after collection of the first stool, subsequent specimens may not be necessary.	Diagnosis from a single stool examination depends on the experience of the laboratory scientist, proper collection, and the parasite load in the specimen. In a series of three stool specimens, commonly all three specimens are not positive and/or may be positive for different organisms.
Examine a second stool only after the first is negative and the patient is still symptomatic.	With additional examinations, yield of protozoa increases (*Entamoeba histolytica,* 22.7%; *Giardia lamblia,* 11.3%; and *Dientamoeba fragilis,* 31.1%).	Assumes the second (or third) stool is collected within the recommended 10-day period for a series of stools; protozoa are shed periodically. May be inconvenient for patient.
Examination of a single stool and an immunoassay (enzyme immunoassay [EIA], fluorescent antibody [FA], lateral or vertical flow cartridge). This approach is a mix: one immunoassay may be acceptable; however, immunoassay testing of two separate specimens may be required to confirm the presence of *Giardia* antigen. One O&P examination is generally insufficient.	If the examinations are negative and the patient's symptoms subside, probably no further testing is required.	Patients may show symptoms (off and on), so ruling out parasitic infections with only a single stool and one fecal immunoassay may be difficult. If the patient remains symptomatic, then even if two *Giardia* immunoassays are negative, other protozoa may be missed (*Entamoeba histolytica/Entamoeba dispar* group, *Dientamoeba fragilis, Cryptosporidium* spp., microsporidia). It is not recommended to perform both the O&P and fecal immunoassay automatically as a stool examination for parasites.
Pool three specimens for examination; perform one concentration and one permanent stain (the laboratory pools the specimens).	Three specimens are collected by the patient (three separate collection vials) over 7–10 days; pooling by the laboratory may save time and expense.	Organisms present in low numbers may be missed because of the dilution factor once the specimens have been pooled.

Microscopic Examination

High-quality clinical-grade binocular compound brightfield microscopes, kept in good working condition, are essential for examining specimens for parasites. Organism identification depends on morphologic differences found after careful examination using a regular brightfield microscope at low (100×), high dry (400×), and oil immersion (1000×) magnifications. The use of a 50× or 60× oil-immersion objective for scanning can be very helpful, particularly when the 50× oil and 100× oil-immersion objectives are side by side. The microscope should be set up using Köhler illumination, which maximizes the brightness and uniformity of the light that contacts the specimen, providing optimal viewing conditions.

A stereoscopic microscope is recommended for larger specimens (e.g., arthropods, tapeworm proglottids, various artifacts). The total magnification usually varies from approximately 10× to 45×, either with a zoom capacity or with fixed objectives (0.66×, 1.3×, 3×) used with 5× or 10× oculars. Depending on the density of the specimen or object to be examined, the light source must be directed from under the stage or onto the top of the stage.

Because size is an essential factor for the accurate description and identification of parasites, especially for the characterization of fecal protozoa, a stage micrometer and calibrated ocular must be used for final identification. The stage micrometer typically has a 0.1-mm line with increments every 0.01 mm. This stage micrometer line is then viewed using the ocular at each objective magnification on the microscope to calibrate the ocular's scaled line. This allows the microbiologist to determine the exact size of the parasitic element using the ocular (Fig. 46.3).

TABLE 46.9 **Fecal Fixatives Used in Diagnostic Parasitology (Intestinal Tract Specimens)**

Fixative	Concentration	Permanent Stained Smear Trichrome, Iron-Hematoxylin, Special Stains/*Coccidia* and *Microsporidia*	Immunoassays: *Giardia lamblia* *Cryptosporidium* spp.	Comments
5% or 10% formalin	Yes	No	Yes	Concentrations and IAs (EIA, FA, Rapids)
5% or 10% buffered formalin	Yes	No	Yes	Concentrations and IAs (EIA, FA, Rapids)
MIF	Yes	Polychrome IV stain	ND	No published data
SAF	Yes	Iron-hematoxylin best	Yes	Concentrations, permanent stains, and IAs (EIA, FA, Rapids)
Schaudinn's (Hg base) no PVA[a]	Rare	Yes	No	Permanent stains; Hg interferes with IAs; primarily used with fresh stool specimens (no fixative collection vials)
Schaudinn's (Hg base) with PVA[a]	Rare	Yes	No	Permanent stains; Hg and PVA interfere with IAs; considered gold standard fixative for permanent stains
Schaudinn's (Cu base) with PVA[b]	Rare	Yes	No	Permanent stains; PVA interferes with IAs; stains not as good as with Schaudinn's fixative using Hg or Zn
Schaudinn's (Zn base) with PVA[c]	Rare	Yes	No	Permanent stains; PVA interferes with IAs; the same fixative as TOTAL-FIX without PVA (see Commentary)
Ecofriendly ECOFIX (PVA)[d]	Rare	Yes	No	Permanent stains; PVA interferes with IAs; works best with ECOSTAIN; Wheatley's trichrome second best
Universal fixative,[e] ecofriendly TOTAL-FIX	Yes	Yes	Yes	No formalin, no mercury, no PVA; concentrations, permanent stains, special stains, fecal IAs

Commentary

The most common collection option (original public health approach) is a two-vial system: one vial of 5% or 10% formalin or buffered formalin and one vial of fixative containing the plastic adhesive polyvinyl alcohol (PVA). The formalin vial is used for concentration and fecal immunoassays, and the PVA vial is used for the permanent stained smear. Regulations for formalin originally were developed for industry, not the clinical laboratory, where amounts of formalin tend to be quite low. However, a laboratory using any amount of formalin must be monitored.

SEMIUNIVERSAL FIXATIVES

Examples of a semiuniversal fixative include sodium acetate–acetic acid–formalin (SAF) (no mercury or PVA; *contains formalin*) and ECOFIX (no mercury or formalin; *contains PVA*).

UNIVERSAL FIXATIVE

Currently, TOTAL-FIX is the only fixative that contains *no* formalin, *no* PVA, and *no* mercury. TOTAL-FIX can be used without adding PVA to the fixative; adequate drying time for smears before staining is the most important step (minimum of 1 hour in 37°C incubator; more time is required for thicker fecal smears). This fixative can be used for concentration, permanent stained smear, special stains for coccidia or microsporidia, and fecal immunoassays for *Giardia* and *Cryptosporidium* spp.

FORMALIN FIXATIVE

Formalin has been used for many years as an all-purpose fixative that is appropriate for helminth eggs and larvae and for protozoan cysts, oocysts, and spores. Two concentrations are commonly used: 5%, which is recommended for preservation of protozoan cysts, and 10%, which is recommended for helminth eggs

Continued

TABLE 46.9 Fecal Fixatives Used in Diagnostic Parasitology (Intestinal Tract Specimens)—cont'd

and larvae. Although 5% is often recommended for all-purpose use, most commercial manufacturers provide 10%, which is more likely to kill all helminth eggs. To help maintain organism morphology, the formalin can be buffered with sodium phosphate buffers (i.e., neutral formalin). Selection of specific formalin formulations is at the user's discretion. *Aqueous formalin permits examination of the specimen as a wet mount only, a much less accurate technique than a permanent stained smear for identifying intestinal protozoa.* However, the fecal immunoassays for *Giardia duodenalis* and *Cryptosporidium* spp. can be performed from the aqueous formalin vial. Fecal immunoassays for the *Entamoeba histolytica/E. dispar* group are limited to fresh or frozen fecal specimens or Cary-Blair transport medium. After centrifugation, special stains for the coccidia (modified acid-fast stains) and microsporidia (modified trichrome stains) can be performed from the concentrate sediment obtained from formalin-preserved stool material. Use of the sediment provides a more sensitive test.

OCCUPATIONAL SAFETY AND HEALTH ADMINISTRATION REGULATIONS ON THE USE OF FORMALDEHYDE

Formaldehyde has been in use for more than a century as a disinfectant and preservative, and it is found in a number of industrial products. Disagreement exists about the carcinogenic potential of lower levels of exposure, and epidemiologic studies of the effects of formaldehyde exposure among humans have given inconsistent results. Studies of industry workers with known exposure to formaldehyde report little evidence of increased cancer risk. In addition, people with asthma appear to respond no differently than healthy individuals after exposure to concentrations of formaldehyde up to 3 ppm. The federal Occupational Safety and Health Administration (OSHA) requires all workers to be protected from dangerous levels of vapors and dust. Formaldehyde vapor is the most likely air contaminant to exceed the regulatory threshold in a laboratory, particularly in anatomic pathology. Current OSHA regulations require vapor levels not to exceed 0.75 ppm (measured as a time-weighted average [TWA]) and 2 ppm (measured as a 15-minute short-term exposure). OSHA requires monitoring for formaldehyde vapor wherever formaldehyde is used in the work place. The laboratory must have evidence at the time of inspection that formaldehyde vapor levels have been measured. Both 8-hour and 15-minute exposures must have been determined.

If each measurement is below the permissible exposure limit and the 8-hour measurement is below 0.5 ppm, no further monitoring is required as long as laboratory procedures remain constant. If the 0.5-ppm, 8-hour TWA or the 2-ppm, 15-minute level is exceeded, monitoring must be repeated semiannually. If either the 0.75-ppm, 8-hour TWA or the 2-ppm, 15-minute level is exceeded (very unlikely in a routine microbiology laboratory setting), employees must be required to wear respirators. Accidental skin contact with aqueous formaldehyde must be prevented with the use of proper clothing and equipment (gloves, laboratory coats). The amendments of 1992 add medical removal protection provisions to supplement the existing medical surveillance requirements for employees suffering significant eye, nose, or throat irritation and for those experiencing dermal irritation or sensitization from occupational exposure to formaldehyde. In addition, these amendments establish specific hazard-labeling requirements for all forms of formaldehyde, including mixtures and solutions composed of at least 0.1% formaldehyde in excess of 0.1 ppm. Additional hazard labeling, including a warning label that formaldehyde presents a potential cancer hazard, is required where formaldehyde levels, under reasonably foreseeable conditions of use, may potentially exceed 0.5 ppm. The final amendments also provide for annual training of all employees exposed to formaldehyde at levels of 0.1 ppm or higher.

Note: The use of monitoring badges may not be a sensitive enough method to correctly measure the 15-minute exposure level. Contact the OSHA office in your institution for monitoring options. Usually, the accepted method involves monitoring airflow in the specific area or areas in the laboratory where formaldehyde vapors are found.

POLYVINYL ALCOHOL ADHESIVE (NOT A FIXATIVE)

PVA is a water-soluble, synthetic polymer used as a viscosity-increasing agent in pharmaceuticals, as an adhesive in parasitology fecal fixatives, and as a lubricant and protectant in ophthalmic preparations. PVA is defined as a water-soluble polymer made by hydrolysis of a polyvinyl ester (e.g., polyvinyl acetate). It is used in adhesives, as a textile and paper sizer, and for emulsifying, suspending, and thickening solutions. PVA is not a fixative, but rather an adhesive to help glue stool material onto the slide; this is the only purpose of PVA as an additive to parasitology fecal fixative formulations.

PVA is a plastic resin that is incorporated into Schaudinn's fixative. Although some laboratories may perform a fecal concentration from a PVA-preserved specimen, some parasites do not concentrate well, and some do not exhibit the typical morphology that would be seen in concentration sediment from a formalin-based fixative. PVA fixative solution is highly recommended as a means of preserving cysts and trophozoites for later examination. Use of PVA fixative also allows specimens to be shipped (by regular mail service) from any location in the world to a laboratory for examination. PVA fixative is particularly useful for liquid specimens and should be used in the ratio of three parts PVA to one part fecal specimen.

Note: Very detailed information on all fixative options can be found in Garcia LS. *Diagnostic Medical Parasitology*. 6th ed. Washington, DC: ASM Press; 2016.

Cu, Copper; *EIA,* enzyme immunoassay; *FA,* fluorescent antibody; *Hg,* mercury; *IA,* immunoassay; *MIF,* merthiolate-iodine-formalin fixative; *ND,* no data; *PVA,* polyvinyl alcohol; *Rapids,* cartridge-format, membrane-flow IAs; *SAF,* sodium acetate–acetic acid–formalin; *Zn,* zinc.

[a] These two fixatives use the mercuric chloride base in the Schaudinn's fixative; this formulation is still considered the gold standard against which all other fixatives are evaluated (organism morphology after permanent staining).

[b] This modification uses a copper sulfate base rather than mercuric chloride; the morphology of stained organisms is not as good as with Hg or Zn.

[c] This modification (proprietary formula) uses a zinc base rather than mercuric chloride and works well with both trichrome and iron-hematoxylin.

[d] This fixative uses a combination of ingredients but is prepared from a proprietary formula (contains PVA).

[e] This modification uses a combination of ingredients, including zinc, but is prepared from a proprietary formula. The aim is to provide a universal fixative that can be used for the fecal concentration, permanent stained smear, and available immunoassays for *Giardia duodenalis, Cryptosporidium* spp., and *Entamoeba histolytica.* However, currently, fecal immunoassays for the *E. histolytica* require fresh or frozen specimens; testing can also be performed from stool submitted in Cary-Blair transport medium.

Microscopy for parasitology is labor intensive and requires significant knowledge and skills for the identification of the organisms. Techcyte Inc. (Lindon, Utah), has developed a digital artificial intelligence system for identifying O&Ps from stool samples. The system preclassifies the slides by screening out negative samples before the technologist reviews the positive slides for organism identification. The system is designed to reduce technologist time and cost.

Intestinal Tract

Stool specimens are the most common specimen submitted to the diagnostic laboratory for parasite identification. As a result, the most commonly performed procedure in parasitology is the traditional examination for O&Ps, although the use of rapid fecal immunoassays and molecular techniques has greatly increased over the past 10 years. Several other diagnostic techniques are available for the recovery and identification of parasitic organisms from the intestinal tract. Although many laboratories do not routinely offer all these relatively simple and inexpensive techniques, the clinician should be familiar with the relevance of information obtained from them. It is rarely necessary to examine stool specimens for scolices and proglottids of cestodes and adult nematodes and trematodes in order to

TABLE 46.10 **Common Human Parasites: Diagnostic Specimens, Tests, and Positive Findings**

Organism	Infection Acquired	Location in Host	Diagnostic Specimen	Diagnostic Test[a]	Positive Specimen	Comments
Intestinal Amebae *Entamoeba histolytica* *Entamoeba bangladeshi* *Entamoeba dispar* *Entamoeba hartmanni* *Entamoeba coli* *Entamoeba moshkovskii* *Entamoeba polecki* *Endolimax nana* *Iodamoeba bütschlii* *Blastocystis hominis*	Ingestion of food or water contaminated with infective cysts; fecal-oral transmission.	Intestinal tract; *E. histolytica* infection may disseminate to the liver (extraintestinal amebiasis); *Blastocystis* strains are pathogenic or nonpathogenic; cannot differentiate on morphology.	Stool; sigmoidoscopy specimens.	O&Ps examination; stained sigmoidoscopy slides; stool immunoassays.	Trophozoites and/or cysts.	Many of the protozoa can look very much alike; see diagnostic tables for details; immunoassays for *E. histolytica/E. dispar* group and *E. histolytica* (fresh, frozen stool, Cary Blair required).
Free-Living Amebae *Naegleria fowleri* *Acanthamoeba* spp. *Balamuthia mandrillaris* *Sappinia* spp.	Contaminated water or soil; dust, contaminated eye solutions; organisms may enter through nasal mucosa, travel to brain via olfactory nerve.	CNS; eye.	CSF, corneal scrapings, biopsy, eye care solutions; CSF examination **STAT request.**	Stains, culture, FA, biopsy; *B. mandrillaris* cannot be grown on agar culture, whereas *N. fowleri* and *Acanthamoeba* species can.	Trophozoites or cysts.	CNS disease life threatening with *N. fowleri (PAM);* other CNS infections more chronic (GAE); keratitis can lead to blindness.
Intestinal Flagellates *Giardia duodenalis* *Dientamoeba fragilis* *Chilomastix mesnili* *Pentatrichomonas hominis*	Ingestion of food or water contaminated with infective cysts or trophozoites *(D. fragilis, T. hominis);* fecal-oral transmission.	Intestinal tract.	Stool; duodenal specimens or Entero-Test capsule (string test) for *Giardia duodenalis.*	O&P examination; wet preparations or stains of duodenal material; stool immunoassays (can use fresh or formalin fixed specimens; no PVA); need two specimens for IA for *G. duodenalis.*	Trophozoites or cysts	*G. duodenalis* is very difficult to recover; stool immunoassays are more sensitive than routine O&Ps examinations; *D. fragilis* requires permanent stain for identification.
Urogenital Flagellates *Trichomonas vaginalis*	Sexually transmitted; wet towels less likely but possible.	Urinary tract; genital system; males may be asymptomatic.	Vaginal secretions, prostatic fluid, often recovered in urine sediment	Wet preparations, culture, immunoassays; molecular testing.	Trophozoites	Often diagnosed by motility in urine sediment or wet preparations.
Intestinal Ciliate *Neobalantidium coli*	Ingestion of food or water contaminated with infective cysts; fecal-oral transmission.	Intestinal tract.	Stool.	O&Ps examination; wet preparations better than permanent stained smear.	Trophozoites and/or cysts	Not common in the United States; associated with pigs; seen in proficiency testing specimens.

TABLE 46.10 **Common Human Parasites: Diagnostic Specimens, Tests, and Positive Findings—cont'd**

Organism	Infection Acquired	Location in Host	Diagnostic Specimen	Diagnostic Test[a]	Positive Specimen	Comments
Intestinal Coccidia *Cryptosporidium* spp. *Cyclospora cayetanensis* *Cystoisospora belli*	Ingestion of food or water contaminated with infective oocysts; fecal-oral transmission.	Intestinal tract; *Cryptosporidium* spp. can disseminate to other tissues in compromised host (lung, gallbladder).	Stool; biopsy; duodenal specimen; sputum.	Modified acid-fast stains; stool immunoassays; concentration, wet prep for *C. belli.*	Oocysts in stool or scrapings; other developmental stages in tissues.	*Cryptosporidium* spp. cause severe diarrhea in compromised patient; nosocomial transmission.
Intestinal Microsporidia[b] *Enterocytozoon bieneusi* *Encephalitozoon intestinalis*	Ingestion of food or water contaminated with infective spores; fecal-oral transmission.	Intestinal tract; organisms can disseminate to other body sites (kidney).	Stool; biopsy.	Modified trichrome stains; optical brightening agents; experimental immunoassays; biopsy and histology (tissue Gram stains).	Spores in stool; other developmental stages in tissues.	Can cause serious diarrhea in compromised host.
Microsporidia; Other Body Sites *Encephalitozoon* spp. *Anncaliia vesicularum* *Microsporidium* *Pleistophora* *Trachipleistophora* *Vittaforma* *Tubulinosema*	Ingestion of food or water contaminated with infective spores; fecal-oral transmission; inhalation; direct environmental contact to eyes; probably hands to eyes.	All tissues.	All body fluids and/or tissues relevant, depending on *body* site.	Modified trichrome stains; optical brightening agents; experimental immunoassays; biopsy and histology (tissue Gram stains).	Spores in stool, urine, other body fluids; developmental stages in tissues.	Can cause serious diarrhea in compromised host; a number of eye infections documented in immunocompetent patients.
Tissue Protozoa *Toxoplasma gondii*	Ingestion of raw meat; oocysts from cat feces.	Eye, CNS in compromised patient.	Biopsies (any tissue), CSF.	Serology, tissue culture; recovery from CSF.	Positive serology; recovery of trophozoites in CSF.	Many people have positive serologies for *T. gondii;* infections are serious in immunocompromised patients.
Intestinal Nematodes *Enterobius vermicularis* *Trichuris trichiura* *Ascaris lumbricoides* Hookworm *Strongyloides stercoralis*	Ingestion of food or water contaminated with infective eggs; penetration of skin by infective larvae in soil.	Intestine; *S. stercoralis* may disseminate (hyperinfection), primarily in immunocompromised patients.	Stool; duodenal contents *(S. stercoralis);* cellophane tape preps or paddles for *E. vermicularis.*	O&Ps examination; special concentrates and cultures; examination of tapes for *E. vermicularis.*	Adult worms, eggs and/or larvae, depending on the roundworm involved.	Review direct and indirect life cycles (migration through heart, lung, trachea to intestine), 4–6 consecutive tapes required to rule out *Enterobius* infection.

TABLE 46.10 **Common Human Parasites: Diagnostic Specimens, Tests, and Positive Findings—cont'd**

Organism	Infection Acquired	Location in Host	Diagnostic Specimen	Diagnostic Test[a]	Positive Specimen	Comments
Tissue Nematodes						
VLM, OLM (*Toxocara* spp.)	Ingestion of infective eggs.	Migration through tissues.	Serum.	Serology.	Positive serology.	Human is accidental host for VLM, OLM, and CLM.
CLM (dog/cat hookworm)	Skin penetration of larvae.	Skin tracks, migration.	Visual inspection.	Presence of tracks/skin.	Eosinophilia, visual tracks.	
Trichinella spp.	Ingestion of raw pork.	Muscle.	Serum, muscle biopsy.	Serology, squash prep.	Positive serology, larvae.	Outbreaks still occur.
Anisakis, others	Ingestion of raw marine fish.	Intestine.	Submission of larvae.	ID of larvae.	Positive larval ID.	Sometimes identified only after surgical removal.
Intestinal Cestodes	Ingestion of:	Intestine.				Eggs for the two *Taenia* spp. look alike; gravid proglottid or scolex is needed for identification.
Taenia saginata (beef)	Raw beef.		Stool and/or proglottids.	O&Ps, India ink proglottids.	Eggs, proglottid branches.	
Taenia solium (pork)	Raw pork.		Stool and/or proglottids.	O&P, India ink proglottids.	Eggs, proglottid branches.	
Diphyllobothrium latum	Raw freshwater fish.		Stool and/or proglottids.	O&P.	Eggs, proglottid shape.	
Hymenolepis nana	Tapeworm eggs.		Stool.	O&Ps.	Eggs.	
Hymenolepis diminuta	Grain beetles.		Stool.	O&Ps.	Eggs.	
Dipylidium caninum	Fleas from dogs/cats.		Stool and/or proglottids.	O&Ps.	Eggs, proglottid shape.	
Tissue Cestodes	Ingestion of:					
Echinococcus granulosus	Eggs from dog tapeworm.	Liver, lung, and so on.	Serum, hydatid cyst aspirate; biopsy.	Serology, centrifugation of fluid; histology.	Positive serology; hydatid sand, tapeworm. Tissue.	*E. granulosus* (enclosed cyst).
Echinococcus multilocularis	Eggs from fox tapeworm.					*E. multilocularis* (cyst wanders through tissue).
Taenia solium (pork)	Eggs from human tapeworm.	CNS, subcutaneous tissues.	Serum, scans, biopsy.	Serology, films, histology.	Positive serology, positive scans, tapeworm tissue.	Small, enclosed cysticerci (cysticercosis).

TABLE 46.10 Common Human Parasites: Diagnostic Specimens, Tests, and Positive Findings—cont'd

Organism	Infection Acquired	Location in Host	Diagnostic Specimen	Diagnostic Test[a]	Positive Specimen	Comments
Intestinal Trematodes	Ingestion of metacercariae:					
Fasciolopsis buski	On water chestnuts.	Intestine.	Stool.	O&Ps examination; *M. yokogawai, H. heterophyes* eggs very small; use high dry power.	Eggs in stool.	Eggs of *F. buski* look identical to those of the liver fluke, *Fasciola hepatica*.
Metagonimus yokogawai	In raw fish.					
Heterophyes heterophyes						
Liver and Lung Trematodes	Ingestion of metacercariae.					
Fasciola hepatica	On watercress.	Liver.	Stool.	O&Ps.	Eggs in stool.	Eggs of *F. hepatica* look almost identical to those of *F. buski;* lung fluke eggs in sputum resemble brown metal filings.
Clonorchis sinensis	In raw fish.	Liver, bile ducts.	Stool, duodenal drainage.	O&Ps.	Eggs in stool, and so on.	
Paragonimus spp.	In raw crabs.	Lung.	Stool, sputum.	O&Ps.	Eggs in stool. and/or sputum.	
Blood Trematodes						
Schistosoma mansoni	Skin penetration of cercariae released from the freshwater snail intermediate host.	Veins over the large intestine.	Because the adult worms may become located in the "incorrect" veins, both urine and stool (unpreserved) should be examined.	O&Ps; hatching test for egg viability (all specimens collected with no preservatives); concentrates performed with saline, not water.	Eggs in stool and/or urine.	When schistosomiasis is suspected, stool, random urine, and 24-h urine specimen (collected with no preservatives).
Schistosoma haematobium		Bladder.				
Schistosoma japonicum; Schistosoma mekongi		Small intestine.				
Malaria		Preerythrocytic				
Plasmodium vivax	Infection through mosquito bite, blood transfusion, shared drug needles; transplacental.	Liver.	Drawn immediately: **STAT request.** Blood draw every 6 h until confirmed as positive or negative.	Thick, thin blood films; rapid immunoassay methods (not yet FDA approved in United States); concentration methods.	Parasites present.	*P. falciparum* and *P. knowlesi* infections are medical emergencies; complete patient history mandatory (travel, prophylaxis, prior history); Giemsa or other bloodstain recommended.
Plasmodium ovale		Blood.				
Plasmodium malariae		Blood.				
Plasmodium knowlesi		Blood.				
Plasmodium falciparum		Blood. Blood plus capillaries of deep tissues (spleen, liver, bone marrow).				
Babesiosis	Tick borne; transfusion; organ transplants.	Blood.	Blood.	Thick, thin blood films.	Parasites present.	Can mimic ring forms of *P. falciparum;* patient will have no travel history outside of United States.
Babesia spp.						

Continued

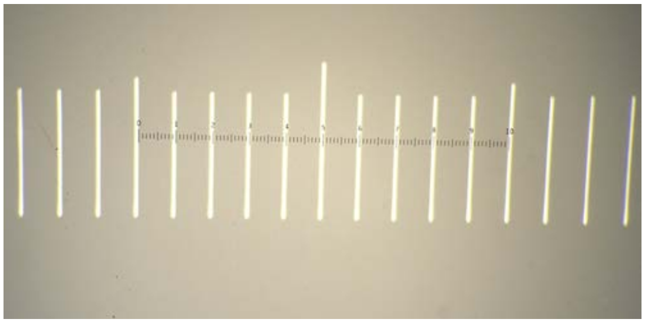
TABLE 46.10 **Common Human Parasites: Diagnostic Specimens, Tests, and Positive Findings—cont'd**

Organism	Infection Acquired	Location in Host	Diagnostic Specimen	Diagnostic Test[a]	Positive Specimen	Comments
Trypanosomes						
Trypanosoma brucei gambiense	Bite of tsetse fly.	Blood, lymph nodes, CNS.	Blood, node aspirate, CSF.	Thick, thin films.	Trypomastigotes.	African sleeping sickness more common with *T. brucei gambiense.*
Trypanosoma brucei rhodesiense	Bite of tsetse fly.	Blood, lymph nodes, CNS.		Thick, thin films.	Trypomastigotes.	
Trypanosoma cruzi	Feces of triatomid bug (kissing bug) (bug feces scratched into bite site).	Blood, striated muscle (e.g., heart, GI tract).	Blood, cardiac changes, muscle biopsy.	Thick, thin films, histology; culture.	Trypomastigotes in blood, amastigotes in tissue.	Chagas disease (American trypanosomiasis) (xenodiagnosis an option).
Leishmaniae						
Leishmania tropica complex (cutaneous)	Bite of sand fly.	Macrophages of skin.	Skin biopsy.	Stained smears, cultures.	Amastigotes in clinical specimens indicated.	Animal inoculation rarely used; some research labs now using PCR.
Leishmania braziliensis complex (mucocutaneous)		Skin, mucous membranes.	Skin, membrane biopsy.	Stained smears, cultures.		
Leishmania donovani complex (visceral)		Spleen, liver, bone marrow (RE system).	Blood, bone marrow, liver/spleen biopsy.	Thick, thin blood films; stained smears, cultures.		
Filarial Nematodes						
Wuchereria bancrofti (S)	Bite of mosquito.	Lymphatics (adults), blood (microfilariae), nodules (adults), skin, eye (microfilariae).	Blood.	Thick and thin films; various concentrations.	Microfilariae.	Elephantiasis possible; periodicity a factor in finding microfilariae; some microfilariae sheathed (S), some not (NS).
Onchocerca volvulus (NS)	Black fly.		Skin snips, blood; biopsy nodule.	Biopsy, tease skin apart in water; thick and thin films.	Microfilariae; adult in tissue nodules.	
Less Common						
Loa loa (S)	Black gnat.	Eye (adults), lymphatics (adults), blood (microfilariae) for all three.	Blood.	Thick, thin films; various concentrations.	Microfilariae, adult worm.	"African eye worm."
Brugia malayi (S)	Mosquito.				Microfilariae.	
Mansonella spp. (NS)	Mosquito.					

CLM, Cutaneous larva migrans; *CNS,* central nervous system; *CSF,* cerebrospinal fluid; *FA,* fluorescent antibody; *FDA,* Food and Drug Administration; *GAE,* granulomatous amoebic encephalitis; *IA,* immunoassay; *ID,* identification; *NS,* not sheathed; *OLM,* ocular larva migrans; *O&P,* ova and parasite; *PAM,* primary amoebic meningoencephalitis; *PCR,* polymerase chain reaction; *RE,* reticuloendothelium system; *S,* sheathed; *VLM,* visceral larva migrans

[a] Although serologic tests are not always mentioned, they are available for a number of parasitic infections. Unfortunately, most are not routinely available. Contact your state Public Health Laboratory or the Centers for Disease Control and Prevention (CDC) in Atlanta, Georgia.

[b] The microsporidia are classified with the fungi.



• **Fig. 46.3** Stage and ocular micrometer.

confirm the diagnosis or to identify the organism to the species level.

Other specimens from the intestinal tract—such as duodenal aspirates or drainage, mucus from the Entero-Test Capsule technique, and sigmoidoscopy material—can also be examined as wet preparations and as permanent stained smears after processing with trichrome or iron-hematoxylin staining.

Ova and Parasite Examination

The traditional O&Ps examination comprises three separate protocols: the direct wet mount, the concentration technique and indirect wet mount examination, and the permanently stained smear.

The **direct wet mount,** which requires fresh stool, is designed to enable the detection of motile protozoan trophozoites. The specimen is examined microscopically at low and high dry magnifications (100×, entire 22- by 22-mm cover slip; 400×, one-third to one-half of a 22- by 22-mm cover slip) (Box 46.1). However, because of potential problems resulting from the lag time between specimen passage and receipt in the laboratory, the direct wet examination has been eliminated from the routine O&Ps examination in many laboratories in the United States in favor of specimens collected in stool preservatives. The direct wet preparation is not performed for specimens received in the laboratory in preservatives. The various fixatives available are included in Table 46.9. Each preservative or combination of preservatives has advantages and disadvantages for different types of parasites and for different laboratory methods. Each laboratory should consider the types of parasites most commonly seen in their location and population and should select the preservatives that maximize the detection of such parasites.

The second part of the O&Ps is the **indirect** examination after specimen concentration, which is designed to facilitate recovery of protozoan cysts, coccidian oocysts, microsporidial spores, and helminth eggs and larvae (Box 46.2). Both flotation and sedimentation methods are available; the most common procedure is the formalin–ethyl acetate sedimentation method (previously the formalin-ether method) (Fig. 46.4). The concentrated specimen sediment can be examined as a wet preparation with or without iodine using low and high dry magnifications (100×, 400×) as indicated for the direct wet smear examination.

• BOX 46.1 Direct Smear: Review

Principle

To detect the presence of motile forms of parasites (primarily protozoan trophozoites or larvae); to diagnose organisms that cannot be identified from the permanent stain methods; to allow quick diagnosis of heavily infected patients; to estimate the worm burden of a patient.

Specimen

Any fresh liquid or soft stool specimen that has not been refrigerated or frozen.

Reagents

0.85% NaCl; Lugol's or D'Antoni's iodine.

Examination

Low-power examination (100×) of entire 22- by 22-mm cover slip preparation (both saline and iodine); high dry power examination (400×) of at least one-third of the cover slip area (both saline and iodine).

Results

Results from the direct smear examination should be considered presumptive. However, some organisms can be identified definitively (*Giardia duodenalis* cysts and *Entamoeba coli* cysts, helminth eggs and larvae, *Cystoisospora belli* oocysts). The report should be considered "preliminary"; the final report includes the results of the concentration and permanent stained smear.

Notes and Limitations

When iodine is added to the preparation, the organisms are killed and motility is lost. Specimens submitted in stool preservatives and fresh, formed specimens should not be examined using this procedure; the concentration and permanent stained smear techniques should be performed instead. Oil immersion examination (1000×) is not recommended (the organism morphology is not that clear).

The third part of the O&Ps examination is the permanently stained smear, which is designed to facilitate the identification of intestinal protozoa (Box 46.3). The permanently stained smear is the most important procedure performed to confirm the diagnosis of intestinal protozoan infections.

Several staining methods are available; the two most commonly used are the Wheatley modification of the Gomori tissue trichrome stain and the iron-hematoxylin stain (Fig. 46.5). This part of the O&PS examination is critical for confirmation of suspicious objects seen in the wet examination and for identification of protozoa that may not have been visible in the wet preparation. Permanently stained smears are examined using oil immersion objectives (600× or 800× for screening and 1000× for final review of 300 or more oil-immersion fields). The permanently stained smears also provide a permanent record for reexamination or confirmation.

Modified acid-fast stains are necessary for the identification of intestinal coccidia (Box 46.4), and modified trichrome stains are recommended for identification of

• BOX 46.2 Concentration: Review

Principle

To concentrate the parasites present, either through sedimentation or by flotation. The concentration is specifically designed to allow recovery of protozoan cysts, coccidian oocysts, microsporidian spores, and helminth eggs and larvae.

Specimen

Any stool specimen that is fresh or preserved in formalin (most common), polyvinyl alcohol (PVA; mercury based or non–mercury based), sodium acetate–acetic acid–formalin (SAF), merthiolate-iodine-formalin (MIF), or the newer fixatives for the single-vial system—universal fixatives containing no mercury, formalin, or PVA.

Reagents

Formalin, ethyl acetate, zinc sulfate 5% or 10% (specific gravity, 1.18 for fresh stool and 1.20 for preserved stool); 0.85% sodium chloride (NaCl); Lugol's or D'Antoni's iodine.

Examination

Low-power examination (100×) of entire 22- by 22-mm cover slip preparation (iodine recommended but optional); high dry power examination 400×) of at least one-third of the cover slip area (both saline and iodine).

Results

Results from the concentration examination should be considered presumptive. However, some organisms can be identified definitively (*Giardia duodenalis* cysts and *Entamoeba coli* cysts, helminth eggs and larvae, *Cystoisospora belli* oocysts). The report should be considered "preliminary" and should be coordinated with the findings from the permanent smear.

Notes and Limitations

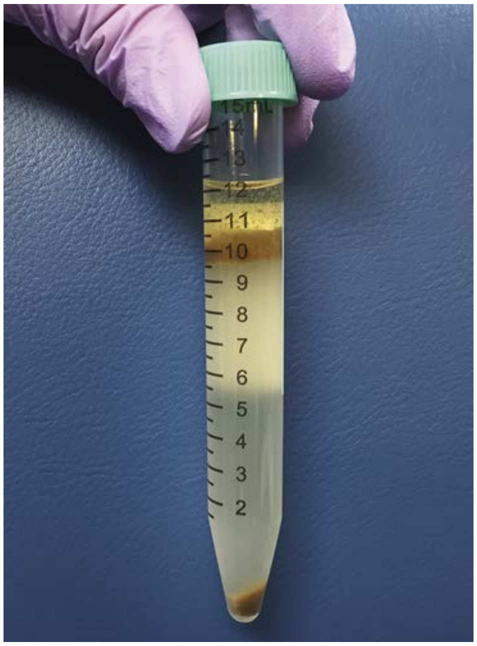
Formalin–ethyl acetate sedimentation concentration is most commonly used. Zinc sulfate flotation may not detect operculated or heavy eggs (*Clonorchis* eggs, unfertilized *Ascaris* eggs). For the flotation technique, both the surface film and sediment must be examined before a negative result is reported. Smears prepared from concentrated stool are normally examined at low power (100×) and high dry power (400×). Oil-immersion examination (1000×) may be used with caution because the morphology of some organisms may not be clear. The addition of too much iodine may obscure helminth eggs (i.e., it produces an effect that mimics debris).

intestinal microsporidia (Box 46.5). These stains are specifically designed to enable the identification of coccidian oocysts and microsporidian spores, respectively.

Fig. 46.6 provides a diagrammatic overview of the processing of fecal specimens for parasite identification.

Recovery of the Tapeworm Scolex

The procedure for the recovery of the tapeworm scolex is rarely requested in the United States and is no longer clinically relevant because of the effective use of medication to treat tapeworm infections. However, stool specimens may be examined for scolices and gravid proglottids of cestodes for species identification. This procedure requires mixing a small amount of feces with water and straining the mixture through a series of wire screens (graduated from coarse to fine mesh) to look for scolices and proglottids. The appearance of scolices after therapy is an indication of successful treatment. If the scolex has not been passed, it may still be attached to the mucosa. Because the scolex can continue to produce new proglottids, the infection will continue. If this occurs, the patient must be retreated to eradicate the infection completely.



• **Fig. 46.4** Formalin–ethyl acetate concentration test tube after centrifugation showing four layers; from the bottom: sediment, formalin layer, debris plug, and ethyl acetate layer.

Examination for Pinworm

Enterobius vermicularis, **pinworm** or **seatworm,** a roundworm parasite commonly found in children worldwide. The adult female worm migrates out of the anus, usually at night, and deposits her eggs in the perianal area. The adult female (8 to 13 mm long) may occasionally be found on the surface of a stool specimen or on the perianal skin. Because the eggs are usually deposited around the anus, they are not commonly found in feces and must be detected by other diagnostic means. Diagnosis of pinworm infection is usually based on the recovery of eggs, which are described as thick-shelled, football-shaped eggs with one slightly flattened side. Often, each egg contains a fully developed embryo and is infective within a few hours after being deposited (Fig. 46.7).

Sigmoidoscopy Material

Material obtained from sigmoidoscopy can be helpful in the diagnosis of amebiasis that has gone undetected by routine fecal examination. However, a series of at least three routine stool examinations for parasites should be completed before a sigmoidoscopy examination is performed. A sigmoidoscopy specimen should be processed immediately. All three methods of examination are recommended (direct,

• BOX 46.3 Permanent Stained Smear: Review

Principle

To allow the examination and recognition of detailed organism morphology under oil-immersion examination (100× objective for a total magnification of 1000×), primarily enabling the recovery and identification of intestinal protozoa.

Specimen

Any stool specimen that is fresh or preserved in polyvinyl alcohol (PVA; mercury based or non–mercury based), sodium acetate–acetic acid–formalin (SAF), merthiolate-iodine-formalin (MIF), or the newer single vial–system fixatives (universal fixatives).

Reagents

Trichrome, iron-hematoxylin, modified iron-hematoxylin, polychrome IV, or chlorazol black E stains and their associated solutions; dehydrating solutions (alcohols and xylenes or xylene substitutes); mounting fluid (optional). The use of true absolute alcohol (100% ethanol) is preferred over the use of 95%/5% alcohol.

Examination

The entire smear should be examined on low power (100×) for the presence of large parasite forms such as larvae or helminth eggs. Oil-immersion examination (1000×) should include at least 300 fields; additional fields may be required if suspect organisms have been seen in the wet preparations from the concentrated specimen.

Results

Most suspected protozoa and/or human cells can be confirmed by examination of the permanently stained smear. These reports should be categorized as “final” and are reported as such (the direct wet smear and the concentration examination provide “preliminary” results).

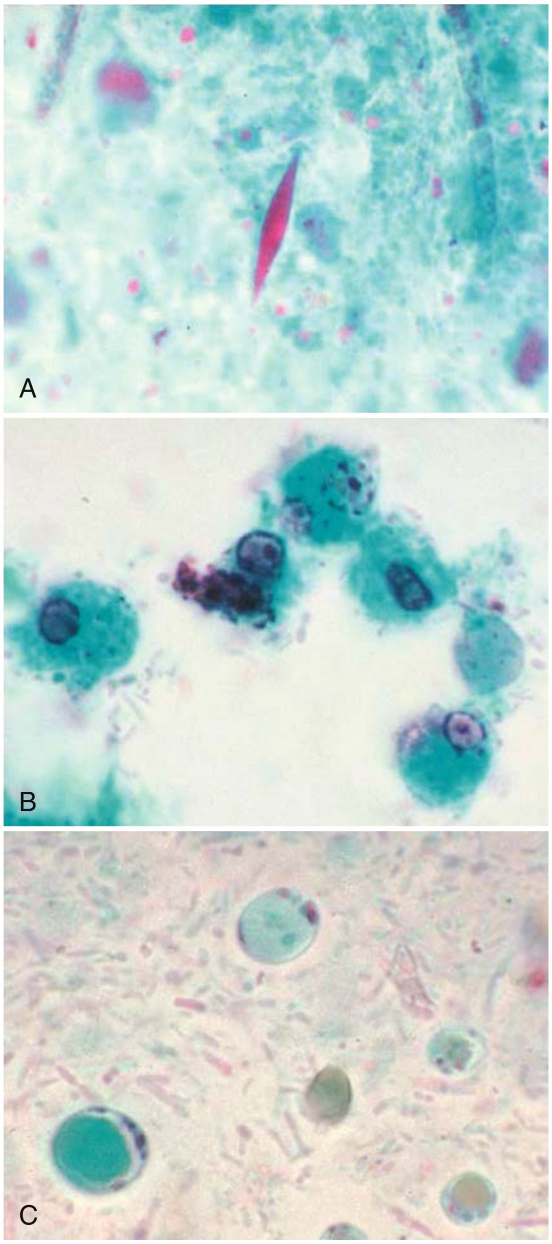
Notes and Limitations

The most commonly used stains are trichrome and iron-hematoxylin. Unfortunately, helminth eggs and larvae may take up the stain inconsistently and are not easily identified from the permanent stained smear. Coccidian oocysts and microsporidian spores also require other staining methods for identification.

Permanent stained smears are examined under oil-immersion examination (1000×). The slide may be screened using the 50× or 60× oil-immersion objectives, but the results should not be reported until the examination has been completed using the 100× oil-immersion lens. Confirmation of intestinal protozoa (both trophozoites and cysts) is the primary purpose of this technique.

Important Reminder

When nonmercury fixatives or one of the single-vial options (usually a zinc-based proprietary formula or one of the universal fixatives) is used, the iodine-alcohol step can be eliminated. After drying, the slides can be placed directly into the stain (trichrome or hematoxylin). However, if fecal specimens have been preserved with mercury-based fixatives, the iodine-alcohol step must be included in the routine staining protocol as well as subsequent rinse steps to remove the mercury and iodine. Some laboratories leave the staining protocol as is, including the iodine-alcohol step, which does not harm smears preserved with non–mercury based fixatives.



• **Fig. 46.5** Stool material stained with Wheatley’s trichrome stain. (A) Charcot-Leyden crystals. (B) Polymorphonuclear leukocytes. (C) *Blastocystis hominis* central body forms (larger objects) and yeast cells (smaller, more homogeneous objects).

concentration, permanent smear). However, depending on the availability of trained personnel, proper fixatives, or the amount of specimen obtained, one or two procedures may be used. It is important to note that even the most thorough examination will be meaningless if the specimen has been improperly collected, fixed, and transported.

Duodenal Drainage

In patients infected with *G. duodenalis* or *S. stercoralis*, routine stool examinations may not be sufficient to identify the infecting organisms. Duodenal drainage material may increase the likelihood of identifying the parasites. However, the “falling leaf” motility often described for *Giardia*

• BOX 46.4 Modified Acid-Fast Permanent Stained Smear: Review

Principle

To provide contrasting colors for background debris and parasites. This technique is designed to allow examination and recognition of acid-fast characteristics of organisms under high dry power (40× objective, for a total magnification of 400×), primarily allowing recovery and identification of intestinal coccidian oocysts. The internal morphology of sporozoites can be seen within some *Cryptosporidium* oocysts under oil immersion (1000×); *Cyclospora* oocysts do not have a specific internal morphology.

Specimen

Any stool specimen that is fresh or preserved in formalin, sodium acetate–acetic acid–formalin (SAF), or the newer fixatives for the single-vial system (universal fixatives).

Reagents

Kinyoun's acid-fast stain, modified Ziehl-Neelsen stain, and their associated solutions; dehydrating solutions (alcohols and xylenes or xylene substitutes); mounting fluid (optional). The decolorizing agents are less intense than the acid alcohol used in routine acid-fast staining (this is what makes these "modified" acid-fast procedures). The recommended decolorizer is 1%–3% sulfuric acid. Many laboratories use 1% so that the *Cyclospora* oocysts retain more color.

Examination

High dry examination (400×) of at least 300 fields; additional fields may be required if suspicious organisms have been seen but are not clearly acid-fast stained.

Results

Identification of *Cryptosporidium* and *Cystoisospora* oocysts should be possible. *Cyclospora* oocysts, which are twice the size of *Cryptosporidium* oocysts, should be visible but tend to be more acid-fast variable. Although microsporidia are acid-fast, their small size makes recognition very difficult. Final laboratory results depend heavily on the appearance of the quality control (QC) slides and comparison with positive patient specimens.

Notes and Limitations

Both the cold and hot modified acid-fast methods are excellent for staining coccidian oocysts. Some clinicians believe that the hot method may result in better stain penetration, but the differences are probably minimal. Procedure limitations are related to specimen handling (proper centrifugation speeds and time, use of no more than two layers of wet gauze for filtration, and complete understanding of the difficulties in recognizing microsporidial spores). In addition, some controversy exists over whether the organisms lose the ability to take up acid-fast stains after long-term storage in 10% formalin. The organisms are more difficult to find in specimens from patients who do not have the typical watery diarrhea (more formed stool contains more artifact material).

• BOX 46.5 Modified Trichrome Permanent Stained Smear: Review

Principle

This technique is designed to allow examination and recognition of organism morphology under oil immersion examination (100× objective, for a total magnification of 1000×), primarily allowing recovery and identification of intestinal microsporidial spores. The internal morphology (horizontal or diagonal "stripes") may be seen in some spores under oil immersion.

Specimen

Any stool specimen that is fresh or preserved in formalin, sodium acetate–acetic acid–formalin (SAF), or the newer fixatives for the single-vial system (universal fixatives).

Reagents

Modified trichrome stain (using high dye–content chromotrope 2R) and associated solutions; dehydrating solutions (alcohols, xylenes, or xylene substitutes); mounting fluid (optional).

Examination

Oil immersion examination (1000×) of at least 300 fields; additional fields may be required if suspect organisms have been seen but are not clearly identified.

Results

Identification of microsporidial spores may be possible; however, their small size makes recognition difficult. Final laboratory results depend heavily on the appearance of the quality control (QC) slides and comparison with positive patient specimens.

Notes and Limitations

Because of the difficulty in getting dye to penetrate the microsporidial spore wall, this staining approach can be helpful. Procedure limitations are related to specimen handling (proper centrifugation speeds and time, use of no more than two layers of wet gauze for filtration, and complete understanding of the difficulties in recognizing microsporidial spores because of their small size [1–3 μm]).

Commercial Suppliers

Suppliers must be asked about specific fixatives and whether the fecal material can be stained with the modified trichrome stains and modified acid-fast stains. They should also be asked whether the fixatives prevent the use of any of the newer fecal immunoassay methods available for several of the intestinal amebae, flagellates, coccidia, and microsporidia.

trophozoites in fresh stool samples is rarely seen in these preparations. The organisms may be caught in mucus strands, and the movement of the flagella on the *Giardia* trophozoites may be the only subtle motility visible. *Strongyloides* larvae are usually very motile. It is important to keep the light intensity low for visualization of the moving parasites.

The duodenal fluid typically contains mucus, and the organisms tend to be located in the mucus threads. Therefore, centrifugation of the specimen before examination is important. Fluorescent antibody or immunoassay detection kits (*Cryptosporidium* or *Giardia*) can also be used with fresh or formalinized material. It is important to check the package insert of each kit to see which specimen types are acceptable.

If a presumptive diagnosis of giardiasis is reached as a result of a wet prep examination, the cover slip can be

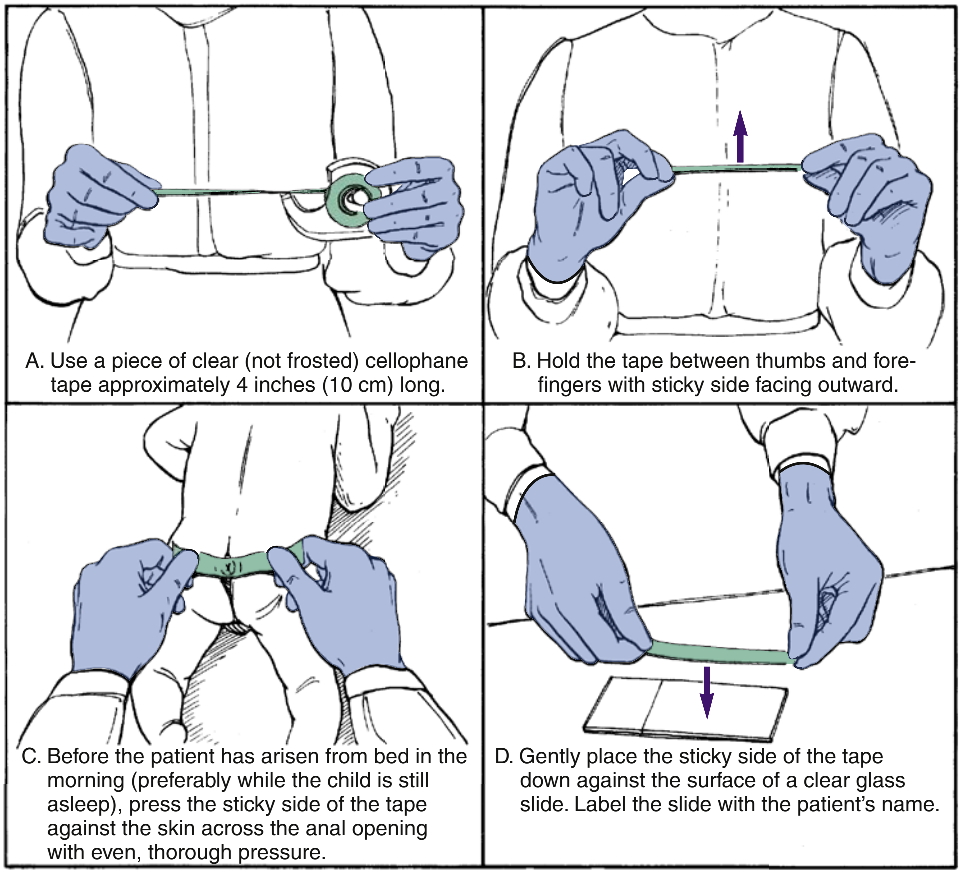
removed and the specimen fixed with Schaudinn's fluid, other fixatives containing polyvinyl alcohol (PVA), or a "universal fixative" (i.e., no formalin, mercury, or PVA) for subsequent staining with trichrome or iron-hematoxylin. If the amount of duodenal material submitted is very small, permanent stains can be prepared in lieu of using a portion of the specimen for a wet prep. This approach provides a permanent record; it may also improve the visualization of parasites using an oil-immersion examination of the stained specimen at 1000× compared with the examination of unstained organisms with minimal motility at a lower magnification.

Duodenal Capsule Technique (Entero-Test)

The duodenal capsule technique is a simple, convenient method for collecting duodenal contents, thus eliminating the need for intestinal intubation. The technique involves the use of a length of nylon cord coiled inside a gelatin capsule. The cord protrudes through one end of the capsule and is taped to the side of the patient's face. The capsule is swallowed. The gelatin dissolves in the stomach, and the weighted cord is carried by peristalsis into the duodenum. The cord is attached to the weight by a slipping mechanism; the weight is released and passes out in the stool when the cord is retrieved after 4 hours. The mucus collected on the cord is examined using the direct wet mount method for parasites, including *S. stercoralis, G. duodenalis, Cryptosporidium* spp., microsporidia, and the eggs of *Clonorchis sinensis.*

Urogenital Tract Specimens

T. vaginalis is typically identified by the examination of wet preparations of vaginal or urethral discharges, prostatic secretions, or urine sediment. Multiple specimens may be needed to detect the organisms. The specimens should be diluted with a drop of saline and examined for motile



A. Use a piece of clear (not frosted) cellophane tape approximately 4 inches (10 cm) long.

B. Hold the tape between thumbs and forefingers with sticky side facing outward.

C. Before the patient has arisen from bed in the morning (preferably while the child is still asleep), press the sticky side of the tape against the skin across the anal opening with even, thorough pressure.

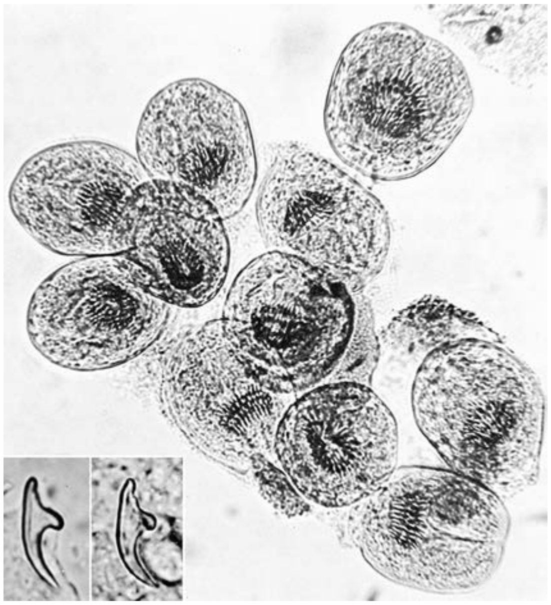
D. Gently place the sticky side of the tape down against the surface of a clear glass slide. Label the slide with the patient's name.

• **Fig. 46.7** Method of collecting a cellophane (Scotch) tape preparation for pinworm diagnosis. This method dispenses with the tongue depressor, requiring only tape and a glass microscope slide. The tape must be pressed deep into the anal folds.

organisms under low power (100×) with reduced illumination. As the jerky motility begins to diminish, the undulating membrane may often be observed under high dry power (400×). Unfortunately, the overall sensitivity of wet mount examinations is limited compared with culture and/or molecular testing, such as polymerase chain reaction (PCR) analysis. Stained smears are usually not necessary for the identification of *T. vaginalis.* The number of false-positive and false-negative results reported from stained smears supports the value of confirmation by observation of motile organisms from the direct mount, culture media, or more sensitive direct antigen detection methods.

Sputum

Although not a common specimen, expectorated sputum may be submitted for parasitic examination. Organisms found in sputum that may cause pneumonia, pneumonitis, or Loeffler syndrome include the migrating larval stages of *A. lumbricoides, S. stercoralis,* and hookworm; the eggs of *Paragonimus* spp.; *Echinococcus granulosus* hooklets (Fig. 46.8); and the protozoa *Entamoeba histolytica, Entamoeba gingivalis, Trichomonas tenax, Cryptosporidium* spp., and possibly the microsporidia. Some of the smaller organisms must be differentiated from fungi such as *Candida* spp., *Pneumocystis jiroveci,* and *Histoplasma capsulatum.* In a *Paragonimus* infection, the sputum may be



• **Fig. 46.8** *Echinococcus granulosus,* cyst. (Enlarged for detail, 500×).

viscous, streaked with blood, and tinged with brownish flecks, which are clusters of eggs ("iron filings").

Induced sputa are collected after patients have used appropriate cleansing procedures to reduce oral contamination. The induction protocol is critical for the success of the procedure, and well-trained individuals such as respiratory therapists are needed to recover the organisms.

Aspirates

Examination of aspirated material for the diagnosis of parasitic infections may be extremely valuable, particularly when routine testing methods have failed to demonstrate the presence of the organisms. These specimens should be transported to the laboratory immediately after collection and processed as quickly as possible. Aspirates include liquid specimens collected from a variety of body sites. Aspirates most commonly processed in the parasitology laboratory include fine-needle aspirates and duodenal aspirates. Fluid specimens collected by bronchoscopy include bronchoalveolar lavages and bronchial washings.

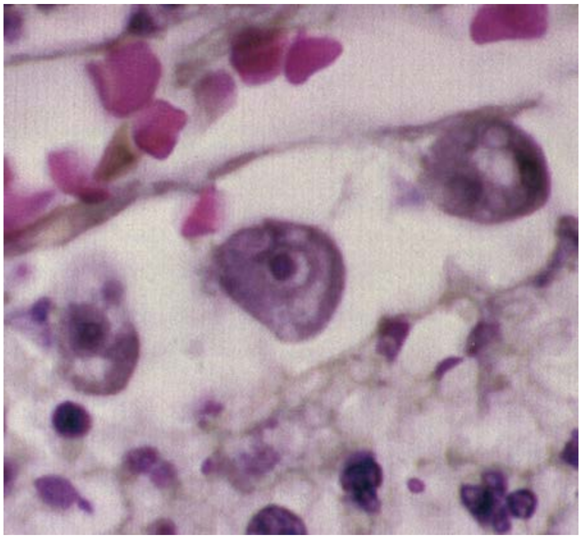
Fine-needle aspirates may be submitted for slide preparation, culture, or both. Aspirates of cysts and abscesses for amebae may require concentration by centrifugation, digestion, microscopic examination for motile organisms in direct preparations, cultures, and microscopic evaluation of stained preparations. Aspiration of cyst material (usually liver or lung) for diagnosis of hydatid disease usually is performed when surgical techniques are used for cyst removal. The aspirated fluid is submitted to the laboratory and examined for hydatid sand (scolices) or hooklets; absence of this material does not rule out the possibility of hydatid disease because some cysts are sterile.

Bone marrow aspirates for *Leishmania* and *Trypanosoma cruzi* amastigotes or *Plasmodium* spp. require staining with any of the blood stains (Giemsa, Wright's, Wright-Giemsa combination, rapid stains, or Field's stain). Giemsa stain is the preferred stain for blood parasites because it provides better visibility of intracellular details for optimal morphology. Examination of specimens may confirm an infection previously missed by examination of routine blood films.

Cases of primary amoebic meningoencephalitis (PAM) are rare, but examination of spinal fluid may reveal the causative agent, *Naegleria fowleri,* one of the free-living amebae (Fig. 46.9). Although rare, this disease has a very high mortality rate. For this reason, a cerebrospinal fluid (CSF) sample with a request for examination for parasites is always considered a STAT procedure.

Biopsy Specimens

Biopsy specimens are recommended for diagnosis of tissue parasite infections. Impression smears, teased, and squash preparations of biopsy tissue from skin, muscle, cornea, intestine, liver, lung, and brain can be used for this purpose, in addition to standard histologic preparations. An impression smear is a collection of cells, microorganisms, or fluids produced by pressing the surface of the tissue specimen against a slide for review. Squash preparations are described in Chapter 6. Tissue for examination using permanent sections or electron microscopy should be fixed as specified by the processing laboratory. In certain cases, a biopsy may be the only means of confirming a suspected parasitic problem. Specimens examined as fresh material rather than as tissue sections should be kept moist in saline and submitted to the laboratory immediately.



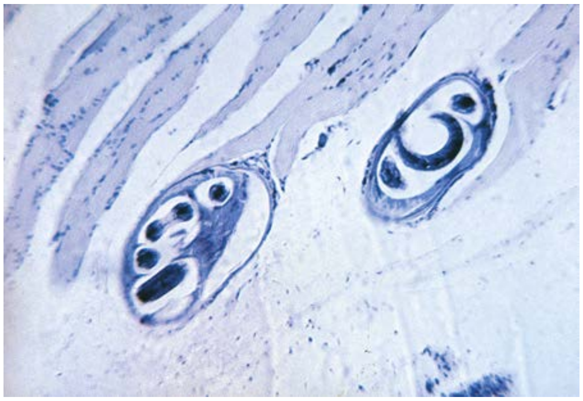
• **Fig. 46.9** *Naegleria fowleri* in brain tissue (hematoxylin and eosin stain).

Detection of parasites in tissue depends in part on specimen collection and adequate material to perform the recommended diagnostic procedures. Biopsy specimens are usually small and may not be representative of the diseased tissue. Multiple tissue samples often improve diagnostic results. To optimize the yield from any tissue specimen, all areas should be examined by as many procedures as possible. Tissues are collected using invasive procedures, many of which are very expensive and lengthy; consequently, these specimens deserve the most comprehensive procedures possible. A muscle biopsy for diagnosis of infection with *Trichinella* spp. can be processed as a routine histology slide or can be examined as a squash preparation (Fig. 46.10).

Tissue submitted in a sterile container on a sterile sponge dampened with saline may be used for cultures of protozoa after mounts for direct examination or impression smears for staining have been prepared. If cultures will be processed for parasites, sterile slides should be used for smear and mount preparation. Examination of tissue impression smears is detailed in Table 46.11.

Blood

Depending on the life cycle, a number of parasites may be recovered from blood specimens. Although organisms may be motile in fresh whole blood, species identification is typically accomplished from examination of permanently stained thick and thin blood films (Fig. 46.11). Blood films can be prepared from fresh, whole blood containing no anticoagulants, anticoagulated blood, or sediment from the various concentration procedures. The two most



• **Fig. 46.10** *Trichinella* spp. larvae encysted in muscle.

commonly used hematology stains are Wright's and Giemsa stains. Many clinical laboratories use a commercial stain for hematology that is a combination of Wright's and Giemsa. The stain of choice is Giemsa stain because it provides optimal detail of intracellular malarial and other blood-borne parasites. However, blood parasites can also be seen on blood films stained using Wright's or other stains, including rapid staining options. Delafield's hematoxylin stain is often used to improve visibility of the microfilarial sheath. Multiple smears should be made as soon as the specimen is received in the laboratory, but initially only one should be stained and observed for parasites. The remaining slides can be stained with routine or specialized stains depending on what is observed on the first slide.

A request for examination of blood films for parasites is always a STAT request. Examination of any blood smear for parasitology should be performed by a highly experienced laboratory scientist.

Thin Blood Films

In any examination of thin blood films for parasitic organisms, the initial screening should be completed using the low-power microscope objective (10×).

Depending on the training and experience of the laboratory scientist, examination of a thin film for parasites usually takes 15 to 20 min (300 or more oil immersion fields at a magnification of 1000×). Some use a 50× or 60× oil-immersion objective to screen stained blood films; however, the chance is greater that small parasites (e.g., *Plasmodium* spp., *Babesia* spp., *Leishmania donovani*) will be missed at the lower total magnification (500× or 600×) compared with the 1000× total magnification achieved using the 100× oil-immersion objective.

Microfilarial organisms are rarely present in large numbers. Frequently only a few organisms are identified in each thin film preparation. Because microfilariae are carried with the smear during preparation and typically located at the edges or feathered end of the thin film, the entire film should be scanned to ensure that no microfilariae are missed. The feathered end of the film should be examined for intracellular and extracellular parasites. Because the cells in the feathered end are spread further apart, the morphology and size of the infected red blood cells (RBCs) may be more clearly visible (Box 46.6).

Before a smear is reported as negative for the presence of parasites, a minimum of 300 fields should be examined. The request for blood film examination should be considered a STAT procedure, and all results (negative and positive) should be reported by telephone to the physician as soon as possible. If a result is positive, the appropriate government agencies (local, state, and federal) should be notified within a reasonable time, in accordance with guidelines and laws. It is important to note that one negative set of blood films is not sufficient to rule out blood parasites.

Both malaria and *Babesia* infections have been missed with automated differential instruments, delaying treatment. Although these instruments are not designed to detect intracellular blood parasites, the inability of the automated systems to distinguish between uninfected RBCs and those infected with parasites may pose diagnostic problems. Because automated systems may not be able to detect intracellular parasites, a manual differential should always be performed whenever a blood sample is submitted for parasitology.

Thick Blood Films

In the preparation of a thick blood film, the greatest concentration of blood cells is in the center of the film. The examination should be performed at low magnification to detect microfilariae. Examination of a thick film usually requires 5 to 10 min (approximately 100 oil-immersion fields). A search for malarial organisms and trypanosomes should be completed using oil immersion (total magnification of 1000×). Intact RBCs are commonly seen at the very periphery of the thick film; if infected, such cells may prove useful in the diagnosis of malaria (Box 46.7). However, a thin film preparation should always be used to confirm speciation of malarial and other blood parasite organisms.

Buffy Coat Films

L. donovani, trypanosomes, and *H. capsulatum* (a fungus with intracellular elements resembling those of *L. donovani*) may be detected in the peripheral blood. The parasite or fungus is detected in the neutrophils and large mononuclear cells found in the buffy coat (a layer of white blood cells seen just above the red cell layer after centrifugation of whole citrated blood). With *L. donovani,* the nuclear material stains dark red-purple, and the cytoplasm is light blue. In contrast, *H. capsulatum* is visible as a large dot of nuclear material (dark red-purple) surrounded by a clear halo. Trypanosomes and microfilariae may also concentrate with the buffy coat cells due to their size.

Direct Detection Methods

Significant progress has been made in the development and application of molecular methods for the diagnosis of parasitic infections, including the use of purified or

TABLE 46.11 Examination of Impression Smears

Tissue	Possible Parasite	Stain[a]
Lung	Microsporidia	Modified trichrome, acid-fast stain, Giemsa, tissue Gram stain, optical brightening agent (calcofluor), methenamine silver, electron microscopy (EM)

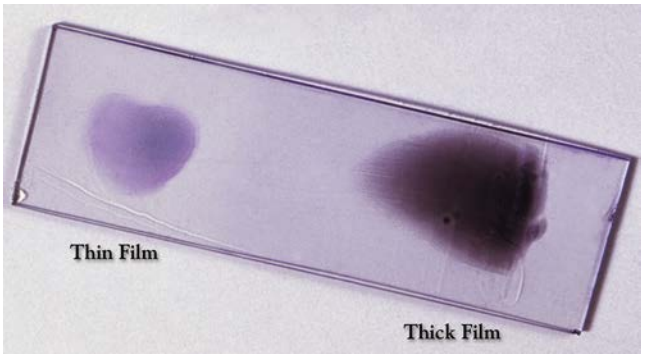
[a] Whenever Giemsa stain is mentioned in the table, any bloodstain is acceptable: Giemsa, Wright's, Wright-Giemsa combination, rapid blood stains.



• **Fig. 46.11** Thin and thick blood smear for the identification of blood parasites. Most commonly used for identifying *Plasmodium* or *Trypanosoma* spp.

recombinant antigens and nucleic acid probes. The presence of parasite-specific antigen indicates current disease. Nucleic acid–based parasitic diagnostic tests are primarily available in specialized research or reference centers. PCR and other nucleic acid probe tests have been reported for almost all species of parasites. The demand for implementation of direct detection using molecular methods will continue to increase as the cost of these tests decreases and automation increases.

Intestinal Parasites

Immunoassays are generally simple and enable the simultaneous performance of many tests, thereby reducing overall costs. Antigen detection in stool specimens is often limited to the detection of one or two pathogens simultaneously. A routine O&P examination should also be performed to detect other parasitic pathogens. The current commercially available antigen tests (direct fluorescent antibody [DFA], enzyme immunoassay [EIA], indirect fluorescent antibody [IFA], and the cartridge formats) have excellent sensitivity and specificity compared with routine microscopy. Available antigen detection tests are listed in Table 46.12. The most common immunoassays are designed to confirm infection with *E. histolytica, G. duodenalis,* and *Cryptosporidium* spp.

Blood Parasites

Several new blood parasite antigen detection systems are available and have been effectively tested in field trials. Several quick screening tests are available for malaria using an immunochromogenic or antigen-capture EIA system (Table 46.12). Although these simple rapid methods are appropriate for population screening, a blood film from a positive patient must be examined to confirm the diagnosis and properly identify the species. Commercial PCR testing kits are currently available for *Plasmodium* spp. and *Wuchereria bancrofti.* Some of the rapid test kits for *Plasmodium* can detect all of the species that commonly infect humans but may not be able to differentiate the individual species. Other PCR kits are designed to specifically identify *P. falciparum.* Because PCR techniques

• BOX 46.6 Thin Blood Films: Review

Principle

This technique is designed to allow examination and recognition of detailed organism morphology under oil-immersion examination (100× objective, for a total magnification of 1000×), primarily allowing recovery and identification of *Plasmodium* spp., *Babesia* spp., *Trypanosoma* spp., *Leishmania donovani,* and filarial blood parasites. The thin blood film is routinely used for specific parasite identification, although the number of organisms per field is significantly reduced compared with the thick blood film. The primary purpose is to allow malarial parasites to be visualized in the RBCs and to assess the size of infected RBCs compared with that of uninfected RBCs. RBC morphology is preserved using this method.

Specimen

Finger-stick blood, whole blood, or anticoagulated blood (ethylenediaminetetraacetic acid [EDTA] recommended). Multiple smears should be made within 1 h of collection, but initially only one smear should be stained. Additional smears can be stained if needed by different methods to enhance identification.

Reagents

Giemsa stain (films must be prefixed with absolute methanol before staining), Wright's stain (the stain contains the fixative), or Wright-Giemsa stains and their associated solutions; mounting fluid (optional).

Examination

Oil-immersion examination (1000×) of at least 300 fields; additional fields may be required if suspect organisms have been seen in the thick blood film. The slide may be screened using the newer 50× or 60× oil-immersion objectives, but the results should not be reported until the examination has been completed using the 100× oil-immersion lens. A blood film must be examined totally at a lower power to rule out the presence of microfilariae, which tend to be found near the edges of the smear.

Results

The thin blood film is routinely used for parasite identification to the species level (*Plasmodium* spp.). Both the thick and thin films should be examined before the final result is reported.

Notes and Limitations

The thin blood film is prepared exactly as one used for a differential count. A well-prepared film is thick at one end and thin at the other. The use of clean, grease-free slides is mandatory; long streamers of blood indicate that the slide used as a spreader was dirty or chipped. Streaks in the film usually are caused by dirt; holes in the film indicate grease on the slide. Although Giemsa stain is the stain of choice, blood parasites can be seen using other stains; however, the parasite morphology and color may not be consistent with that described for Giemsa-stained organisms. Giemsa stain does not stain the sheath of *Wuchereria bancrofti;* hematoxylin-based stains (e.g., Delafield's hematoxylin) are recommended for these organisms. The WBCs on the stained blood film serve as the quality control; if the WBC morphology and color are acceptable, then any parasites present will also appear normal and will be acceptable. Alternately, previously positive patient smears (if available) can be fixed with methanol and air dried, then stored in a sealed container at –70°C. These QC slides should be brought to room temperature before staining.

• BOX 46.7 Thick Blood Films: Review

Principle

This technique is designed to allow examination and recognition of detailed organism morphology under oil-immersion examination (100× objective, for a total magnification of 1000×), primarily allowing recovery and identification of *Plasmodium* spp., *Babesia* spp., *Trypanosoma* spp., *Leishmania donovani,* and filarial blood parasites. The thick blood film is routinely used for detection of parasites, because the number of organisms per field is much greater than with the thin blood film. The primary purpose is to allow examination of a larger volume of blood than is seen with the thin blood film. RBC morphology is not preserved using this method.

Specimen

Finger-stick blood, whole blood, or anticoagulated blood (ethylenediaminetetraacetic acid [EDTA] recommended).

Reagents

Giemsa stain, Wright's stain, or Wright-Giemsa stains and their associated solutions; mounting fluid (optional).

Examination

Oil-immersion examination (1000×) of at least 300 fields; additional fields may be required if suspect organisms have been seen in the thin blood film. The slide may be screened using the newer 50× or 60× oil-immersion objectives, but the results should not be reported until the examination has been completed using the 100× oil-immersion lens. A blood film must be examined at a lower power to rule out the presence of microfilariae.

Results

The thick blood film is used to detect the presence of parasites; final identification may require examination of the thin blood film. Both should be examined before the final result is reported.

Notes and Limitations

The thick blood film is prepared by spreading a few drops of blood (using a circular motion) over an area approximately 2 cm in diameter. If whole blood is used, the examiner should continue stirring about 30 s to prevent the formation of fibrin strands. The use of clean, grease-free slides is mandatory. The film is allowed to air-dry at room temperature (heat is never applied to these films). Although Giemsa stain is the stain of choice, blood parasites can be seen using other stains; however, the parasite morphology and color may not be consistent with that described for Giemsa-stained organisms. Giemsa stain does not stain the sheath of *Wuchereria bancrofti;* hematoxylin-based stains (e.g., Delafield's hematoxylin) are recommended for these organisms. The WBCs on the stained blood film serve as the quality control; if the WBC morphology and color are acceptable, then any parasites present will also appear normal and will be acceptable. Alternately, previously positive patient smears (if available) can be held fixed with methanol and air-dried, then stored in a sealed container at −70°C. The QC slides should be brought to room temperature before staining.

can amplify the parasite's DNA, it can detect infection even when the number of parasites is low. It can also be used to confirm species identification when the morphology is unclear.

Cultivation

Parasite culture techniques are not routinely used to detect parasite infections in the United States. Any laboratory providing these types of cultures must maintain stock quality control (QC) cultures of specific organisms, often obtained from the American Type Culture Collection (ATCC). The relevant QC organisms are cultured simultaneously with the patient specimen, thus providing some assurance that the culture system functioned properly. The methods for *in vitro* culture are often complex, and QC is difficult and not feasible in the routine diagnostic laboratory. Some techniques may be available in certain institutions, particularly those in which research and consulting services are available. The cultivation of parasites is an essential technique for laboratories developing diagnostic testing methods, for epidemiologic analysis of outbreaks, for testing for drug resistance, or for the analysis of parasite life cycles.

Although *T. vaginalis* can be easily detected in vaginal or urethral secretions as well as urine sediment, accurate identification may require an experienced laboratory scientist. Several test kits are commercially available that allow quick culture confirmation of *Trichomonas* infection. OSOM *Trichomonas* and InPouch TV are two of the methods commonly used in physicians' offices or clinics. *Trichomonas* culture is very sensitive and specific, but it may take up to 7 days for growth. Physicians may request cultures when a patient is suspected to have a *Trichomonas* infection but is negative by microscopic examination. This is an example of an **axenic** culture method, in which the parasites are grown in pure culture without augmentation with bacteria.

Keratitis caused by *Acanthamoeba* may be confirmed by microscopic observation but also by culture of the parasite. Corneal scrapings or contact lenses are inoculated onto nutrient agar that has an overlay of *Escherichia coli* or *Enterobacter* spp., which serves as a food source for the ameba. The plate is observed for up to 7 days to detect the organism's growth on the agar surface. Identification of the organism is confirmed by microscopic morphology or PCR. This culture technique is called **monoxenic** because a single known bacterial species is used to help cultivate the organism. This same culture technique is used to recover and confirm granulomatous amebic encephalitis (GAE) caused by *Acanthamoeba* or PAM caused by another free-living amebic parasite, *N. fowleri.* In both cases, because of the critical nature of the infection, the organism identification must be confirmed by PCR or other antigen confirmation methods.

Larval-Stage Nematodes

The use of certain fecal culture methods (sometimes referred to as **coproculture**) is especially helpful for detecting light infections of hookworm, *S. stercoralis,* and *Trichostrongylus* spp. The rearing of infective-stage nematode larvae improves the diagnosis of hookworm and trichostrongyle infections, because the eggs of these species are identical and differentiation is based on larval morphology. These techniques are also useful for obtaining infective-stage larvae for research

Accessed June 29, 2019.

purposes. Diagnostic methods available include the **Harada-Mori** filter paper strip culture, the Petri dish/slant filter paper culture, the agar plate method, and the charcoal culture.

Blood Protozoa

Leishmaniasis is often diagnosed by observation of the nonmotile **amastigote** stage of the parasite on blood smears, particularly as intracellular forms within monocytes and macrophages. The extracellular motile form, or **promastigote** stage found in tissue specimens, can also be cultured in specialized media (Novy-MacNeal-Nicolle [NNN] medium). This method is not part of a routine analysis in the clinical laboratory.

Recent breakthroughs have allowed scientists to cultivate the malarial parasites that infect humans and a number of other animal species. Although not used for diagnosis of malaria in the clinical laboratory, the ability to cultivate *Plasmodium* species has led to a number of significant developments, including a better understanding of the life cycle, development of analytical testing methods such as PCR, and research leading to the development of protective vaccines.

A unique cultivation method involves the use of intermediate hosts to isolate a parasitic organism from a human host. This technique is called **xenodiagnosis.** It was primarily used for the detection of chronic Chagas disease caused by *T. cruzi.* The insect vector Triatomid bug was allowed to take a blood meal from the patient and was examined for the presence of the trypanosomes in its gut. In addition to the detection of Chagas disease, other now archaic xenodiagnostic methods have been used to detect leishmaniasis and onchocerciasis.

Serodiagnosis

Serodiagnosis, or testing patient serum for the presence of antibodies, has been available for many years. However, serologic methods for the detection and identification of parasitic infections are not routinely offered by most clinical laboratories because of their high cost, difficulty of interpretation, low test volume, and limited sensitivity and specificity. Direct parasite detection and/or detection of parasite antigens are the methods of choice in all but a few situations. In parasitic infections where the organism reproduces in the host tissues, continuous antigenic stimulation of the host's immune system occurs as the infection progresses. In these cases, there is a positive correlation between clinical symptoms and serologic test results. Serodiagnosis is recommended when the collection of a direct specimen may cause significant risk to the patient, as with echinococcosis or cysticercosis. Serodiagnosis is also recommended when the infection may be widespread, making specimen collection difficult, as with infections caused by *Toxoplasma* or *Toxocara* spp. Standard serologic techniques used in the laboratory for parasitic diagnostics include latex agglutination, enzyme-linked immunosorbent assay (ELISA)/EIA, IFA, and immunoblot techniques.

The Centers for Disease Control and Prevention (CDC) offers a number of serologic procedures for diagnostic purposes, some of which are not available elsewhere. Regulations for submitting specimens to the CDC may vary from state to state. Each laboratory should check with the appropriate county or state department of public health for specific instructions. Additional information on procedures and the interpretation of test results may be obtained directly from the CDC: http://www.cdc.gov/parasites/.

Prevention

The prevention of human parasitic infections is directly linked to understanding the life cycles of the various organisms and their modes of infection (Table 46.4). Preventive measures include avoiding direct exposure, as by improving personal hygiene, ensuring proper sanitation, and eliminating sexual activities that may involve fecal-oral contact. Adequate water treatment (including filtration) may be required, in addition to overall awareness of environmental sources of infection. In some cases, avoiding contaminated environmental water and soil sources may be important; for example, this is mandatory in dealing with systems of contact lens care, methods of sinus irrigation methods, potential infection with free-living amebae from municipal water supplies.

Chemoprophylactic agents to prevent clinical symptoms are given to individuals traveling to areas where malaria is endemic. These medications are effective against the erythrocytic forms but do not actually prevent infection with malaria; that is, the drugs do not prevent sporozoites from entering the host, traveling to the liver, and beginning the preerythrocytic developmental cycle. In general, chloroquine is the drug of choice, although different regimens may be used for chloroquine-resistant strains of malaria and for different species of malaria.

Vector control and awareness of transmission through blood transfusions, shared drug needles, congenital infections, and organ transplants are also important considerations in preventing human parasitic disease. Careful monitoring of the blood supply is required to prevent the transmission of parasites. This is particularly important in areas of the world where blood-borne parasites play a large role in human disease or in the case of blood donors who have recently traveled to endemic areas.

Adequate cooking of meat that may be infected is also important; cultural habits may influence the handling and eating of raw or poorly cooked foods. Prevention depends on a thorough understanding of the life cycle and epidemiology of all parasites that cause human disease. This information is critical to the prevention of human disease caused either by parasites limited to the human host or by parasites that can cause disease in humans and other animal hosts.

An example of a global initiative to eliminate parasitic infection can be seen in the management of Guinea worm disease, caused by the parasite *Dracunculus medinensis*. Individuals become infected with the worms by drinking contaminated water. In 1980, the CDC, World Health Organization (WHO), and other partners began a campaign to provide access to clean drinking water as well as identifying sources of potential infection. In 1986, there were 3.5 million cases of Guinea worm disease, primarily in Africa. Thanks to the efforts of the global Guinea Worm Eradication Program, only 25 human cases from Chad, Ethiopia, and South Sudan were reported worldwide in 2016. The ultimate goal is complete elimination of the parasite.

(WHO Collaborating Center for Research Training and Eradication of Dracunculiasis. Guinea Worm Wrap Up #245Cdc-pdf External, 2017, Centers for Disease Control and Prevention [CDC]: Atlanta, Georgia.)

Ectoparasites

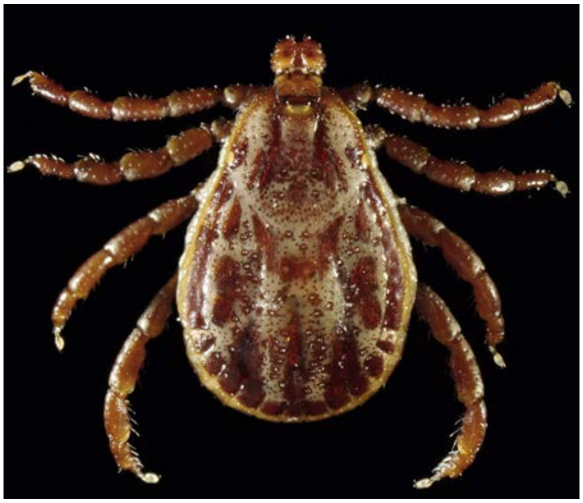
Ectoparasites, member of the phylum Arthropoda, can affect human health in several ways. Arthropods can act as biologic vectors of disease, as when mosquitoes transmit malaria or when ticks transmit Lyme disease during a blood meal. They can also act as mechanical vectors—for example, when flies or cockroaches help transmit bacteria to food or water, causing enteric diseases. Mites and lice can act as biologic vectors of disease, but they can also cause disease directly by their presence (lice infestation) and the body's reaction to them (scabies). Although not true parasites, members of the Arthropoda can also affect humans through venomous bites (spiders) or stings (scorpions). Any arthropod that breaks the skin can also cause a secondary bacterial infection at the injury site (Table 46.13).

TABLE 46.13 **Arthropods (Ectoparasites)**

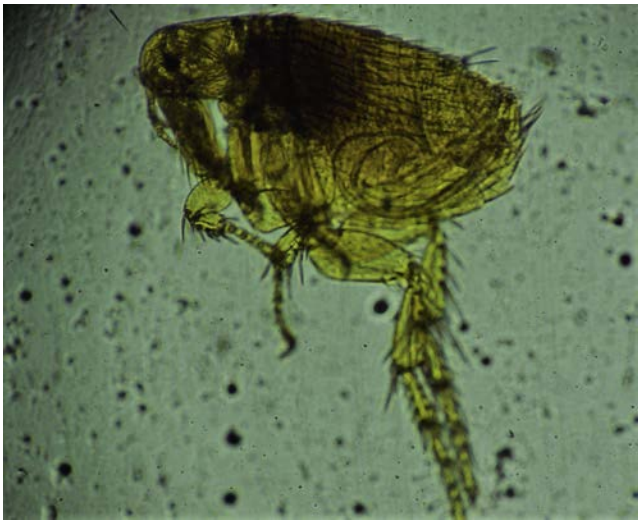
Arthropods	Organisms Transmitted	Other Impacts
Arachnida		
Ticks (Four pairs of legs; two pairs of mouth parts; no antennae; larval, nymph, and adult stages; separate sexes)	*Anaplasma* *Arboviruses* *Babesia* spp. *Borrelia burgdorferi* (Lyme disease) *Borrelia* sp. (relapsing fever) *Ehrlichia* spp. *Francisella* sp. *Rickettsia* spp. *Flavivirus* (tick-borne encephalitis)	Secondary bite wound infections Tick paralysis (toxin)
Mites, infestation	St. Louis encephalitis western equine encephalitis *Rickettsia* sp.	Scabies (infestation) pruritus
Spiders		Venom reaction to bite (e.g., brown recluse, black widow)
Scorpions		Venom reaction to sting (e.g., bark scorpion)
Insecta		
Fleas (three pairs of legs; rear legs much larger)	*Dipylidium caninum* *Hymenolepis nana* *Hymenolepis diminuta* *Yersinia pestis* *Rickettsia typhi* (murine typhus) *Francisella* sp.	Pruritus, site of bite
Flies 1–2 pairs of wings; separate head, thorax, and abdomen)	*Trypanosoma rhodesiense* *Trypanosoma gambiense* *Leishmania* spp. *Onchocerca volvulus* *Loa loa* *Bartonella* (Oroya fever)	Mechanical transfer of disease; poor sanitation (dysentery, cholera)

TABLE 46.13 **Arthropods (Ectoparasites)—cont'd**

Arthropods	Organisms Transmitted	Other Impacts
Bugs (three pairs of legs; some have wings)	*Trypanosoma cruzi* (Triatomids including bed bugs)	Bite wound reactions; pruritus Mechanical transfer of disease; poor sanitation (dysentery, cholera, e.g., cockroaches)
Lice (wingless; three segments)	*Borrelia* (relapsing fever) *Bartonella* (trench fever) *Rickettsia prowazeki* (typhus)	Pruritus reaction to infestation; waste products
Mosquitoes (three pairs of legs, three segments; long abdomen; 3000+ species)	*Plasmodium* spp. *Wuchereria bancrofti* *Brugia malayi* *Arboviruses* *Flaviviruses* (dengue, yellow fever) *Togaviruses* (encephalitis)	Bite reaction—pruritus

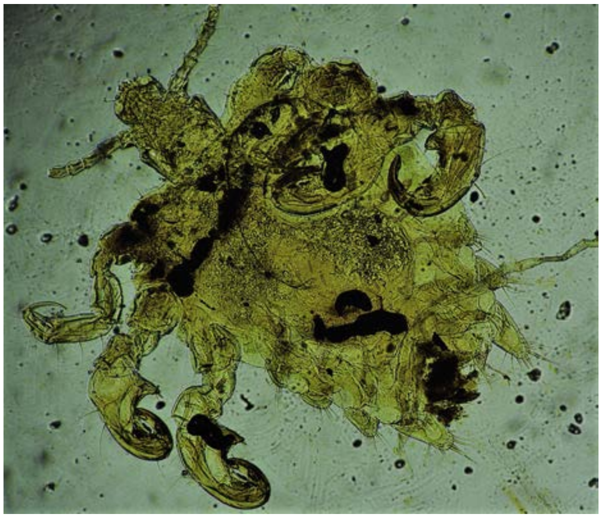


• **Fig. 46.12** Dorsal view of a male Rocky Mountain wood tick, *Dermacentor andersoni*. This tick species is a known North American vector of *Rickettsia rickettsii*, which is the etiologic agent of Rocky Mountain spotted fever (RMSF). (Courtesy the Division of Parasitic Diseases/Centers for Disease Control and Prevention.)



• **Fig. 46.13** *Xenopsylla cheopis,* the Oriental rat flea, the primary vector of bubonic plague and murine typhus. (400×)

Ectoparasites can be directly observed without a microscope, but it is better to place them in 70% to 95% ethanol to maintain their morphology and color and examine them using a stereomicroscope or low power on a light microscope. Permanent fixation can be obtained using Permount (Fisher Scientific, Pittsburgh, PA). Arthropods have four characteristics: a chitinized exoskeleton, pairs of jointed legs or appendages, bilateral symmetry, and a hemocele. Members of the Arachnida (ticks, mites, spiders, and scorpions) have four pairs of appendages (legs) (Fig. 46.12), whereas members of the Insecta (flies, lice, fleas, bugs, and mosquitoes) have three pairs of appendages (legs and wings) (Figs. 46.13 and 46.14). Identification is based on recognizing the morphologic characteristics of the arthropod and carefully describing the head, thorax, and abdomen as well as noting the number of legs or other appendages and the presence of antennae.



• **Fig. 46.14** *Pediculus* sp., louse that infests humans and transmits a variety of diseases including endemic typhus, trench fever, and relapsing fever.

Chapter Review

1. Which of the following is essential for a complete and accurate fecal examination for O&Ps?
   a. Antigen detection using specific antibodies
   b. Direct wet mount for motility of the organisms
   c. Permanent stained slide
   d. Concentration wet mount
   e. Culture for specific organisms
2. Which specimen is most likely to provide recovery of *Trichomonas vaginalis*?
   a. Urine
   b. Urethral discharge
   c. Vaginal discharge
   d. Feces
   e. Biopsy tissue
3. Examination of sputum may be necessary to diagnose infection with
   a. *Paragonimus* spp.
   b. *Trichinella spiralis*
   c. *Wuchereria bancrofti*
   d. *Giardia duodenalis*
   e. *Taenia saginata*
4. Which of the following is a key characteristic of the thick blood film?
   a. It allows the parasite to be seen inside the RBCs.
   b. It allows identification of parasites to the species level.
   c. Less slide area must be examined compared with a thin blood film.
   d. It should not be made using anticoagulated or fresh blood.
   e. It allows counting of the infected RBCs to determine the relative parasite burden.
5. **True or False**
   ______ When using fecal fixatives, it is mandatory to thoroughly mix the stool specimen with the fixative.
   ______ Collection of a single stool is sufficient to confirm a negative result for the O&PS examination.
   ______ One of the more common intestinal nematodes is *Ascaris lumbricoides.*
   ______ The most relevant diagnostic tests for the recovery and identification of *Babesia* spp. are the thick and thin blood films.
   ______ Parasitic serology for antibody detection is critical for the diagnosis of intestinal protozoa.
6. **Matching:** *Match each term with the correct description.*

   ______ free-living amebae
   ______ fecal concentration
   ______ *Trichinella* spp.
   ______ *Cryptosporidium* spp.
   ______ trichrome
   ______ microsporidia
   ______ leishmaniasis
   ______ pinworm
   ______ amebiasis
   ______ 10% formalin

   a. sedimentation method
   b. permanent stain for fecal specimens
   c. impression smears
   d. CSF examination
   e. sigmoidoscopy examination
   f. a fecal fixative used in O&PS examination
   g. modified acid-fast stain
   h. modified trichrome stain
   i. cellophane (Scotch) tape preparation
   j. examination of biopsy specimen

PROCEDURE 46.1

Formalin-Ether (Formalin–Ethyl Acetate) Sedimentation Techniques

Principle

Formalin fixes eggs, larvae, oocysts, and spores so that they are no longer infectious and also preserves their morphology. Fecal debris is extracted into the ethyl acetate phase of the solution, freeing the sedimented parasitic elements from at least some of the artifact material in the stool. Numerous ether substitutes are available; the term ethyl acetate used throughout this chapter is used in the general sense (ether substitute).

Method

1. Transfer ¼ to ½ teaspoon of fresh stool into 10 mL of 5% or 10% formalin in a 15-mL shell vial, unwaxed paper cup, or 16- by 125-mm tube (the container used may vary depending on individual preference) and mix thoroughly. Let stand 30 min for adequate fixation.
2. Filter this material (use a funnel or pointed paper cup with the end cut off) through two layers of gauze into a 15-mL centrifuge tube.
3. Add physiologic saline or 5% or 10% formalin to within ½ inch (1.5 cm) of the top and centrifuge for 10 min at 500 g.
4. Decant; 0.5–1 mL of sediment should have been produced. Resuspend the sediment in saline to within ½ inch (1.5 cm) of the top and centrifuge again for 10 min at 500 g. This second wash may be eliminated if the supernatant fluid after the first wash is light tan or clear.
5. Decant and resuspend the sediment in 5% or 10% formalin (with the tube only half full). If the amount of sediment left at the bottom of the tube is very small, do not add ethyl acetate in step 6; merely add the formalin, then spin, decant, and examine the remaining sediment.
6. Add approximately 3 mL of ethyl acetate, stopper the tube, invert, and then shake vigorously for 30 s. Hold the tube so that the stopper is directed away from your face; remove the stopper carefully to prevent spraying of material caused by pressure in the tube (best performed under a biohazard hood).
7. Centrifuge for 10 min at 500 g. Four layers should result: a small amount of sediment in the bottom of the tube, containing the parasites; a layer of formalin; a plug of fecal debris on top of the formalin layer; and a layer of ether substitute at the top (Fig. 46.9).

8. Free the plug of debris by ringing with an applicator stick and decant all the fluid. Use a cotton-tipped applicator to remove debris from the sides of the test tube. After proper decanting, a drop or two of fluid remaining on the side of the tube will drain down to the sediment. Mix the fluid with the sediment and prepare a wet mount for examination.

The formalin–ethyl acetate sedimentation procedure may be used on material preserved with polyvinyl alcohol (PVA), although steps 1 and 2 differ as follows:

1. Fixation time with PVA should be at least 30 min. Mix the contents of the PVA bottle (stool-PVA mixture: one part stool to two or three parts PVA) with applicator sticks. Immediately after mixing, pour approximately 2–5 mL of the stool-PVA mixture (the amount varies, depending on the viscosity and density of the mixture) into a 15-mL shell vial, 16- by 125-mm tube, or similar container and add approximately 10 mL of physiologic saline or 5% or 10% formalin.
2. Filter this material (use a funnel or paper cup with the pointed end cut off) through two layers of gauze into a 15-mL centrifuge tube.

Steps 3 through 8 are the same for both fresh and PVA-preserved material.

Note: Tap water may be substituted for physiologic saline throughout this procedure; however, saline is recommended. Some workers prefer to use 5% or 10% formalin for all the rinses (steps 3 and 4).

When the sediment in the bottom of the tube is being examined,

1. Prepare a saline mount (one drop of sediment and one drop of saline solution mixed together) and scan the whole 22- by 22-mm cover slip under low power for helminth eggs or larvae.
2. Iodine may be added to aid detection of protozoan cysts; the specimen should be examined under high dry power. If iodine is added before low power scanning, make sure that the iodine is not too strong; otherwise, some of the helminth eggs will stain so darkly that they will be mistaken for debris.
3. Occasionally, a precipitate is formed when iodine is added to the sediment obtained from a concentration procedure with PVA-preserved material. The precipitate is formed from the reaction between the iodine and excess mercuric chloride that has not been thoroughly rinsed from the PVA-preserved material. The sediment can be rinsed again to remove any remaining mercuric chloride, or the sediment can be examined as a saline mount without the addition of iodine.

PROCEDURE 46.2

Wheatley's Trichrome Stain for Fecal Specimens (Modification of Gomori's Trichrome Stain for Tissue)

Principle

The internal elements that distinguish among cysts and trophozoites can best be visualized with a stain that enhances the morphologic features. In addition, such a stained smear provides a permanent record of the results.

Reagents

A. Formula

Chromotrope 2R	0.6 g
Light green SF	0.3 g
Phosphotungstic acid	0.7 g
Acetic acid (glacial)	1 mL
Distilled water	100 mL

B. Stain Preparation

1. Add 1 mL of glacial acetic acid to the dry components.
2. Allow the mixture to stand for 15–30 min to "ripen"; then add 100 mL of distilled water. This preparation gives a uniform and reproducible stain; the stain should be purple. Store in Coplin jars.

Method

1. Prepare fresh fecal smears or polyvinyl alcohol (PVA) smears as described.
2. Place in 70% ethanol for 5 min. (This step may be eliminated for PVA smears.)
3. Place in 70% ethanol plus D'Antoni's iodine (dark reddish brown) for 2–5 min.
4. Place in two changes of 70% ethanol: one for 5 min[a] and one for 2–5 min.
5. Place in trichrome stain solution for 10 min.
6. Place in 90% ethanol, acidified (1% acetic acid), for up to 3 s (do not leave the slides in this solution any longer).
7. Dip once in 100% ethanol.
8. Place in two changes of 100% ethanol for 2–5 min each.[a]
9. Place in two changes of xylene or toluene for 2–5 min each.[a]
10. Mount in Permount or other mounting medium; use a No. 1 thickness coverglass.

Expected Results

Background debris will be green, and protozoa will show blue-green to purple cytoplasm. The nuclei and inclusions will be red or purple-red and sharply delineated from the background.

Note: If you are currently using one of the stool fixatives that contains a mercuric chloride substitute (e.g., zinc sulfate), remember that the proficiency testing specimens you receive for permanent staining may have been preserved in PVA using the mercuric chloride fixative base. If you use the trichrome staining method for your mercuric chloride substitute fixatives, you may have eliminated the 70% alcohol/iodine step and the following 70% alcohol rinse steps from your method. However, when you stain the proficiency testing fecal smears, you must incorporate the iodine step and the next 70% alcohol rinse steps back into your staining protocol before placing your slides into the trichrome stain. These two steps are designed to remove the mercury from the smear and then to remove the iodine; when your slide is placed into the trichrome stain, both the mercury and iodine are no longer present in the fecal smear. If you fail to incorporate these two steps into your staining protocol, the quality of your proficiency testing stained smears will be poor.

Although you may be using mercuric chloride substitute fixatives, both the iodine/70% alcohol and subsequent 70% alcohol rinse steps before the trichrome stain can be used with no damage to the slides. However, some proficiency testing specimens have been fixed using mercuric chloride and will require the iodine and subsequent alcohol rinses before the trichrome staining step. All steps after the trichrome stain would remain the same for either type of fixative.

[a] At this stage, slides can be held several hours or overnight.

PROCEDURE 46.3

Modified Iron-Hematoxylin Stain (With Carbolfuchsin Step)

Principle

The internal elements that distinguish among cysts and trophozoites can be visualized with a stain that enhances the morphologic features. In addition, the stained smear provides a permanent record of the results.

Reagents

A. Mayer's Albumin

Add glycerin to an equal quantity of fresh egg white. Mix gently and thoroughly. Store at 4°C and indicate an expiration date of 3 months. Mayer's albumin from commercial suppliers can normally be stored at 25°C for 1 year (e.g., Product #756, E.M. Diagnostic Systems, 480 Democrat Road, Gibbstown, NJ 08027; [800] 443–3637).

B. Stock Solution of Hematoxylin Stain

Hematoxylin powder	10 g
Ethanol (95% or 100%)	1000 mL

1. Mix well until dissolved.
2. Store in a clear glass bottle, in a light area. Allow to ripen for 14 days before use.
3. Store at room temperature with an expiration date of 1 year.

C. Mordant

Ferrous ammonium sulfate $[Fe(NH_4)_2(SO_4)_2 \bullet 6 H_2O]$	10 g
Ferric ammonium sulfate $[FeNH_4(SO_4)_2 \bullet 12 H_2O]$	10 g
Hydrochloric acid (HCl) (concentrated)	10 mL
Add distilled water to 1000 mL	

D. Working Solution of Hematoxylin Stain

1. Mix equal quantities of stock solution of stain and mordant.
2. Allow mixture to cool thoroughly before use (prepare at least 2 h before use). The working solution should be made fresh every week.

E. Picric Acid

Mix equal quantities of distilled water and an aqueous saturated solution of picric acid to make a 50% saturated solution.

F. Acid-Alcohol Decolorizer

Hydrochloric acid (HCl)	30 mL (concentrated)
Alcohol to 1000 mL	

G. 70% Alcohol and Ammonia

70% alcohol	50 mL
Ammonia (enough to bring the pH to approximately 8.0)	0.5–1 mL

H. Carbolfuchsin

Basic fuchsin (solution A): Dissolve 0.3 g basic fuchsin in 10 mL of 95% ethanol.

Phenol (solution B): Dissolve 5 g of phenol crystals in 100 mL distilled water. (Gentle heat may be needed.)

1. Mix solution A with solution B.
2. Store at room temperature. Solution is stable for 1 year.

Method

1. Slide preparation:
   a. Place 1 drop of Mayer's albumin on a labeled slide.
   b. Mix the sediment from the sodium acetate–acetic acid–formalin (SAF) concentration well with an applicator stick.
   c. Add approximately 1 drop of the fecal concentrate to the albumin and spread the mixture over the slide.
2. Allow the slide to air dry at room temperature (the smear appears opaque when dry).
3. Place the slide in 70% alcohol for 5 min.
4. Wash in a container of tap water (not running water) for 2 min.
5. Place the slide in Kinyoun's stain for 5 min.
6. Wash the slide in running tap water (i.e., a constant stream of water into a container) for 1 min.
7. Place the slide in acid/alcohol decolorizer for 4 min.[a]
8. Wash the slide in running tap water (a constant stream of water into a container) for 1 min.
9. Place the slide in the iron-hematoxylin working solution for 8 min.
10. Wash the slide in distilled water (in a container) for 1 min.
11. Place the slide in the picric acid solution for 3–5 min.
12. Wash the slide in running tap water (a constant stream of water into a container) for 10 min.
13. Place the slide in 70% alcohol plus ammonia for 3 min.
14. Place the slide in 95% alcohol for 5 min.
15. Place the slide in 100% alcohol for 5 min.
16. Place the slide in two changes of xylene for 5 min.

Procedure Notes

1. The first 70% alcohol step acts with the Mayer's albumin to "glue" the specimen to the glass slide. The specimen may wash off if insufficient albumin is used or if the slides are not completely dry before staining.
2. The working hematoxylin stain should be checked each day by adding a drop of stain to alkaline tap water. If a blue color does not develop, prepare a fresh working stain solution.
3. The picric acid differentiates the hematoxylin stain by removing more stain from fecal debris than from the protozoa and removing more stain from the organism's cytoplasm than from the nucleus.
4. When properly stained, the background should be various shades of gray-blue, and protozoa should visible. The cytoplasm will stain a medium-blue cytoplasm and the nuclei will stain a dark blue–black.

[a] This step can also be performed as follows:

a. Place slide in acid/alcohol decolorizer for 2 min.
b. Wash slide in running tap water (constant stream of water into container) for 1 min.
c. Place slide in acid/alcohol decolorizer for 2 min.
d. Wash slide in running tap water (constant stream of water into container) for 1 min.
e. Continue staining sequence with step 9 above (iron hematoxylin working solution).

PROCEDURE 46.4

Modified Acid-Fast Stain for Coccidia

Reagents

A. Carbolfuchsin

Basic fuchsin	4 g
Phenol	8 mL
Alcohol (95%)	20 mL
Distilled water	100 mL

Dissolve the basic fuchsin in the alcohol; then add the water slowly while shaking. Melt the phenol in a 56°C water bath and add 8 mL to the stain, using a pipette with a rubber bulb.

B. Decolorizer

Ethanol (95%)	97 mL
Concentrated HCl	3 mL

Working under a chemical fume hood, add the hydrochloric acid to the alcohol slowly.

C. Counterstain

Methylene blue	0.3 g
Distilled water	100 mL

"Cold" Modified Acid-Fast Stain Method (Kinyoun)

1. Spin an aliquot of 10% formalinized stool for 10 min at 500 *g*.
2. Remove the upper layer of sediment with a pipette and place a thin layer on a microscope slide.

   NOTE: If the stool specimen contains a large amount of mucus, 10 drops of 10% potassium hydroxide (KOH) can be added to the sediment (step 2), which is vortexed, rinsed with 10% formalin, and respun before smear preparation. Some laboratories use this approach routinely before smear preparation.
3. Heat-fix the smear at 70°C for 10 min.
4. Stain the fixed smear for 3–5 min (no heat necessary).
5. Wash in distilled, filtered water and shake off excess water.
6. Flood with decolorizer for approximately 1 min. Check to see that no more red color runs when the slide is tipped. Add a bit more decolorizer for very thick slides or those that continue to bleed red dye.
7. Wash thoroughly with filtered water as previously and shake off excess.
8. Flood with counterstain for approximately 1 min.
9. Wash with distilled water and drain by standing slides upright. Do not blot dry.

The staining of acid-fast organisms may be accelerated by the addition of a detergent or wetting agent. Tergitol No. 7 (Sigma Chemical Co., St. Louis, MO) may be used. Add 1 drop of Tergitol No. 7 to every 30–40 mL of the Kinyoun's carbolfuchsin stain.

Acid-fast bacteria stain red with carbolfuchsin stains. The background color depends on the counterstain: methylene blue imparts a blue color to non–acid-fast material, brilliant green results in a green background, and picric acid results in yellow.

"Hot" Modified Acid-Fast Stain Method

1. Spin an aliquot of 10% formalinized stool for 10 min at 500 *g*.
2. Remove the upper layer of sediment with a pipette and place a thin layer on a microscope slide.

   NOTE: If the stool specimen contains a large amount of mucus, 10 drops of 10% potassium hydroxide (KOH) can be added to the sediment (step 2), which is vortexed, rinsed with 10% formalin, and respun before smear preparation. Some laboratories use this approach routinely before smear preparation.
3. Heat fix the smear at 70°C for 10 min.
4. Place the slide on a staining rack and flood with carbolfuchsin.
5. Heat to steaming and stain for 5 min. If the slide begins to dry, add more stain without additional heating.
6. Rinse the smear with tap or distilled water.
7. Decolorize with 5% aqueous sulfuric acid for 30 s (thicker smears may require a longer time).
8. Rinse the smear with tap or distilled water, drain, and flood the smear with methylene blue counterstain for 1 min.
9. Rinse with tap or distilled water, drain, and air dry.

From Kinyoun JJ. A note on Uhlenhuths method for sputum examination, for tubercle bacilli. *Am J Pub Health.* 1915;5:867.

PROCEDURE 46.5

Modified Trichrome Stain for Microsporidia (Weber-Green)

Principle

The oval shape, spore wall, and diagonal or horizontal "stripe" that distinguish microsporidia spores can best be visualized with a stain that enhances the morphologic features. In addition, such a stained smear provides a permanent record of the results.

Reagents

A. Modified Trichrome Stain

Chromotrope 2R	6 g[a]
Fast green	0.15 g
Phosphotungstic acid	0.7 g
Acetic acid (glacial)	3 mL
Distilled water	100 mL

1. Prepare the stain by adding 3 mL of acetic acid to the dry ingredients. Allow the mixture to stand (ripen) for 30 min at room temperature.
2. Add 100 mL of distilled water. A properly prepared stain is dark purple.
3. Store in a glass or plastic bottle at room temperature. The shelf life is at least 24 months.

B. Acid-Alcohol

90% ethyl alcohol	995.5 mL
Acetic acid (glacial)	4.5 mL

Prepare by combining the two solutions.

Method

1. Using a 10-μL aliquot of unconcentrated, preserved liquid stool (5% or 10% formalin or sodium acetate–acetic acid–formalin [SAF]), prepare the smear by spreading the material over an area 45 × 25 mm.
2. Allow the smear to air-dry.
3. Place the smear in absolute methanol for 5 min.
4. Allow to air-dry.
5. Place in trichrome stain for 90 min.
6. Rinse in acid-alcohol for no longer than 10 s.
7. Dip the slides several times in 95% alcohol. Use this step as a rinse.
8. Place in 95% alcohol for 5 min.
9. Place in 100% alcohol for 10 min.
10. Place in xylene substitute for 10 min.
11. Mount with a cover slip (No. 1 thickness), using mounting medium. Check the specimen for adherence to the slide.
12. Examine the smears under oil immersion (×1000) and read at least 100 fields; the examination time probably will be at least 10 min per slide.

Expected Results

Known parasites should be detected readily. If the smear is thoroughly fixed and the stain has been performed correctly, the spores are ovoid and refractile and the spore wall is bright pinkish red. Occasionally the polar tube can be seen either as a stripe or as a diagonal line across the spore. Most of the bacteria and other debris tend to stain green. However, some bacteria and debris stain red.

[a] 10 times the normal trichrome stain formula.

PROCEDURE 46.6

Modified Trichrome Stain for Microsporidia (Ryan-Blue)

Principle

The oval shape, spore wall, and diagonal or horizontal "stripe" that distinguish microsporidia spores can be visualized with a stain that enhances the morphologic features. In addition, such a stained smear provides a permanent record of the results.

Numerous variations to the modified trichrome (Weber-Green) stain were attempted to improve the contrast between the color of the spores and the background staining. Optimal staining was achieved by modifying the composition of the trichrome solution. This stain is also available commercially from several suppliers. The specimen can be fresh stool or stool that has been preserved in 5% or 10% formalin, sodium acetate–acetic acid–formalin (SAF), or some of the newer single vial–system fixatives. Actually, any specimen other than tissue believed to contain microsporidia can be stained by this method.

Reagents

A. Trichrome Stain (Modified for Microsporidia) (Ryan-Blue)

Chromotrope 2R	6 g[a]
Aniline blue	0.5 g
Phosphotungstic acid	0.25 g
Acetic acid (glacial)	3 mL
Distilled water	100 mL

1. Prepare the stain by adding 3 mL of acetic acid to the dry ingredients. Allow the mixture to stand (ripen) for 30 min at room temperature.
2. Add 100 mL of distilled water and adjust the pH to 2.5 with 1 M hydrochloric acid (HCl). A properly prepared stain is dark purple. The staining solution should be protected from light.
3. Store in a glass or plastic bottle at room temperature. The shelf life is at least 24 months.

B. Acid-Alcohol (Procedure 46.5)

Method

1. Using a 10-μL aliquot of unconcentrated preserved liquid stool (5% or 10% formalin or sodium acetate–acetic acid–formalin [SAF]), prepare the smear by spreading the material over an area 45 by 25 mm.
2. Allow the smear to air-dry.
3. Place the smear in absolute methanol for 5 or 10 min.
4. Allow the smear to air-dry.
5. Place in trichrome stain for 90 min.
6. Rinse in acid-alcohol for no longer than 10 s.
7. Dip slides several times in 95% alcohol. Use this step as a rinse (no longer than 10 s).
8. Place in 95% alcohol for 5 min.
9. Repeat step 8.
10. Place in 100% alcohol for 10 min.
11. Place in xylene substitute for 10 min.
12. Mount with a cover slip (No. 1 thickness), using mounting medium.
13. Examine smears under oil immersion (1000×) and read at least 100 fields; the examination time probably will be at least 10 min per slide.

Expected Results

Known parasites should be detected readily. If the smear is thoroughly fixed and the stain has been performed correctly, the spores are ovoid and refractile and the spore wall is bright pinkish red. Occasionally the polar tube can be seen either as a stripe or as a diagonal line across the spore. Most of the bacteria and other debris tend to stain blue. However, some bacteria and debris stain red.

Procedure Notes for Modified Trichrome Staining Methods (Weber or Ryan)

1. Positive control smears must be stained and examined each time patient specimens are stained and examined.
2. Because of the difficulty in achieving stain penetration through the spore wall, prepare thin smears and do not reduce the staining time in trichrome. Also, make sure the slides are not left too long in the decolorizing agent (acid-alcohol). If the control organisms are too light, leave them in the trichrome longer and shorten the time to two dips in the acid-alcohol solution. Also, remember that the 95% alcohol rinse after the acid-alcohol should be performed quickly to prevent additional destaining from the acid-alcohol reagent.
3. When purchasing the chromotrope 2R, obtain the highest dye content available. Two sources are Harleco (Gibbstown, NJ) and Sigma Chemical Co. (dye content among the highest [85%]). Fast green and aniline blue can be obtained from Allied Chemical and Dye (New York City, NY).
4. In the final stages of dehydration, the 100% ethanol and the xylenes (or xylene substitutes) should be kept as free of water as possible. Coplin jars must have tight-fitting caps to prevent both evaporation of reagents and absorption of moisture. If the xylene becomes cloudy after the addition of slides from 100% alcohol, return the slides to 100% alcohol and replace the xylene with fresh stock.

Procedure Limitations for Modified Trichrome Staining Methods (Weber or Ryan)

1. Although this staining method stains the microsporidia, the range of stain intensity and the small size of the spores cause some difficulty in identifying these organisms. Because this procedure results in the staining of many other organisms or objects in stool specimens, differentiation of the microsporidia from surrounding material is still difficult. In addition, some slight size variation occurs among the spores.
2. If the patient has severe watery diarrhea, less artifact material is present in the stool to confuse with the microsporidial spores. If the stool is semiformed or formed, the amount of artifact material is much greater, and the spores are much harder to detect and identify. Also, remember that the number of spores varies according to the stool consistency (the more diarrheic the stool, the more spores that are present).
3. Those who developed some of these techniques believe that concentration procedures result in an actual loss of microsporidial spores; therefore, the use of unconcentrated, formalinized stool is strongly recommended. However, no data indicate the centrifugation speeds and other parameters used in the study.
4. In the University of California Los Angeles Clinical Microbiology Laboratory, unpublished data have indicated that centrifugation at 500 *g* for 10 min increases dramatically the number of microsporidial spores available for staining (from the concentrate sediment). This is the same protocol used for centrifugation of all stool specimens, regardless of the suspected organism.
5. Do not use wet gauze filtration (an old standardized method of filtering stool before centrifugation) with too many layers of gauze that may trap organisms and prevent them from flowing into the fluid to be concentrated. No more than two layers of gauze should be used. Commercially available concentration systems that use metal or plastic screens for filtration also may be used.

[a] Ten times the normal trichrome stain formula.

PROCEDURE 46.7

Modified Trichrome Stain for Microsporidia (Kokoskin; Hot Method)

Principle

The oval shape, spore wall, and diagonal or horizontal “stripe” that distinguish microsporidia spores can be visualized with a stain that enhances the morphologic features. Changes in temperature (from room temperature to 50°C) and in the staining time (from 90 to 10 min) have been recommended as improvements for the modified trichrome staining methods. In addition, such a stained smear provides a permanent record of the results.

Method

1. Using a 10-μL aliquot of unconcentrated, preserved liquid stool (5% or 10% formalin or sodium acetate–acetic acid–formalin [SAF]), prepare the smear by spreading the material over an area 45 by 25 mm.
2. Allow the smear to air-dry.
3. Place the smear in absolute methanol for 5 min.
4. Allow the smear to air-dry.
5. Place in trichrome stain for 10 min at a temperature of 50°C.
6. Rinse in acid-alcohol for no longer than 10 s.
7. Dip the slides several times in 95% alcohol. Use this step as a rinse (no longer than 10 s).
8. Place in 95% alcohol for 5 min.
9. Place in 100% alcohol for 10 min.
10. Place in xylene substitute for 10 min.
11. Mount with a cover slip (No. 1 thickness), using mounting medium.
12. Examine smears under oil immersion (1000×) and read at least 100 fields; the examination time probably will be at least 10 min per slide.

PROCEDURE 46.8

Staining Thin Films: Giemsa Stain

Principle

Spreading the blood cells in a thin layer allows easier visualization of the size of red cells, inclusions, and extracellular forms.

Method

1. Fix blood films in absolute methanol (acetone-free) for 30 s.
2. Allow the slides to air-dry.
3. Immerse the slides in a solution of 1 part Giemsa stock (commercial liquid stain or stock prepared from powder) to 10–50 parts of Triton-buffered water (pH 7.0–7.2). Stain 10–60 min (see Procedure note). Fresh working stain should be prepared from stock solution each day.
4. Dip slides briefly in Triton X-100 buffered water.
5. Drain thoroughly in the vertical position and allow to air-dry.

Note: A good general rule for stain dilution and staining time is as follows: if the dilution is 1:20, stain for 20 min; if 1:30, stain for 30 min; and so forth. However, a series of stain dilutions and staining times should be tested to determine the best dilution and time for each batch of stock stain.

Expected Results

Giemsa stain colors the components of blood as follows: erythrocytes, pink-orange to pale gray-blue depending on the pH of the stain; nuclei of white blood cells, purple and pale purple cytoplasm; eosinophilic granules, bright purple-red; neutrophilic granules, deep pink-purple. Parasitic forms are blue to purple, with reddish nuclei. Their characteristic morphologies are used for differentiation. Inexperienced workers may confuse platelets with parasites.

PROCEDURE 46.9

Staining Thick Films: Giemsa Stain

Principle

A large amount of blood can be examined for parasitic forms by lysing the red blood cells and staining for parasites. The lack of methanol fixation allows lysis of red blood cells by the aqueous stain solution. Although parasites can be found in the larger volume of blood, definitive morphologic criteria necessary for specific organism identification may be more difficult to see.

Method

The procedure followed for thick films is the same as for thin films, except that the first two steps are omitted. If the slide has a thick film at one end and a thin film at the other, fix only the thin portion and then stain both parts of the film simultaneously.

Note: Although Giemsa stain has been used for many years, a number of bloodstains can be used for blood parasites (e.g., Giemsa, Wright's, and Wright-Giemsa combination, rapid bloodstains). Different stains produce somewhat different colors for the cell nuclei and cytoplasm; however, color variability is also seen with Giemsa stain depending on pH. Regardless of the stain used, the quality control is built into the slide; the colors seen in any parasites present mimic those seen in the white blood cells (WBCs). Therefore, the WBCs serve as the quality control organisms. It is not mandatory to use actual blood parasites as the quality control organisms. Alternately, previously positive patient smears (if available) can be held fixed with methanol and air-dried, then stored in a sealed container at −70°C. The QC slides should be brought to room temperature before staining.

PROCEDURE 46.10

Calibration of the Ocular Micrometer

Principle

Exact determination of size is a critical standard in the correct identification of parasite elements, especially protozoa found in fecal specimens. For that reason, each microscope used for parasite identification should have a calibrated ocular micrometer.

Materials

1. Ocular micrometer disk installed in one of the eyepieces of the microscope (ocular). The ocular micrometer is used to measure items seen through the microscope.
2. Stage micrometer used to calibrate the ocular micrometer. For highest accuracy, the micrometer should be certified by an agency such as National Institute of Standards and Technology (NIST).

Method

1. Insert the ocular micrometer disk into one of the oculars on the microscope.
2. Place the stage micrometer slide on the microscope stage.
3. Align the ocular scale to the stage micrometer and focus so that you are able to clearly view both the large (0.1 mm) and the small (0.01 mm) increments
4. Move the stage micrometer so that the "0" line on the ocular micrometer aligns with the "0" line on the stage micrometer.

5. Find a point as far down the scale as possible where the ocular and stage micrometer scales match.
6. Count the number of ocular micrometer spaces that align with the number of millimeters on the stage micrometer.

- For example: If 0.5 mm on the stage micrometer aligns with 42 ocular micrometer spaces, then 0.5 mm/42 = 0.0119 mm/ocular micrometer space.
- Because parasites are typically reported in micrometers, this should be converted to micrometers by multiplying by 1000.
- Therefore 0.0119 mm/ocular space × 1000 μm/mm = 11.9 μm/ocular micrometer space.
- This procedure should be repeated for each objective on the microscope.

7. The calibration is microscope-specific, so if more than one microscope is used, each microscope must be calibrated.
8. Calibrations should be posted by the microscope for each magnification.
9. Calibration should be repeated annually, after each cleaning, or when an objective or ocular lens has been changed.

47

Intestinal Protozoa

OBJECTIVES

1. Describe the basic life cycle, distinguishing morphologic characteristics, clinical disease (if pathogenic), laboratory diagnosis, and prevention for the organisms discussed in this chapter.
2. Define and identify the following parasitic structures: trophozoite, cyst, oocyst, spore, pseudopodia, flagella, cilia, chromatoidal bars, karyosome, central vacuole, cyst form, axoneme, cytostome, spiral groove, undulating membrane, ventral disc, shepherd's crook, axostyle, macronucleus, micronucleus, apical complex, sporocyst, sporozoite, spore, sarcocyst, and polar tubule.
3. Define life cycle processes, including merogony, gametogony, sporogony, schizogony, and the associated organism(s) and stages.
4. Correlate the parasitic life cycles with the specific diagnostic stages for the organisms listed.
5. Distinguish pathogenic from nonpathogenic protozoa.

PARASITES TO BE CONSIDERED

Protozoa

- Amoebae (intestinal)
  - *Entamoeba bangladeshi*
  - *Entamoeba histolytica*
  - *Entamoeba dispar**
  - *Entamoeba coli*
  - *Entamoeba gingivalis*
  - *Entamoeba hartmanni*
  - *Entamoeba moshkovskii*
  - *Entamoeba polecki*
  - *Endolimax nana*
  - *Iodamoeba bütschlii (buetschlii)*
  - *Blastocystis* spp.
- Flagellates (intestinal)
  - *Giardia duodenalis*
  - *Chilomastix mesnili*
  - *Pentatrichomonas hominis*
  - *Retortamonas hominis*
- Amoeba flagellate
  - *Dientamoeba fragilis*
- Ciliates (intestinal)
  - *Neoblantidium coli*

Entamoeba histolytica is considered a true pathogen, and *Entamoeba dispar* is used to designate nonpathogens. Additional morphologically identical species, *Entamoeba moshkovskii* and *Entamoeba bangladeshi,* have been identified which are associated with noninvasive diarrhea. Although it was previously reported that 16% of identified *E. dispar* trophozoites contain ingested red blood cells, nucleic acid–based methods have been used to resolve this morphological discrepancy. All trophozoites containing red blood cells can be distinctly identified as *E. histolytica* using nucleic acid–based methods. Immunoassay kits and molecular assays are available for identifying the *E. histolytica/E. dispar* group and for differentiating *E. histolytica, E. dispar,* and *E. moshkovskii*. *E. bangladeshi* is a species that is indistinguishable from *E. histolytica* both physically and pathologically; little more is known regarding this species.

The protozoa are unicellular eukaryotic organisms, most of which are microscopic. They have a number of specialized organelles that are responsible for life functions and that allow further division of the group into classes. Most protozoa multiply by binary fission and are ubiquitous worldwide.

The important characteristics of the intestinal protozoa are presented in Tables 47.1–47.7. The clinically relevant intestinal protozoa are generally considered to be *Entamoeba histolytica, Entamoeba moshkovskii, Blastocystis hominis, Giardia duodenalis, Dientamoeba fragilis, Neobalantidium coli, Cystoisospora belli, Cryptosporidium* spp., *Cyclospora cayetanensis,* and the microsporidia. Nonpathogenic intestinal protozoa are listed in various figures and tables but are not discussed in detail.

Amoebae

The class Sarcodina, or Amoebae, includes the organisms capable of movement by means of cytoplasmic protrusions called **pseudopodia.** This group includes free-living organisms, in addition to nonpathogenic and pathogenic organisms found in the intestinal tract and other areas of the body (Tables 47.1 and 47.2). Occasionally, when fresh stool material is examined as a direct wet mount, motile trophozoites may be seen, as well as other, nonparasitic structures (Fig. 47.1).

Entamoeba histolytica

General Characteristics

Living **trophozoites** (motile feeding stage) of *E. histolytica* vary in size from about 12 to 60 µm in diameter. Organisms recovered from diarrheic or dysenteric stools generally are larger than those in formed stool from an asymptomatic individual. The motility has been described as rapid

TABLE 47.1 **Intestinal Protozoa: Trophozoites of Common Amoebae**

Characteristic	*Entamoeba histolytica*	*Entamoeba dispar/ moshkovskii/ bangladeshi*	*Entamoeba hartmanni*	*Entamoeba coli*	*Endolimax nana*	*Iodamoeba bütschlii*
Size[a] (diameter or length)	12–60 µm (usual range, 15–20 µm); invasive forms may be >20 µm	Same size range as *E. histolytica*	5–12 µm (usual range, 8–10 µm)	15–50 µm (usual range, 20–25 µm)	6–12 µm (usual range, 8–10 µm)	8–20 µm (usual range, 12–15 µm)
Motility	Progressive, with hyaline, fingerlike pseudopodia; motility may be rapid	Same motility as *E. histolytica*	Usually nonprogressive	Sluggish, nondirectional; blunt, granular pseudopodia	Sluggish, usually nonprogressive	Sluggish, usually nonprogressive
Nucleus (single) and visibility	Difficult to see in unstained preparations	Difficult to see in unstained preparations	Usually not seen in unstained preparations	Often visible in unstained preparation	Occasionally visible in unstained preparations	Usually not visible in unstained preparations
Peripheral chromatin (stained)	Fine granules, uniform in size and usually evenly distributed; may have beaded appearance.	Fine granules, uniform in size and usually evenly distributed; may have beaded appearance.	Nucleus may stain more darkly than in *E. histolytica*, although morphology is similar; chromatin may appear as solid ring rather than beaded (trichrome).	May be clumped and unevenly arranged on the membrane; may also appear as solid, dark ring with no beads or clumps.	Usually no peripheral chromatin; nuclear chromatin may be quite variable.	Usually no peripheral chromatin.
Karyosome (stained)	Small, usually compact; centrally located but may also be eccentric	Small, usually compact; centrally located but may also be eccentric	Usually small and compact; may be centrally located or eccentric	Large, not compact; may or may not be eccentric; may be diffuse and darkly stained	Large, irregularly shaped; may appear blotlike; many nuclear variations are common; may mimic *E. hartmanni* or *Dientamoeba fragilis*	Large, may be surrounded by refractile granules that are difficult to see ("basket nucleus")
Cytoplasm appearance (stained)	Finely granular, "ground glass" appearance; clear differentiation of ectoplasm and endoplasm; if present, vacuoles are usually small.	Finely granular, "ground glass" appearance; clear differentiation of ectoplasm and endoplasm; if present, vacuoles are usually small.	Finely granular.	Granular, with little differentiation into ectoplasm and endoplasm; usually vacuolated.	Granular, vacuolated.	Granular, may be heavily vacuolated.
Inclusions (stained)	Noninvasive organism may contain bacteria or red blood cells.	Organisms usually contain bacteria; in cytoplasm.	May contain bacteria; no RBCs.	Bacteria, yeast, other debris.	Bacteria.	Bacteria.

[a] These sizes refer to wet preparation measurements. Organisms on a permanent stained smear may be 1 to 1.5 µm smaller as a result of artificial shrinkage.
RBC, Red blood cell.

TABLE 47.2 **Intestinal Protozoa—Cysts of Common Amoebae**

Characteristic	*Entamoeba histolytica/dispar/moshkovskii/bangladeshi*	*Entamoeba hartmanni*	*Entamoeba coli*	*Endolimax nana*	*Iodamoeba bütschlii*
Size[a] (diameter or length)	10–20 μm (usual range, 12–15 μm)	5–10 μm (usual range, 6–8 μm)	10–35 μm (usual range, 15–25 μm)	5–10 μm (usual range, 6–8 μm)	5–20 μm (usual range, 10–12 μm)
Shape	Usually spherical	Usually spherical	Usually spherical; may be oval, triangular, or other shapes; may be distorted on permanent stained slide because of inadequate fixative penetration	Usually oval, may be round	May vary from oval to round; cyst may collapse because of large glycogen vacuole space
Nucleus (number and visibility)	Mature cyst: 4 nuclei Immature cyst: 1–2 nuclei; nuclear characteristics difficult to see on wet preparation	Mature cyst: 4 nuclei; Immature cyst: 1–2 nuclei (2-nucleated cysts very common)	Mature cyst: 8 (occasionally 16 or more nuclei may be seen). Immature cysts with 2 or more nuclei are occasionally seen	Mature cyst: 4 Immature cysts: 2 very rarely seen and may resemble cysts of *Enteromonas hominis*	Mature cyst: 1
Peripheral chromatin (stained)	Peripheral chromatin present; fine, uniform granules, evenly distributed; nuclear characteristics may not be as clearly visible as in trophozoite.	Fine granules evenly distributed on the membrane; nuclear characteristics may be difficult to see.	Coarsely granular; may be clumped and unevenly arranged on membrane; nuclear characteristics not as clearly defined as in trophozoite; may resemble *E. histolytica*.	No peripheral chromatin.	No peripheral chromatin.
Karyosome (stained)	Small, compact, usually centrally located but occasionally may be eccentric	Small, compact, usually centrally located	Large, may or may not be compact and/or eccentric; occasionally may be centrally located	Smaller than karyosome seen in trophozoites but generally larger than those of genus *Entamoeba*	Larger, usually eccentric refractile granules may be on one side of karyosome ("basket nucleus")
Cytoplasm, chromatoidal bodies (stained)	May be present; bodies usually elongate, with blunt, rounded, smooth edges; may be round or oval	Usually present; bodies usually elongate with blunt, rounded, smooth edges; may be round or oval	May be present (less frequently than in *E. histolytica*); splinter shaped with rough, pointed ends	Rare chromatoidal bodies present; occasionally small granules or inclusions seen; fine linear chromatoidals may be faintly visible on well-stained smears	No chromatoidal bodies present; occasionally small granules may be present
Glycogen (stained with iodine)	May be diffuse or absent in mature cyst; clumped chromatin mass may be present in early cysts (stains reddish brown with iodine)	May or may not be present, as in *E. histolytica*	May be diffuse or absent in mature cyst; clumped mass occasionally seen in mature cysts (stains reddish brown with iodine)	Usually diffuse if present (stains reddish brown with iodine)	Large, compact, well-defined mass (stains reddish brown with iodine)

[a] Wet preparation measurements; in permanent stains, organisms usually are 1–2 μm smaller.

TABLE 47.3 **Intestinal Protozoa—Trophozoites of Flagellates**

Protozoa	Shape and Size	Motility	Number of Nuclei and Visibility	Number of Flagella (Usually Difficult to See)	Other Features
Dientamoeba fragilis	Shaped like amebae; 5–15 μm (usual range, 9–12 μm)	Usually nonprogressive; pseudopodia are angular, serrated, or broad lobed and almost transparent.	Percentage may vary, but 40% of organisms have 1 nucleus and 60% have 2 nuclei; not visible in unstained preparations; no peripheral chromatin; karyosome is composed of a cluster of 4–8 granules.	Internal flagella; not visible	Cytoplasm is finely granular and may be vacuolated with ingested bacteria, yeasts, and other debris; may be great variation in size and shape on a single smear.
Giardia duodenalis	Pear-shaped; length 10–20 μm; width, 5–15 μm	"Falling leaf" motility may be difficult to see if organism is in mucus; slight flutter of flagella may be visible using low light (duodenal aspirate or mucus from Entero-Test capsule).	2; not visible in unstained mounts.	4 lateral; 2 ventral, 2 caudal	Sucking disk occupies one half to three fourths of ventral surface; pear-shaped front view, spoon-shaped side view.
Chilomastix mesnili	Pear-shaped; length 6–24 μm (usual range, 10–15 μm); width, 4–8 μm	Stiff, rotary.	1; not visible in unstained mounts.	3 anterior, 1 in cytostome	Prominent cytostome extending one-third to one-half the length of the body; spiral groove across ventral surface.
Pentatrichomonas hominis	Pear-shaped; length 5–15 μm (usual range, 7–9 μm); width 7–10 μm	Jerky, rapid.	1; not visible in unstained mounts.	3–5 anterior, 1 posterior	Undulating membrane extends the length of the body; posterior flagellum extends free beyond end of body.
Trichomonas tenax	Pear-shaped; length 5–12 μm; average of 6.5–7.5 μm; width, 7–9 μm	Jerky, rapid.	1; not visible in unstained mounts.	4 anterior, 1 posterior	Seen only in preparations from mouth; axostyle (slender rod) protrudes beyond the posterior end and may be visible; posterior flagellum extends only halfway down the body; no free end.
Enteromonas hominis	Oval; 4–10 μm (usual range, 8–9 μm); width, 5–6 μm	Jerky.	1; not visible in unstained mounts.	3 anterior, 1 posterior	One side of the body is flattened; posterior flagellum extends free posteriorly or laterally.
Retortamonas intestinalis	Pear-shaped or oval; 4–9 μm (usual range, 6–7 μm); width, 3–4 μm	Jerky.	1; not visible in unstained mount.	1 anterior, 1 posterior	Prominent cytostome extends approximately one half the length of the body.

TABLE 47.4 Intestinal Protozoa—Cysts of Flagellates

Protozoa	Size	Shape	Number of Nuclei	Other Features
Dientamoeba fragilis	5–8 um	Oval to round	1–2	Distinct cyst wall with inner irregular cyst wall. Clear space apparent between outer and inner cyst wall.
Pentatrichomonas hominis, Trichomonas tenax	No cyst stage			
Giardia duodenalis	8–19 µm (usual range, 11–14 µm); width, 7–10 µm	Oval, ellipsoidal, or may appear round	4; not distinct in unstained preparations; usually located at one end	Longitudinal fibers in cysts may be visible in unstained preparations; deep-staining median bodies usually lie across the longitudinal fibers. Shrinkage is common, with the cytoplasm pulling away from the cyst wall; "halo" effect may be seen around the outside of the cyst wall because of shrinkage caused by dehydrating reagents.
Chilomastix mesnili	6–10 µm (usual range, 7–9 µm); width, 4–6 µm	Lemon or pear-shaped with anterior hyaline knob	1; not distinct in unstained preparations	Cytostome with supporting fibrils, usually visible in stained preparation; curved fibril alongside of cytostome, usually referred to as a "shepherd's crook."
Enteromonas hominis	4–10 µm (usual range, 6–8 µm); width, 4–6 µm	Elongate or oval	1–4; usually 2 lying at opposite ends of cyst; not visible in unstained mounts	Resembles *Endolimax nana* cyst; fibrils or flagella usually not seen.
Retortamonas intestinalis	4–9 µm (usual range, 4–7 µm); width, 5 µm	Pear-shaped or slightly lemon-shaped	1; not visible in unstained mounts	Resembles *Chilomastix* cyst; shadow outline of cytostome with supporting fibrils extends above nucleus; "bird beak" fibril arrangement.

TABLE 47.5 Intestinal Protozoa—Ciliates

Protozoa	Shape and Size	Motility	Number of Nuclei	Other Features
Neobalantidium coli trophozoite	Ovoid with tapering anterior end; 50–100 µm long, 40–70 µm wide (usual range, 40–50 µm)	Ciliates: rotary, boring; may be rapid	1 large kidney-shaped macronucleus; 1 small round micronucleus, which is difficult to see even in stained smear; macronucleus may be visible in unstained preparation.	Body covered with cilia, which tend to be longer near cytostome; cytoplasm may be vacuolated.
Cyst	Spherical or oval; 50–70 µm (usual range, 50–55 µm)		1 large macronucleus visible in unstained preparation; micronucleus difficult to see.	Macronucleus and contractile vacuole are visible in young cysts; in older cysts, internal structure appears granular; cilia difficult to see in cyst wall.

TABLE 47.6 **Morphologic Criteria Used to Identify Intestinal Protozoa (Coccidia, *Blastocystis* spp.)**

Protozoa	Shape and Size	Other Features
Cryptosporidium spp. *Cryptosporidium parvum* (humans and animals) *Cryptosporidium hominis* (humans)	Oocyst generally round, 4–6 µm; each mature oocyst contains four sporozoites.	Oocyst, diagnostic stage in stool, sporozoites occasionally visible within oocyst wall; acid-fast positive using modified acid-fast stains; various other stages in life cycle can be seen in biopsy specimens taken from gastrointestinal tract (brush border of epithelial cells) and other tissues; disseminated infection well documented in compromised host; oocysts immediately infective (in both formed and/or watery specimens); nosocomial infections documented; use enteric precautions for inpatients.
Cyclospora cayetanensis	Oocyst generally round, 8–10 µm; oocysts are not mature, no visible internal structure; oocysts may appear wrinkled.	Oocyst, diagnostic stage in stool; acid-fast variable using modified acid-fast stains; color range from clear to deep purple (tremendous variation); best results obtained with decolorizing solution consisting of 1% acid, 3% maximum; oocysts may appear wrinkled (like crumpled cellophane); mimic *Cryptosporidium* oocysts but are twice as large.
Cystoisospora belli	Ellipsoidal oocyst; range 20–30 µm long, 10–19 µm wide; sporocysts rarely seen broken out of oocysts but measure 9–11µm.	Mature oocyst contains two sporocysts with four sporozoites each; usual diagnostic stage in feces is immature oocyst containing spherical mass of protoplasm (intestinal tract). Oocysts are modified acid-fast positive. Whole oocyst may stain pink, but just the internal sporocysts stain if the oocyst is mature.
Sarcocystis hominis *Sarcocystis suihominis*	Oocyst thin-walled and contains two mature sporocysts, each containing four sporozoites; commonly thin oocyst wall ruptures; ovoid sporocysts each measure 10–16 µm long and 7.5–12 µm wide.	Thin-walled oocyst or ovoid sporocysts occur in stool (intestinal tract).
Blastocystis spp.	Organisms are generally round, measure approximately 6–40 µm, and are usually characterized by a large, central body (looks like a large vacuole); this stage has been called the *central body form*.	The more amebic form can be seen in diarrheal fluid but is difficult to identify. The central body forms vary tremendously in size, even on a single fecal smear; this is the most common form seen. Routine fecal examinations may indicate a positive rate much higher than other protozoa; some laboratories report figures of 20% and higher.

and unidirectional. Although this characteristic motility is described, **amebiasis** rarely is diagnosed based on motility seen in a direct wet mount. The cytoplasm is differentiated into a clear outer ectoplasm and a more granular inner endoplasm.

E. histolytica has directional and progressive motility, whereas the other amebae tend to move more slowly and at random. Motility is rarely seen even in a fresh direct wet mount from a patient with diarrhea or dysentery. The cytoplasm is generally more finely granular, and the presence of red blood cells (RBCs) in the cytoplasm is considered diagnostic for *E. histolytica* (Fig. 47.2); however, most patient samples do not demonstrate trophozoites with ingested red blood cells.

Permanent stained smears demonstrate accurate morphology compared with other techniques.

When the organism is examined on a permanent stained smear (trichrome or iron-hematoxylin stain), the morphologic characteristics of *E. histolytica*, *E. dispar*, *E. moshkovskii,* and *E. bangladeshi* are readily seen. The nucleus is characterized by evenly arranged chromatin on the nuclear membrane and a small, compact, centrally located **karyosome** (condensed chromatin). As mentioned, the cytoplasm usually is described as finely granular, with few ingested bacteria and scant debris in vacuoles. In organisms isolated from a patient with dysentery, RBCs may be visible in the cytoplasm (Fig. 47.3), and such organisms should be identified as *E. histolytica*. Most often, infection with *E. histolytica/dispar* group is diagnosed on the basis of the organism's morphology, without the presence of RBCs. Newer techniques, including nucleic acid–based testing, are now available that provide a more specific identification and differentiation of *Entamoeba* spp. and are discussed later in this chapter.

As part of the life cycle, the trophozoites may condense into a round mass (**precyst**), and a thin wall is secreted around the immature cyst (Fig. 47.4). Two types of inclusions may be found in this immature cyst: a **glycogen mass**

TABLE 47.7 Microsporidia That Cause Human Infection

Microsporidia	Immunocompromised Patient	Immunocompetent Patient	Comments
Common			
Enterocytozoon bieneusi	Chronic diarrhea; wasting syndrome, cholangitis, acalculous cholecystitis, chronic sinusitis, chronic cough, pneumonitis; cause of diarrhea in organ transplant recipients	Self-limiting diarrhea in adults and children; traveler's diarrhea; asymptomatic carriers.	Short-term culture only; three strains identified but not named; AIDS patients with chronic diarrhea (present in 5%–30% of patients when CD4 lymphocyte counts are very low); pigs, nonhuman primates
Encephalitozoon hellem	Disseminated infection; keratoconjunctivitis; sinusitis, bronchitis, pneumonia, nephritis, ureteritis, cystitis, prostatitis, urethritis	Possibly diarrhea.	Cultured *in vitro*; detected in people with traveler's diarrhea and coinfection with *E. bieneusi*; pathogenicity unclear; spores not reported yet from stool; psittacine birds
Encephalitozoon intestinalis	Chronic diarrhea, cholangiopathy; sinusitis, bronchitis, pneumonitis; nephritis, bone infection, nodular cutaneous lesions	Self-limiting diarrhea; asymptomatic carriers.	Cultured *in vitro*; formerly *Septata intestinalis*; AIDS patients with chronic diarrhea; dogs, donkeys, pigs, cows, goats
Encephalitozoon cuniculi	Disseminated infection; keratoconjunctivitis, sinusitis, bronchitis, pneumonia; nephritis; hepatitis, peritonitis, symptomatic and asymptomatic intestinal infection; encephalitis	Not described; two HIV–serologically negative children with seizure disorder (suspect *E. cuniculi* infection) presumably were immunocompromised.	Cultured *in vitro*; wide mammalian host range
Uncommon			
Pleistophora sp.	Myositis (skeletal muscle)	Not described.	Tend to infect fish
Pleistophora ronneafiei	Myositis	Not described.	
Trachipleistophora hominis	Myositis; myocarditis keratoconjunctivitis; sinusitis	Keratitis.	Cultured *in vitro*; AIDS patients
Trachipleistophora anthropophthera	Disseminated infection; keratitis	Not described.	AIDS patients
Anncaliia connori	Disseminated infection	Not described.	Formerly *Nosema connori*; often infects insects; disseminated in infant with SCID
Anncaliia vesicularum	Myositis	Not described.	Formerly *Brachiola vesicularum*
Anncaliia algerae	Myositis; nodular cutaneous lesions	Keratitis.	Formerly *Nosema algerae* or *Brachiola algerae*; cultured *in vitro*; skin nodules in boy with acute lymphocytic leukemia; found in arthropods
Nosema ocularum	Not described	Keratitis.	HIV–serologically negative individual
Vittaforma corneae	Disseminated infection; urinary tract infection	Keratitis.	Formerly *Nosema corneum*; cultured *in vitro*; non-HIV patient
Microsporidium ceylonensis[a]	Not described	Corneal ulcer, keratitis.	HIV–serologically negative individual, autopsy
Microsporidium africanum[a]	Not described	Corneal ulcer, keratitis.	HIV–serologically negative individual, autopsy
Microsporidia (not classified)		Keratoconjunctivitis in a contact lens wearer.	

[a] *Microsporidium* is a collective generic name for microsporidia that cannot be classified. *AIDS,* Acquired immunodeficiency syndrome; *HIV,* human immunodeficiency virus; *SCID,* severe combined immunodeficiency.

and highly refractile **chromatoidal bars** (refractile chromatin structure) with smooth, rounded edges. As the cyst matures (**metacyst**) (Fig. 47.5 and Fig. 47.3), nuclear division occurs, with the production of four nuclei. Often chromatoidals may be absent in the mature cyst. Cyst morphology does not differentiate *E. histolytica, E. dispar, E. moshkovskii*, and *E. bangladeshi*; it may also resemble *Entamoeba coli.* Cyst formation occurs only in the intestinal tract; once the stool has left the body, cyst formation does not occur. The one-, two-, and four-nucleated cysts are infective and represent the mode of transmission from one host to another.

Epidemiology

Amebiasis is caused by infection with the true pathogen, *E. histolytica.* Evidence from molecular studies confirms the differentiation of pathogenic *E. histolytica* and nonpathogenic *E. dispar* (Fig. 47.6) as two distinct species. *E. histolytica* is considered the etiologic agent of **amebic colitis** (Fig. 47.7A) and **extraintestinal abscesses** (amebic liver abscess; Fig. 47.7B), whereas nonpathogenic *E. dispar* produces no intestinal symptoms and is not invasive in humans. Trophozoites found in tissue are diagnostic of extraintestinal *E. histolytica* infection. *E. moshkovskii* has been shown to cause diarrhea in school-age children and immunocompromised individuals. *E. bangladeshi* has been recovered from the feces of symptomatic and asymptomatic children.

Infection is acquired through the fecal-oral route from infective cysts contained in the feces. The cysts can be ingested in contaminated food or drink or contracted from fomites or various sexual practices that include accidental ingestion of fecal organisms. Flies and cockroaches have been implicated as mechanical vectors of contaminated fecal material.

The infection with all *Entamoeba* spp. occurs worldwide, particularly in areas with poor sanitation. It is estimated that *E. histolytica* infection kills more than 100,000 people each year.

Pathogenesis and Spectrum of Disease

The pathogenesis of *E. histolytica* is related to the organism's ability to directly lyse host cells and cause tissue destruction. Amebic lesions show evidence of cell lysis, tissue necrosis, and damage to the extracellular matrix. Evidence indicates that *E. histolytica* trophozoites interact with the host through a series of steps: adhesion to the target cell, phagocytosis, and cytopathic effect. Numerous other parasite factors also play a role. From the perspective of the host, *E. histolytica* induces both humoral and cellular immune responses; cell-mediated immunity is the major human host defense against this complement-resistant cytolytic protozoan.

The presentations of disease are seen with invasion of the intestinal mucosa or dissemination to other organs (most often the liver) or both. However, it is estimated that a small proportion (2% to 8%) of infected individuals have invasive disease beyond the lumen of the bowel. In addition, organisms may be spontaneously eliminated with no disease symptoms.

Asymptomatic Infection

Individuals harboring *E. histolytica* may have either a negative or a weak antibody titer and negative stools for occult

blood. They also may be passing cysts detectable by a routine ova and parasite (O&P) examination. However, these cysts cannot be morphologically differentiated from those of the nonpathogenic species, most of the asymptomatic infections are actually due to *E. dispar*. Although trophozoites may be identified, they will not contain any phagocytized RBCs and cannot be differentiated from the nonpathogenic species. Molecular analyses of organisms isolated from asymptomatic individuals have indicated that the isolates typically identified are *E. dispar* or *E. moshkovskii,* and up to 80% belong to *E. histolytica.* Generally, asymptomatic patients never become symptomatic and may excrete cysts for a short period. Asymptomatic patients identified with *E. histolytica* are at risk for the development of invasive amebiasis.

Intestinal Disease

The incubation period varies from a few days to a much longer time; in an area where *E. histolytica* is endemic, it is impossible to determine exactly when exposure to the organism occurred. Normally, the incubation time ranges from 1 to 4 weeks. Tissue invasion by *E. histolytica* requires a contact-dependent process that involves colonic mucins and amebic lectins in the plasma membrane that mediate adherence to the host mucosa. After adherence, destruction of the host cells involves a process referred to as trogocytosis-like, in which the amebae essentially take bites out of the host cellular membrane. This process is enhanced by *E. histolytica* adherence that induces membrane blebbing that facilitates the **trogocytosis.** *E. histolytica* produces cysteine proteinases utilized in the degradation of colonic mucin glycoproteins, digestion of hemoglobin and villin, inactivation of immune modulators such as interleukin (IL)-18, and the digestion of the host's extracellular matrix. The digestive action of these proteases contributes to the development of amebic ulcers and tissue damage in the intestinal tract. Amebic ulcers often develop in the cecum, appendix, or adjacent portion of the ascending colon; however, they can also be found

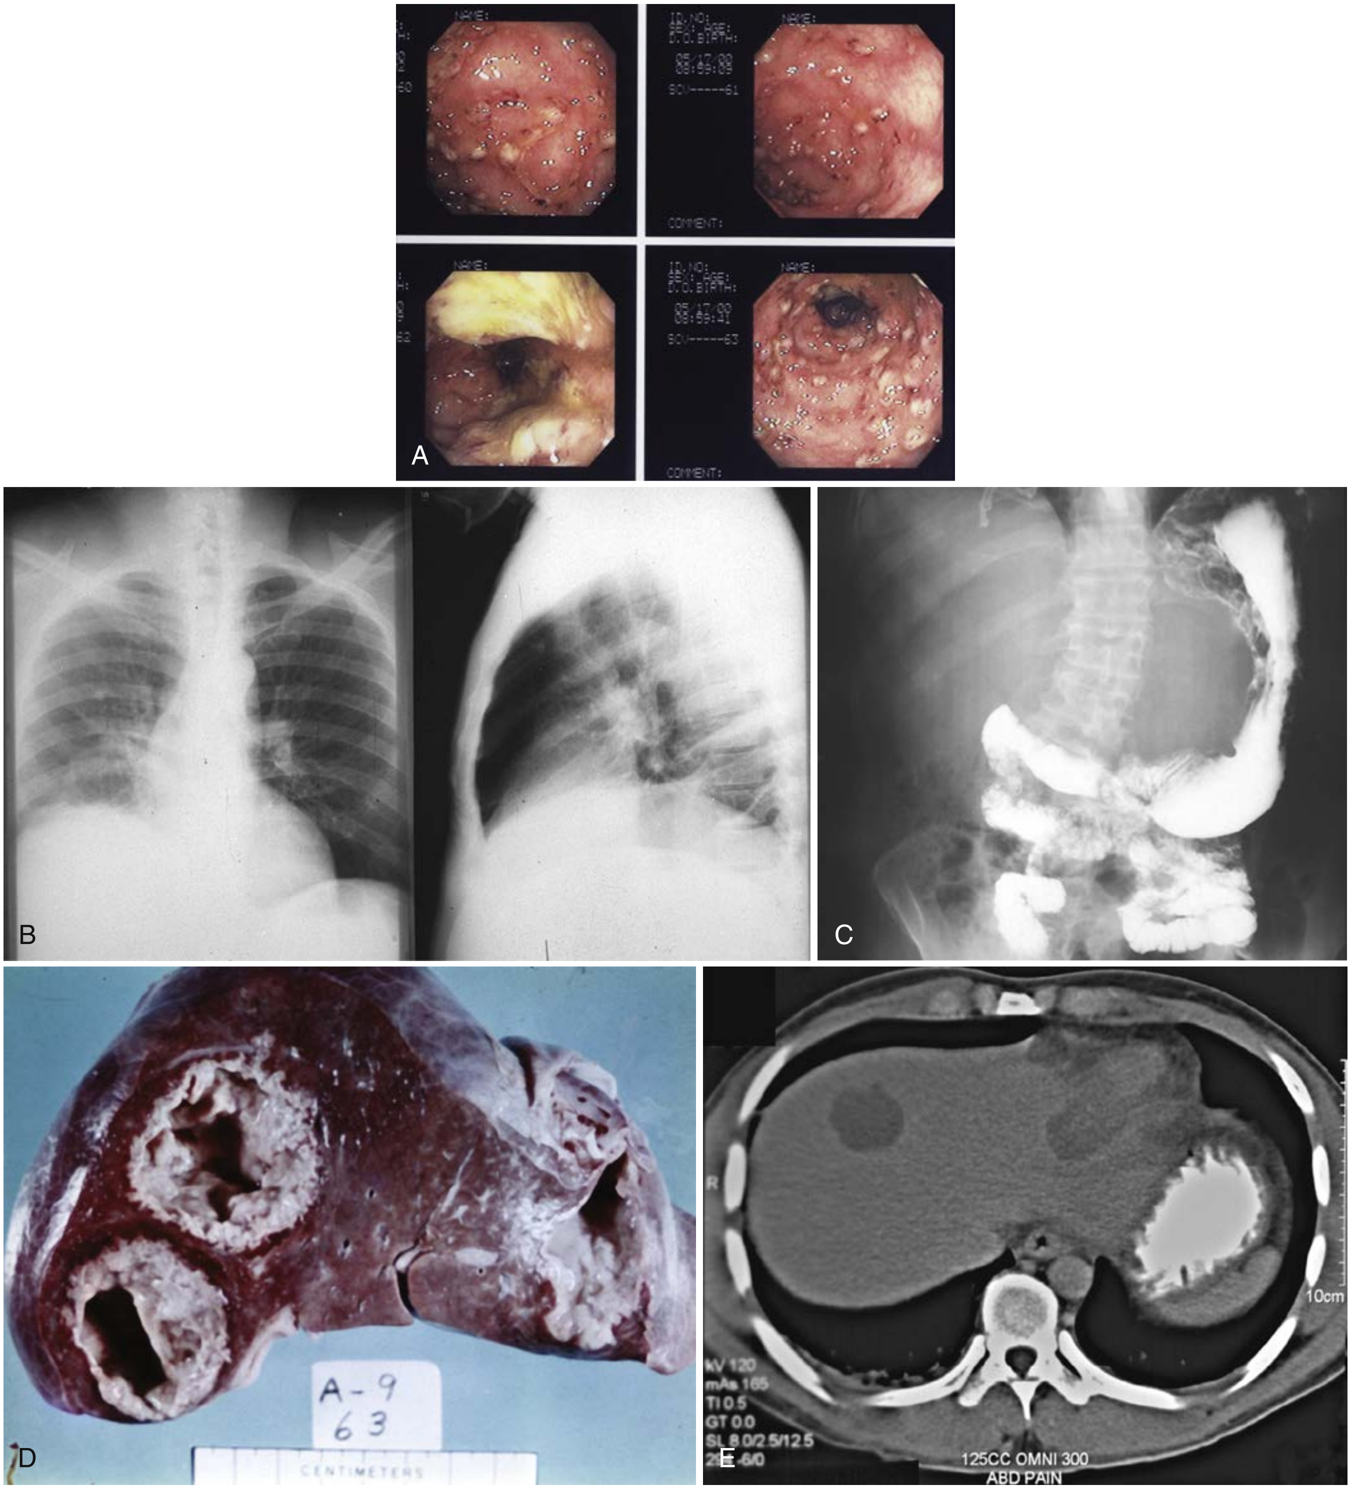
in the sigmoidorectal area. Other lesions may occur from these primary sites. Ulcers usually are raised, with a small opening on the mucosal surface and a larger area of destruction below the surface (i.e., flask-shaped). The mucosal lining may appear normal between ulcers.

Invasive intestinal amebiasis has various clinical forms, all of which are generally acute: amebic diarrhea without dysentery, **dysentery** (bloody diarrhea), or **colitis, ameboma,** and **amebic liver abscess.** Dysentery and diarrhea account for 90% of cases of invasive intestinal amebiasis. The severity of symptoms can range from asymptomatic to severe symptoms that mimic ulcerative colitis. Ameboma, a granulomatous, localized lesion, can occur in patients with chronic ulcerative colitis and may be confused with colon cancer. Patients with colicky abdominal pain, frequent bowel movements, and **tenesmus** (a persistent feeling of needing to pass stool) may present with a gradual onset of disease. With the onset of dysentery, bowel movements are frequent (up to 10 per day). Fever is typically absent, and abdominal distention (swelling) or dehydration



• **Fig. 47.7** Endoscopic and pathologic features of intestinal and extraintestinal amebiasis. (A) Colonoscopic appearance of intestinal amebiasis. (B) Left posteroanterior and right lateral chest radiographs in a patient with amebic liver abscess. (C) Luminal narrowing revealed by a barium-enema examination in a patient with ameboma. (D) Two abscesses in the right lobe and one abscess in the left lobe of a patient with an amebic liver abscess. (E) One abscess in the right lobe and one abscess in the left lobe of a patient with amebic liver abscess, shown on an abdominal computed tomography scan (CT scan).

is uncommon. Although dysentery may last for months, it varies from severe to mild and may lead to weight loss and prostration. In rare severe cases, symptoms may begin very suddenly and include profuse diarrhea, fever, and dehydration with electrolyte imbalances.

Hepatic Disease

Blood flow from the mesenteric veins surrounding the intestine returns blood, via the portal vein, to the liver, most commonly the upper right lobe. Amebae in the submucosa can be carried by the bloodstream to the liver. The onset of symptoms may be gradual or sudden; upper right abdominal pain and fever (38°C to 39°C) are the most consistent findings. Although the liver may be enlarged and tender, liver function tests may be normal or slightly abnormal (jaundice is rare). The abscess can be visualized radiologically, sonically, or by radionuclear scan; most patients have a single abscess in the right lobe of the liver. The most common complication is rupture of the abscess into the pleural space. An abscess also can extend into the peritoneum and through the skin. Hematogenous spread to the brain, lung, pericardium, and other sites is possible.

Pyogenic and amebic liver abscesses are the two most common hepatic abscesses. The severity of a **pyogenic abscess** depends on the bacterial source and the patient's underlying condition. An amebic abscess tends to be more prevalent in those with suppressed cell-mediated immunity, males, and younger individuals. *E. histolytica* cysts and trophozoites can be found in the stools of patients with liver abscess. About 60% of these patients have no intestinal symptoms or any history of dysentery. In addition, the patient's condition should be differentiated from hepatocellular carcinoma and echinococcal cysts (*Echinococcus granulosus,* or hydatid sand; see Chapter 54).

Metastatic Amebiasis

In addition to extraintestinal amebiasis, extraabdominal amebiasis may occur after liver involvement. Thoracic amebiasis is the most common extraabdominal manifestation that presents with empyema, bronchohepatic fistulas, and pericardial abscesses. Pericardial involvement is the second most common extraabdominal presentation resulting in pericarditis. Cerebral amebiasis has been noted after liver abscesses and other rare infections such as in the pharynx, heart, aorta, and scapula.

Laboratory Diagnosis

Routine Methods

The standard O&P examination is the recommended procedure for recovery and identification of *E. histolytica* in stool specimens. Microscopic examination of a direct saline wet mount may reveal motile trophozoites, which may contain RBCs. However, trophozoites with RBCs are identified in a limited number of cases. In many patients who do not present with acute dysentery, trophozoites may be present but do not contain RBCs, and the organisms may be pathogenic *E. histolytica*, or one of the other species: *E. dispar*, *E. moshkovskii,* or *E. bangladeshi.* An asymptomatic individual may have few trophozoites and possibly only cysts in the stool. Although the concentration technique is helpful for demonstrating cysts, the most important technique for the recovery and identification of protozoan organisms is the permanent stained smear (normally stained with trichrome or iron-hematoxylin). A minimum of three specimens collected over a period of not more than 10 days may be required for identification.

Sigmoidoscopy specimens may be very helpful for identifying organisms. At least six areas of the mucosa should be sampled. Smears from these areas should be examined after permanent staining. However, these specimens are not considered a substitute for the recommended minimum of three stool specimens submitted for O&P examination (direct wet mount, concentration, and permanent stained smear). Colonoscopy and biopsy material may also be helpful; however, amebae may be difficult to identify within the biopsy material. Periodic acid-Schiff (PAS) stains or immunoperoxidase with anti–*E. histolytica* antibodies may improve identification and diagnosis.

Liver aspirate material is rarely examined, and often the specimen is not collected properly. Aspirated material must be aliquoted into several different containers as it is removed from the abscess; amebae may be found only in the last portion of the aspirated material, theoretically material from the abscess wall, not necrotic debris from the abscess center.

Antigen Detection

A number of enzyme immunoassay (EIA) reagents are commercially available, and their specificity and sensitivity provide excellent options for the clinical laboratory. Some fecal antigen tests can differentiate the *E. histolytica/E. dispar* group from the rest of the *Entamoeba* spp., such as nonpathogenic *E. coli* or *E. hartmanni* (*E. histolytica* II test, TechLab, Blacksburg, VA). These kits require fresh or fresh frozen stool; fecal preservatives have been found to interfere with the *Entamoeba* spp. reagents. Other kits, such as the *E. histolytica* II test, TechLab, Blacksburg, can differentiate *E. histolytica* from *E. dispar*. Because of the specificity of the immunoassay reagents, the laboratory can inform the physician whether the *E. histolytica*/*E. dispar* group or organisms seen in the stool specimen are pathogenic *E. histolytica.*

If the laboratory does not use these reagents, the presence of *E. histolytica*/*E. dispar* group should be reported to the physician, accompanied by commentary related to the newer information on pathogenicity.

Additional antigen screening test kits are available but are unable to determine the species of amebae. Two examples of these tests include the RIDASCREEN *Entamoeba* (R-Biopharm, Darmstadt, Germany) and the Triage Micro Parasite Panel (Biosite Diagnostics Inc., San Diego, CA). However, the Triage Micro Parasite Panel has the distinct advantage of screening for the major intestinal parasites found in the United States including *G. duodenalis, Cryptosporidium parvum,* and *E. histolytica/E. dispar.*

Depending on each state's requirements, pathogenic *E. histolytica* generally is reported to the public health facility (county).

Histology

A histologic diagnosis of amebiasis can be made when the trophozoites in the tissue are identified. Organisms must be differentiated from host cells, particularly histiocytes and ganglion cells. PAS staining, as previously noted, can be used to help locate the organisms, which appear bright pink with a green-blue background (depending on the counterstain used). Hematoxylin and eosin staining also allows visualization of the typical morphology, thus allowing accurate identification. As a result of sectioning, some organisms exhibit the evenly arranged nuclear chromatin with the central karyosome, and some no longer contain the nucleus.

Nucleic Acid Detection

Nucleic acid–based amplification methods, including polymerase chain reaction (real-time and multiplex assays), have been developed for the identification of *E. histolytica* and *E. dispar.* The polymerase chain reaction assays (PCR) identify unique ribosomal ribonucleic acid (rRNA) or specific episomal (small circular nucleic acid) sequences to differentiate the organisms. Suitable samples for real-time PCR (Chapter 8) detection of *E. histolytica* or *E. dispar* include stool, liver or brain aspirates, cerebrospinal fluid, blood, saliva, and urine samples. Multiplex assays that are capable of detecting multiple types of organisms including viral, bacterial, and parasitic organisms capable of causing gastroenteritis would significantly improve diagnostic testing and enhance patient care. Several multiplex panels are available for the identification of *E. histolytica* including the xTAG Gastrointestinal Panel (Luminex Molecular Diagnostics, Austin, TX) for the detection of *E. histolytica, G. duodenalis,* and *Cryptosporidium* along with 13 bacterial species or pathogenic forms, 2 bacterial toxins, and 3 viral agents that cause gastroenteritis; the RIDAGENE Stool PCR panel (R. Biopharm AG, Darmstadt, Germany) differentiates *Giardia, Cryptosporidium, E. histolytica*, and *Dientamoeba*; the BD MAX Enteric Parasite Panel (Becton, Dickinson and Company, Sparks MD) differentiates *Giardia, Cryptosporidium*, and *E. histolytica*; and the BioFire FilmArray Gastrointestinal Panel that differentiates 13 bacterial, 5 viral, and parasitic pathogens *Cryptosporidium, Cyclospora, E. histolytica*, and *Giardia*. Stool specimens, however, may contain inhibitors that would prevent accurate detection using amplification methods; therefore, it is necessary that all assays include an amplification control. These tests are becoming more widely used and have proven to be more sensitive than microscopy and as sensitive as antigen-based immunoassays.

Antibody (Serologic) Detection

Serologic testing for intestinal disease is rarely recommended unless the patient has true dysentery; even in these cases, the titer (e.g., indirect hemagglutination) may be low and thus difficult to interpret. A definitive diagnosis of intestinal amebiasis should not be made without demonstrating the presence of the organisms and is not useful in the diagnosis of asymptomatic patients. In patients suspected of having extraintestinal disease, serologic tests are diagnostically more effective and a valuable tool in conjunction with either antigen or nucleic acid–based testing. Indirect hemagglutination and indirect fluorescent antibody tests have been reported positive with titers greater than or equal to 1:256 and greater than or equal to 1:200, respectively, in almost 100% of cases of amebic liver abscess. In the absence of STAT serologic tests for amebiasis, the decision on diagnosis must be made on clinical grounds and based on results of other diagnostic tests, such as scans. In addition, antibodies may persist for up to 10 years in patients who have had previous incidences of invasive amebiasis, making diagnosis complicated in subsequent infections.

Reporting of Results

It is important to note, when possible, the full taxonomic name of the infecting organism, including genus and species as well as the life cycle stage or form present, trophozoite or cyst. The laboratory should report *E. histolytica/dispar* group and provide a comment relative to other potentially pathogenic or nonpathogenic species. If full species identification is not available, the physician will be responsible to determine whether treatment is warranted based on the patient's condition and additional clinical information. Quantitation of organisms is not warranted.

Therapy

Two classes of drugs are used in the treatment of amebic infections: luminal amebicides, such as paromomycin, iodoquinol, or diloxanide furoate, and tissue amebicides, such as metronidazole, tinidazole, or dehydroemetine. Because of the differences in drug efficacy, it is important that the laboratory report indicate whether cysts, trophozoites, or both are present in the stool specimen.

Asymptomatic Infection

Patients found to have true *E. histolytica* in the intestinal tract, even if asymptomatic, should be treated to eliminate the organisms. Both diloxanide furoate and iodoquinol or paromomycin can be used to treat cysts in the lumen of the gut. In general, these treatments are ineffective against extraintestinal disease. If the patient is passing trophozoites and cysts, the recommended treatment is a tissue amebicide followed by a luminal amebicide.

The importance of using both luminal and tissue amebicides is emphasized in patients with amebic liver abscesses. Asymptomatic colonization may be present with the true pathogen, *E. histolytica.* In patients treated with a tissue amebicide, generally, a 100% clinical response to the hepatic lesions is seen; however, failure to eliminate the organism from the bowel can lead to secondary bouts with invasive disease and intestinal colonization. In addition, these carriers constitute a public health hazard because of continued shedding of infective cysts. Chemoprophylaxis is not recommended because of the potential for the development of drug resistance in the organisms.

Prevention

Humans are the reservoir host for *E. histolytica,* and infection can be transmitted to other humans, primates, dogs, cats, and possibly pigs. Accidental consumption of sewage-contaminated water provides another route of infection. Amebiasis is considered a zoonotic waterborne infection. The cyst stages are resistant to environmental conditions and can remain viable in the soil for 8 days at 28°C to 34°C, for 40 days at 2°C to 6°C, and for 60 days at 0°C. Cysts normally are removed by sand filtration or destroyed by 200 ppm of iodine, 5% to 10% acetic acid, or boiling. However, an asymptomatic carrier who is a food handler generally is believed to play the most important role in transmission. Proper disposal of contaminated feces is considered the most important preventive measure. Although vaccines have been discussed as a possibility for eliminating human disease, no vaccine is currently available.

Entamoeba coli

General Characteristics

The life cycle of *E. coli* is identical to that of *E. dispar.* After digestion of infective cysts, the organisms exist in the intestinal tract and produce trophozoites. Cyst formation occurs as the gut contents move through the intestinal tract; the excreted cysts are the infective form transmitted to humans and some animals.

E. coli trophozoites may appear larger than those of the other *Entamoeba* spp. and range from 15 to 50 µm in diameter (Figs. 47.3, 47.8, 47.9, and Table 47.1). Motility is sluggish with broad, short pseudopods. In wet preparations, differentiating nonpathogenic *E. coli* from pathogenic *E. histolytica* is almost impossible. On a permanent stained smear viewed at a higher magnification, the cytoplasm is granular with vacuoles containing bacteria, yeasts, and other food materials. The nucleus has a large, blotlike karyosome that may be eccentric rather than centrally located. The chromatin on the nuclear membrane tends to be clumped and irregular.

Early cysts often contain chromatoidal bars, which tend to be splinter-shaped and irregular. Eventually, the nuclei divide until the mature cyst, containing eight nuclei, is formed (Table 47.2 and Figs. 47.3 and 47.8). In rare cases, the number of nuclei reaches 16. The cysts measure 10 to 35 µm in diameter, and as they mature, the chromatoidal bars disappear. When the cyst of *E. coli* matures, it becomes more refractive to fixation; therefore, the cyst may be seen on the wet preparation but not on the permanent stained

• **Fig. 47.10** *Entamoeba coli* cyst (trichrome stain) (poor preservation; typical appearance of some *E. coli* cysts).

smear. Occasionally, on trichrome smears, the cysts appear distorted and somewhat pink (Fig. 47.10).

Epidemiology

Transmission occurs through the ingestion of mature cysts from contaminated food or water. The organism is readily acquired. In some warmer climates or areas with poor sanitation and inadequate disposal of human excreta, the colonization rate with *E. coli* can be high.

Pathogenesis and Spectrum of Disease

E. coli are typically considered nonpathogenic and do not cause disease. However, it is important for the physician to correlate patient signs and symptoms with disease presentation. In addition, a patient that presents with a potential nonpathogenic protozoan may simultaneously be infected with a pathogenic species.

Laboratory Diagnosis

Unless the mature cyst with eight nuclei is seen, the morphologies of the other *Entamoeba* spp. and *E. coli* are similar in the trophozoite and immature cyst stages. Definitive identification may not be possible from examining permanent stained smears. Species specific immunoassay or nucleic acid based testing may be necessary to correctly identify the organism.

Therapy

Specific treatment is not recommended for nonpathogenic *E. coli.* Correct differentiation among the species is critical to good patient care. Because the amebae are acquired through fecal-oral contamination, pathogens and nonpathogens can be found in the same patient. Treatment is not recommended for infection with *E. coli.*

Prevention

Prevention depends on adequate disposal of human excreta and improved personal hygiene, preventive measures that apply to most of the intestinal protozoa.

Entamoeba hartmanni

General Characteristics

The life cycle of *E. hartmanni* is similar to that of *E. dispar,* with differences in size as the key characteristic for proper identification (Figs. 47.11 and 47.12). In wet preparations, *E. hartmanni* trophozoites range in size from 4 to 12 µm in diameter, and cysts range in size from 5 to 10 µm in diameter. On the permanent stained smear, the cysts tend to shrink because of dehydration. Therefore, the sizes of the organisms may be smaller (1 to 1.5 µm) than determined in the wet preparation measurements.

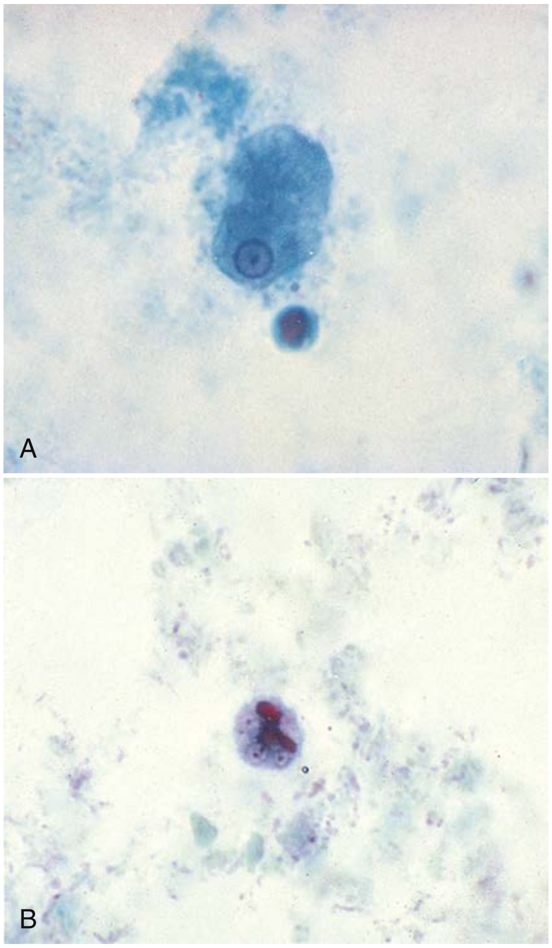
Trophozoites do not ingest RBCs, and their motility is slower (Table 48.1 and Figs. 47.3, 47.11, and 47.12). The morphologic characteristics of *E. hartmanni* are very similar to those of *E. histolytica,* with two exceptions. Commonly, *E. hartmanni* cysts may contain one or two nuclei and the mature cyst contains four nuclei. Mature cysts of *E. hartmanni* may retain their chromatoidal bars, a characteristic not seen in *E. histolytica* or *E. dispar. E. hartmanni*'s chromatoidal bars are similar to those of *E. histolytica* and *E. dispar* but smaller and more numerous (Table 47.2 and Figs. 47.11 and 47.12). At the species level, differentiation between *E. hartmanni* and the other *Entamoeba* spp. depends on size; therefore laboratories are required to use calibrated microscopes that are checked periodically for accuracy.

Epidemiology

Transmission occurs through the ingestion of mature cysts from contaminated food or water. If accurate identifications have been recorded, the colonization rate tends to match that of *E. histolytica.*

Pathogenesis and Spectrum of Disease

E. hartmanni is considered nonpathogenic and does not cause disease.



• **Fig. 47.11** (A) *Entamoeba hartmanni* trophozoite. (B) *E. hartmanni* cyst.

Laboratory Diagnosis

Unless the trophozoites and cysts match the size requirements, they are unlikely to be *E. hartmanni.* Definitive identification relies on examination of permanent stained smears and measurements made with the calibrated microscope, specific immunoassay, or nucleic acid–based testing.

Entamoeba polecki and *Entamoeba gingivalis*

Entamoeba polecki has been identified in human clinical samples but is not believed to be pathogenic. The organism is associated with pigs. The organism resembles the other *Entamoeba* spp., with the exception of containing a sharply defined round or oval mass that may be present on a permanent stained smear. *Entamoeba gingivalis* does not include a cyst stage and is considered nonpathogenic. The organism also ingests white blood cells and fragments may be visualized within vacuoles differentiating *E. gingivalis* from the other *Entamoeba* spp. A few cases of *E. gingivalis* being isolated from clinical specimens have been identified in vaginal, oral, tissue, and pulmonary infections.

Endolimax nana

General Characteristics

Endolimax nana, one of the smaller nonpathogenic amebae, has a worldwide distribution and occurs as commonly as *E. coli.*

E. nana has the same life cycle stages as *E. dispar* and the other nonpathogenic amebae. The trophozoite usually measures 6 to 12 μm in diameter (normal range, 8 to 10 μm) (Figs. 47.13–47.15, and Table 47.1). Although rarely seen, motility is sluggish and nonprogressive with blunt, hyaline pseudopods. In the permanent stained smear, normally no peripheral chromatin is seen on the nuclear membrane, and the karyosome is large, with either a central or an eccentric location in the nucleus (Figs. 47.14 and 47.15). *E. nana* shows more nuclear variation than any of the other amebae and can mimic *D. fragilis* or *E. hartmanni.* The cytoplasm may have small vacuoles containing ingested debris or bacteria, but it also may appear relatively clean.

Cysts usually measure 5 to 10 μm in diameter (normal range, 6 to 8 μm) (Table 47.2). Cysts as large as 14 μm have been seen. The cyst is usually oval to round, with the mature cyst containing four nuclei. The nuclei typically have no peripheral chromatin and are evenly distributed in the cyst. Occasionally, very small, slightly curved chromatoidal bars are present. The two-nucleated stage is not commonly seen, and frequently both trophozoites and cysts are present in clinical specimens.

Epidemiology

Transmission occurs through the ingestion of mature cysts from contaminated food or water. The cysts of *E. nana* are less resistant to desiccation *E. coli. E. nana* is also found in warm, moist climates and in other areas with poor sanitary conditions.

Pathogenesis and Spectrum of Disease

E. nana is considered nonpathogenic and does not cause disease.

Laboratory Diagnosis

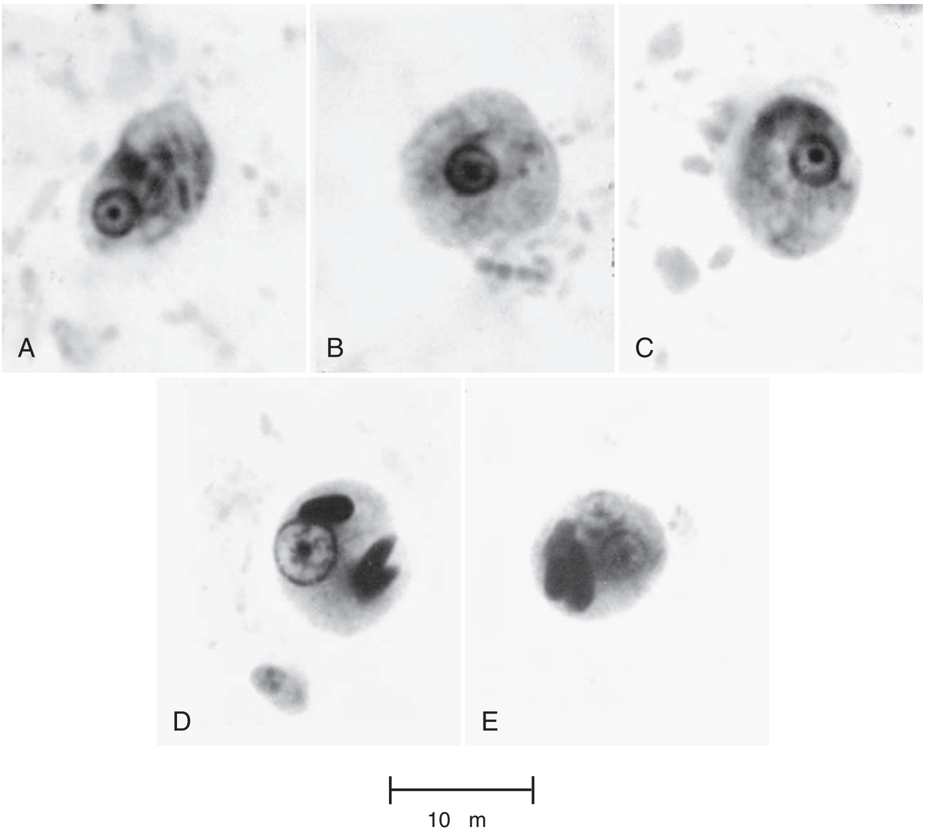
Although cysts sometimes can be seen in a wet preparation, definitive identification of *E. nana* relies on examination of permanent stained smears.

Iodamoeba bütschlii (buetschlii)

General Characteristics

Iodamoeba bütschlii, one of the nonpathogenic amebae, has a worldwide distribution. Generally, the acquisition rate for this organism is not as high as that for *E. coli* and *E. nana.*

The life cycle stages of *I. bütschlii* are the same as those of *E. nana.* The trophozoite varies from 8 to 20 μm in diameter and demonstrates active motility in a fresh stool preparation (Table 47.1). The cytoplasm is granular, containing numerous vacuoles with ingested debris and bacteria. The cytoplasm is more vacuolated than in *E. nana* trophozoites. The nucleus has a large karyosome, which can be either centrally located or eccentric (Figs 47.16 and 47.17). On the permanent stained smear, the nucleus may appear to have a halo, and chromatin granules fan out around the karyosome. If the granules are on one side, the nucleus may appear to have a "basket nucleus" arrangement of chromatin, more commonly seen in the cyst. The trophozoites of *I. bütschlii* and



• **Fig. 47.12** (A–C) Trophozoites of *Entamoeba hartmanni*. (D and E) Cysts of *E. hartmanni*.

E. nana may appear similar and are difficult to differentiate at the species level, even on the permanent stained smear. Both organisms are considered nonpathogenic. *E. nana* is recovered in clinical specimens much more commonly than is *I. bütschlii.*

I. bütschlii cysts are round to oval (Table 47.2). The glycogen vacuole is so large that occasionally the cyst collapses on itself. Because nuclear multiplication does not occur in the cyst form, the mature cyst contains a single nucleus. The cysts measure approximately 5 to 20 μm in diameter and are rarely confused with those of other amebae (Figs. 47.16 and 47.17).

Epidemiology

Transmission of *I. bütschlii* occurs through the ingestion of mature cysts from contaminated food or water. This organism is found in warm, moist climates and in other areas with a low standard of personal hygiene and poor sanitary conditions.

Pathogenesis and Spectrum of Disease

I. bütschlii is considered nonpathogenic and does not cause disease.

Laboratory Diagnosis

Although *I. bütschlii* cysts sometimes can be seen in a wet preparation, definitive identification relies on the examination of permanent stained smears.

Therapy

Specific treatment is not recommended for *I. bütschlii.* Because these nonpathogenic amebae are acquired through fecal-oral contamination, both pathogens and nonpathogens can be identified in the same patient. If few organisms are present, extended microscopic examination and multiple organism measurements are required for definitive identification. It is always important to report pathogens and nonpathogens, because they are acquired in similar ways.

Prevention (Nonpathogenic *Entamoeba*, *Endolimax*, and *Iodamoeba* spp.)

Prevention depends on adequate disposal of human excreta and improved personal hygiene, preventive measures that apply to most of the intestinal protozoa.

Blastocystis spp.

General Characteristics

Blastocystis (Fig. 47.1 and Table 47.6) consists of a number of different subtypes and subspecies that are indistinguishable morphologically, some of which are pathogenic and some of which are nonpathogenic. Although usually listed with the amebae, the organism's classification is still under review; different subtypes eventually may be classified as different species. In addition, based on molecular sequencing of the *SSU* rRNA gene, *Blastocystis* has been placed within a heterogenous group referred to as the **stramenopiles**. This group contains brown algae, slime molds, diatoms, and

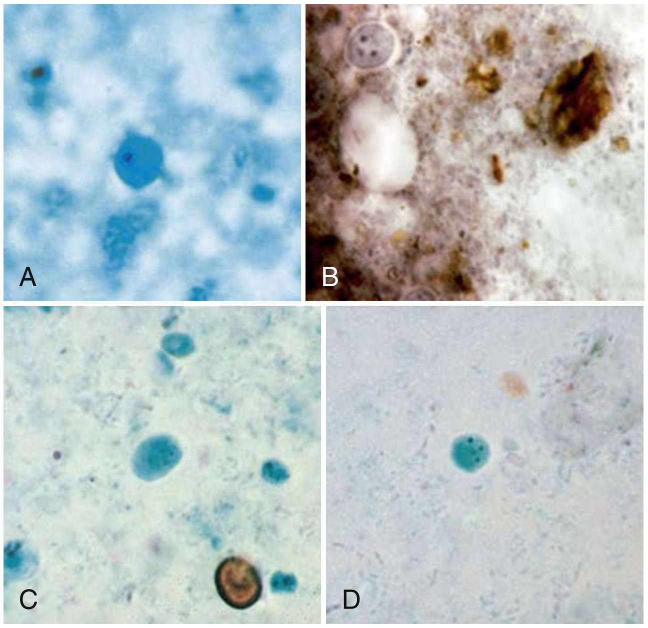
chrysophytes. Although the true role of this organism in terms of disease has been controversial, it is generally considered a causative agent of intestinal disease. The current recommendation is to report the presence of *Blastocystis* spp. and quantitate from the permanent stained smear (i.e., rare, few, moderate, many, packed); this information may be valuable in helping to assess the pathogenicity of the organism in the individual patient.

Blastocystis spp. consists of four major forms. The **cyst form** is the most recently described form of the life cycle stages. Thick-walled cysts are believed to be responsible for external transmission through the fecal-oral route; thin-walled cysts are believed to cause autoinfection. Cysts can vary in shape but are mostly ovoid or spherical. Cyst forms have also been identified that contain multiple vacuoles. The **central vacuole form** (also referred to as the **central body form**) is the most common form found in clinical stool samples. The large central vacuole can occupy most of the cellular volume. The **amoeboid form** is rarely seen but has been identified in stool specimens of patients with diarrhea. The **granular form** can be seen in cultures of *Blastocystis* spp. and is characterized by intracytoplasmic or intravacuolar granules.



• **Fig. 47.15** (A) *Endolimax nana* trophozoite. (B) *E. nana* cyst, iodine stain. (C and D) *E. nana* cyst. (B, Courtesy Dr. Henry Travers, Sioux Falls, SD.)

Epidemiology

Transmission of *Blastocystis* is by the fecal-oral route from infective forms contained in the feces. The organisms can be ingested in contaminated food and drink or acquired from fomites or through various sexual practices that may include accidental ingestion of fecal organisms. As with *E. histolytica,* flies and cockroaches can be responsible for mechanical transmission. Human-to-human and animal-to-human transmission is probably more common than suspected.

Blastocystis is a common intestinal parasite of humans and animals, with a worldwide distribution. Depending on the geographic location, it may be detected in 1% to 40% of fecal specimens. *Blastocystis* may be the most common parasite found in the intestinal tract.

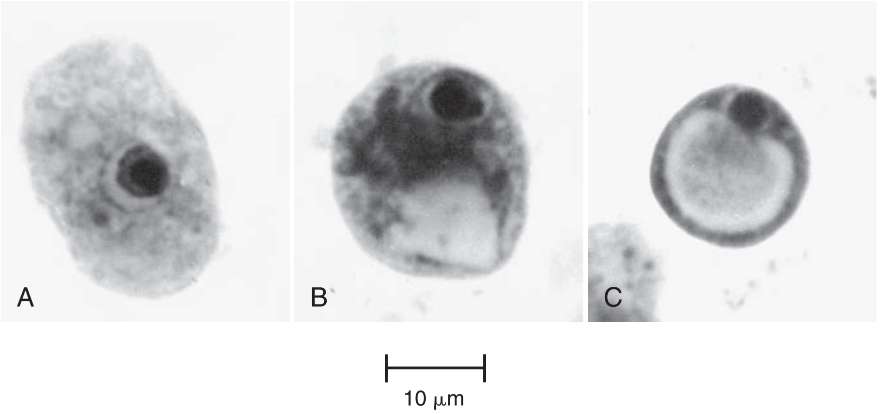
Pathogenesis and Spectrum of Disease

Blastocystis spp. can cause diarrhea, cramps, nausea, fever, vomiting, abdominal pain, and urticaria and may require therapy. A possible relationship between *Blastocystis* and intestinal obstruction and perhaps even infective arthritis has been suggested. In patients with other underlying conditions, the symptoms may be more pronounced. The incidence of this organism appears to be higher than suspected in stools submitted for parasite examination. In symptomatic patients in whom no other etiologic agent has been identified, *Blastocystis* should certainly be considered the possible pathogen. It has been suggested that proteases of genetic subtype 3 could be considered a virulence factor responsible for protein degradation and subsequent pathogenesis.

Laboratory Diagnosis

Routine Methods

Routine stool examinations are very effective in recovering and identifying *Blastocystis* spp.; the permanent stained



• **Fig. 47.16** (A) Trophozoites of *Iodamoeba bütschlii*. (B and C) Cysts of *I. bütschlii*.

smear is the procedure of choice, because examination of wet preparations may not easily reveal the organism. If the fresh stool is rinsed in water before fixation (for the concentration method), *Blastocystis* organisms, other than the cysts, are destroyed, and a false-negative report may result.

Antigen Detection

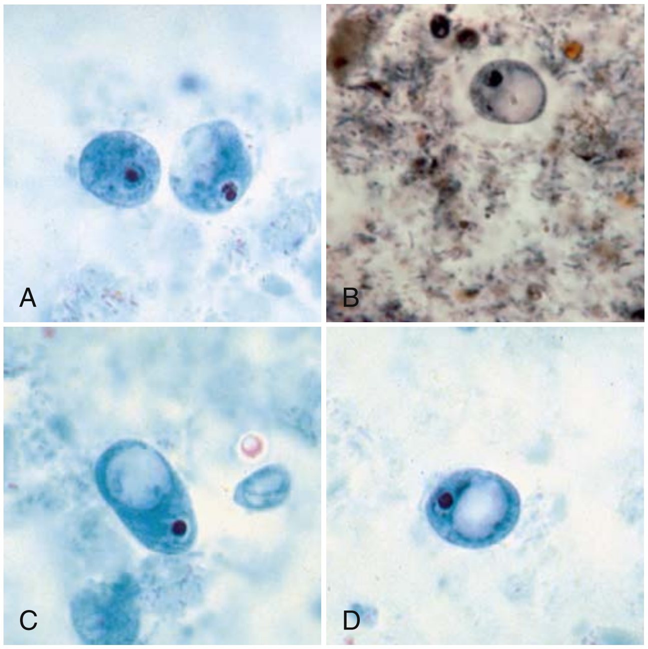
Fecal immunoassays to detect *Blastocystis* antigen have been developed but are of little clinical use. The technique currently used is the enzyme-linked immunosorbent assay (ELISA).

Antibody (Serologic) Detection

ELISA and fluorescent antibody tests have been developed to detect serum antibody to *Blastocystis* spp. infections. A strong antibody response is consistent with the ability of this organism to cause symptoms. In addition, demonstration of serum antibody production both during and after *Blastocystis* symptomatic disease may provide immunologic evidence for the pathogenic role for this protozoan, although it may take 2 years or longer with chronic infections to develop a serologic response.

Reporting of Results

Unlike *E. histolytica,* the presence of *Blastocystis* spp. should be quantitated in the report (i.e., rare, few, moderate, or many). This may provide the clinician with some indication as to whether to consider the infection pathogenic. However, it is not important to state the life cycle stage or form of the organism present, because the central body form is the most common (90%) identified in clinical specimens. It is also important to remember that other possible pathogens should be adequately ruled out before a patient is treated for *Blastocystis* spp. infection.



• **Fig. 47.17** (A) *Iodamoeba bütschlii* trophozoites. (B–D) *I. bütschlii* cyst. (B, Courtesy Dr. Henry Travers, Sioux Falls, SD.)

Therapy

Although clinical evidence is limited, *in vitro* susceptibility studies for numerous drugs have been completed for *Blastocystis* spp. Currently, metronidazole (Flagyl) appears to be the most appropriate drug. TMP-SMX (trimethoprim-sulfamethoxazole) and iodoquinol are also recommended with variable success. *Blastocystis* resistance to metronidazole has been reported.

Prevention

Prevention requires improved personal hygiene and sanitary conditions, in addition to proper disposal of fecal material.

Flagellates

The Mastigophora, or flagellates, have specialized locomotor organelles called flagella; these are long, thin, cytoplasmic extensions that may vary in number and position, depending on the species. Different genera of flagellates may live in the intestinal tract, the bloodstream, or various tissues.

Four common species of flagellates are found in the intestinal tract: *Giardia duodenalis, D. fragilis, Chilomastix mesnili,* and *Pentatrichomonas hominis* (Figs. 47.18–47.25, Tables 47.3 and 47.4). Several other smaller, nonpathogenic flagellates, such as *E. hominis* and *Retortamonas intestinalis* (Fig. 47.18), are rarely seen, and none are identified in the intestinal tract. The **sucking disk** and **axonemes** of *G. duodenalis,* the **cytostome** and **spiral groove** of *C. mesnili,* and the **undulating membrane** of *Trichomonas* spp. are all distinctive criteria for identification (Figs. 47.18–47.25).

G. duodenalis and *D. fragilis* are the flagellates considered pathogenic. *D. fragilis* has been associated with diarrhea, nausea, vomiting, and other nonspecific intestinal complaints. *Trichomonas vaginalis* is pathogenic but occurs in the urogenital tract. *Trichomonas tenax* is occasionally found in the mouth and may be associated with poor oral hygiene.

Giardia duodenalis

General Characteristics

G. duodenalis is the most common cause of intestinal infection worldwide. As a result of molecular techniques, *G. duodenalis* is the accepted species nomenclature for organisms isolated from human clinical specimens. However, significant genetic diversity does exist and has been subdivided into subgenotypes designated as A and B. Subgenotype B is only isolated from human specimens, whereas A has been identified in both animal and human samples. Other than *Blastocystis* spp., *G. duodenalis* is probably the most common protozoan organism identified in individuals in the United States. It causes symptoms ranging from mild diarrhea, flatulence, and vague abdominal pains to acute, severe diarrhea, to **steatorrhea** and a typical malabsorption syndrome. Various documented waterborne and foodborne outbreaks have occurred during the past several years. A number of animals may serve as reservoir hosts for *G. duodenalis.* Differentiation of flagellates is based on overall shape, numbers, and arrangements of flagella.

Both the trophozoite and cyst stages are included in the life cycle of *G. duodenalis.* Trophozoites divide by means of

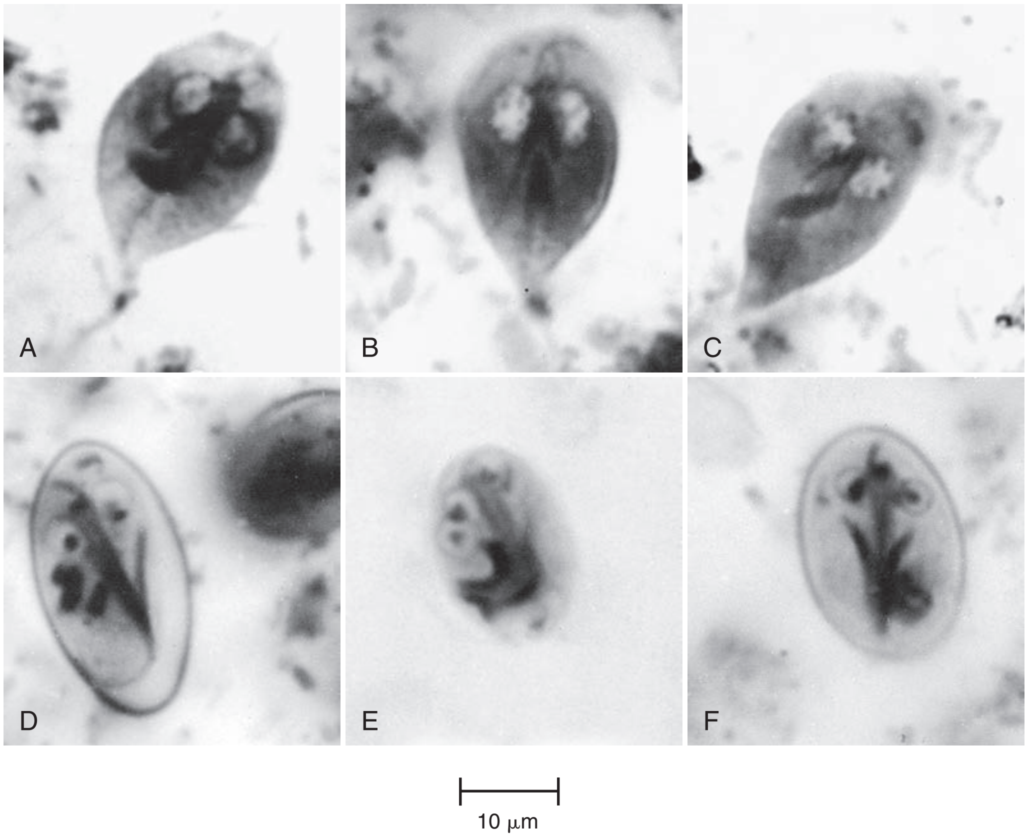
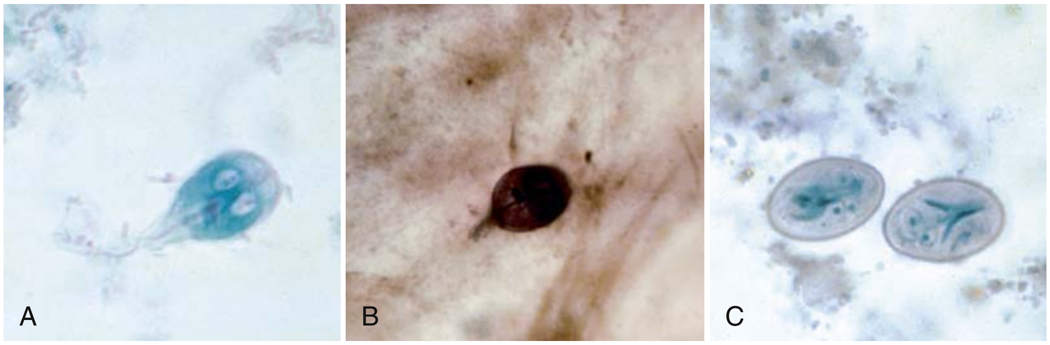
longitudinal binary fission, producing two daughter trophozoites. The organism is found in the crypts in the duodenum. Trophozoites are the intestinal dwelling stage and attach to the epithelium of the host villi by means of the **ventral disk.** The attachment is substantial and results in disk "impression prints" when the organism detaches from the surface of the epithelium. Trophozoites may remain attached to or may detach from the mucosal surface. Because the epithelial surface sloughs off the tip of the villus every 72 hours, the trophozoites apparently detach at that time. *G. duodenalis* trophozoites are teardrop-shaped and have been described as "someone looking at you" (Figs. 47.18–47.20).



• **Fig. 47.19** (A–C) Trophozoites of *Giardia duodenalis*. (D–F) Cysts of *G. duodenalis*.



• **Fig. 47.20** (A) *Giardia duodenalis* trophozoite. (B) *G. duodenalis* trophozoite, iodine stain. (C) *G. duodenalis* cysts. (B, Courtesy Dr. Henry Travers, Sioux Falls, SD.)

Cyst formation takes place as the organisms move down through the jejunum after exposure to biliary secretions. The trophozoites retract the flagella into the axonemes, the cytoplasm becomes condensed, and the cyst wall is secreted (Figs. 47.18–47.20). As the cyst matures, the internal structures are doubled, so that when excystation occurs, the cytoplasm divides, producing two trophozoites. Excystation occurs in the duodenum or appropriate culture medium.

Epidemiology

Transmission of *G. duodenalis* occurs by ingestion of viable cysts. Although contaminated food or drink may be the source, intimate contact with an infected individual may also result in transmission of the organism. This organism is found more frequently in children or in groups living in close quarters. Outbreaks have been associated with poor sanitation facilities or sanitation breakdowns, as evidenced by infections of travelers and campers. Limited information is available on seasonal variations in giardiasis. Some data suggest an association with the cooler, wetter months of the year, which may implicate environmental conditions as advantageous to cyst survival. Certain occupations may place an individual at risk for infection, such as sewage and irrigation workers, who may be exposed to infective cysts. In situations in which young children are grouped together, such as in nursery schools, an increased incidence of exposure and subsequent infection of both children and staff members may be seen. A high incidence

of giardiasis occurs in patients with immunodeficiency syndromes, particularly in those with common variable hypogammaglobulinemia. Giardiasis is the most common cause of diarrhea in these patients and may be associated with mild to severe villus atrophy.

Pathogenesis and Spectrum of Disease

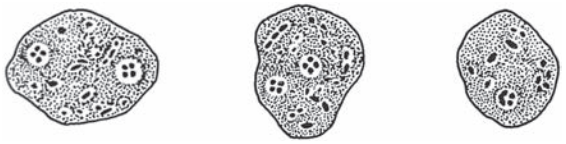
The incubation period for giardiasis ranges from approximately 12 to 20 days. Giardiasis may not be recognized as the cause, because the infection mimics acute viral enteritis, bacillary dysentery, bacterial or other food poisonings, acute intestinal amebiasis, or “traveler’s diarrhea” (toxigenic *Escherichia coli*). However, the type of diarrhea plus the lack of blood, mucus, and cellular exudate is consistent with giardiasis.

Asymptomatic Infection

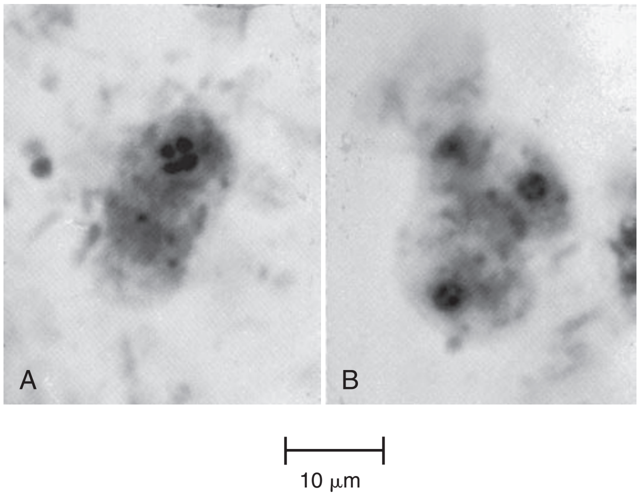
Although the parasites in the crypts of the duodenal mucosa may reach very high numbers, they may not cause a pathologic condition. The organisms feed on the mucous secretions and do not penetrate the mucosa. Although organisms have been seen in biopsy material obtained from inside the intestinal mucosa, others have been seen attached to the epithelium.

Intestinal Disease

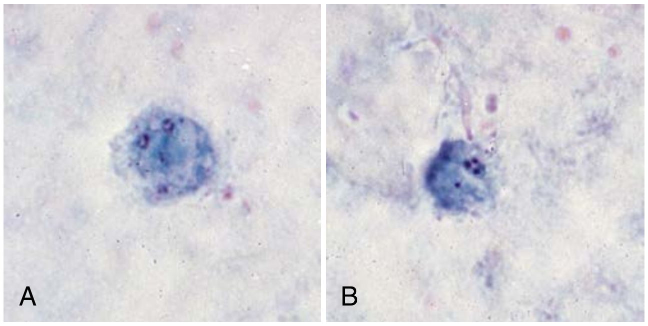
For unknown reasons, symptomatic patients may have irritation of the mucosal lining, increased mucus secretion, and dehydration. The onset of disease may be accompanied by nausea, anorexia, malaise, low-grade fever, and chills, in addition to a sudden onset of explosive, watery, foul-smelling diarrhea. Other symptoms include epigastric pain, flatulence, and diarrhea with increased amounts of fat and mucus in the stool but no blood. Weight loss often



• **Fig. 47.23** Trophozoites of *Dientamoeba fragilis*.



• **Fig. 47.24** (A and B) Trophozoites of *Dientamoeba fragilis*.



• **Fig. 47.25** (A) *Dientamoeba fragilis*, two nuclei. (B) *D. fragilis*, one nucleus.

accompanies these symptoms. Although some speculate that the organisms coating the mucosal lining may act to prevent fat absorption, this does not completely explain the prevention of the uptake of other substances normally absorbed at other intestinal levels. Severe malabsorption has been linked with isolated levothyroxine malabsorption, leading to severe hypothyroidism and secondary impairment of pancreatic function. In both cases, treatment with metronidazole led to complete remission of symptoms. Occasionally the gallbladder is involved, resulting in gallbladder colic and jaundice. *G. duodenalis* has been identified in bronchoalveolar lavage fluid.

Chronic Disease

The acute phase of infection is often followed by a subacute or chronic phase. Symptoms include recurrent, brief episodes of loose, foul-smelling stools and possibly increased distention and foul flatus. Between episodes of mushy stools, the patient may have normal stools or may be constipated. Abdominal discomfort includes marked distention and belching with a rotten-egg taste. Chronic disease must be differentiated from amebiasis; disease caused by other intestinal parasites (e.g., *D. fragilis, Cryptosporidium* spp., *Cyclospora cayetanensis, Cystoisospora belli, Strongyloides stercoralis*); inflammatory bowel disease; and irritable colon. Based on symptoms such as upper intestinal discomfort, heartburn, and belching, giardiasis must be differentiated from duodenal ulcer, hiatal hernia, and gallbladder and pancreatic disease.

Antigenic Variation

Variation of the surface antigen during human infections with *G. duodenalis* has been documented. This capability suggests that variation may provide a mechanism for the organism to escape the host's immune response. The **variant-specific surface proteins (VSPs)** are a family of related, highly unusual proteins covering the surface of the organism. VSPs are resistant to the effects of intestinal proteases, which allows the parasites to survive in the protease-rich small intestine. Antigenic variation at the surface membrane of trophozoites is common; seemingly, the higher the rate of change, the more likely it is that a chronic infection would persist.

Laboratory Diagnosis

Routine Methods

Routine stool examinations are normally recommended for the recovery and identification of intestinal protozoa. However, in the case of *G. duodenalis,* because the organisms are attached securely to the mucosa by means of the sucking disk, a series of five or six stool samples may be examined without recovering the organism. The organisms also tend to be passed in the stool on a cyclic basis. The Entero-Test capsule can be helpful for recovering the organisms, as can the duodenal aspirate. Although cysts often can be identified on the wet stool preparation, many infections may be missed without examination of a permanent stained smear. If material from the string test (Entero-Test, HDC Corp., San Jose, CA) or mucus from a duodenal aspirate is submitted, it should be examined as a direct wet preparation for motility; however, motility may be represented by nothing more than a slight flutter of the flagella, because the organism is caught up in the mucus. After diagnosis, the positive specimen can be preserved as a permanent stain.

Antigen Detection

The development of fecal immunoassays to detect *Giardia* antigen in stool has dramatically improved the sensitivity seen with the routine O&P examination. The ELISA has been used to detect *Giardia* antigen in feces. Fluorescent methods with monoclonal antibodies have also proven extremely sensitive and specific in detecting *G. duodenalis* in fecal specimens. Other products are available as a cartridge format that uses an immunochromatographic strip–based detection system for *G. duodenalis* and/or *Cryptosporidium* spp. Any antigen detection system should always be reviewed for compatibility with stools submitted in preservatives rather than fresh specimens. Some limitations exist on the use of kits for organisms in the genus *Entamoeba.* However, commercial reagent kits for detecting *Giardia* and *Cryptosporidium* spp. can be used with formalin-based stool preservatives or with fresh or frozen specimens. Many of these cartridge format tests provide an answer within 10 minutes and are equal to or better than other immunoassays with regard to sensitivity and specificity. Many of the methods are being used to test patients suspected of having giardiasis or those who may be involved in an outbreak.

The detection of antigen in stool or visual identification of organisms by using monoclonal antibody reagents indicates current infection. The value of these detection assays as rapid, reliable immunodiagnostic procedures has been emphasized by the increase in *Giardia* infections and the greater awareness of particular incidences (e.g., nursery school settings). Because the organisms are shed so sporadically, use of a fecal immunoassay does not eliminate the need to analyze multiple stool specimens for sensitive detection of *G. duodenalis;* a minimum of two stools should be tested. If the first specimen is negative, it may represent a false negative.

Antibody Detection

Unfortunately, serodiagnostic procedures for antibody detection do not fulfill the criteria necessary for wide clinical use, particularly because they may indicate either past or present infection.

Histology

Trophozoites are detectable in the duodenum and proximal jejunum; however, mucosal invasion generally has been found in areas in which necrosis or mechanical trauma was present. Changes range from normal to almost complete villus atrophy, with a greater density of inflammatory infiltrate in the lamina propria when villus atrophy is present. The amount of villus damage seems to correlate with the degree of malabsorption. Apparently, patients with giardiasis also have reduced mucosal surface areas compared with control patients.

Histologic changes in the mucosal architecture in immunodeficient patients with giardiasis also range from mild to severe villus atrophy. It appears that giardiasis produces a more severe degree of villus damage in patients with hypogammaglobulinemia. In patients with acquired immunodeficiency syndrome (AIDS), giardiasis does not appear to be an important pathogen, although the infection has been identified in this group and in homosexual males.

Nucleic Acid Detection

There are three multiplex assays available in the United States to detect *G. duodenalis,* as previously discussed in this chapter.

Results and Reporting

It may be necessary to examine up to six stool specimens to rule out an infection with *Giardia* sp. This is because the organism remains securely attached to the intestinal mucosa, resulting in poor shedding or visibility in a stool specimen. Organisms may also be passed intermittently or in cycles. A positive stool specimen does not require quantitation.

Prevention

The most effective practice for preventing the spread of infection in a childcare setting is thorough hand washing by the children, staff members, and visitors. Rubbing the hands together under running water is the most important part of washing away infectious organisms. Premoistened towelettes or wipes and waterless hand cleaners should not be used as substitutes for washing the hands with soap and running water. These guidelines are not limited to giardiasis but include all potentially infectious organisms.

Because wild animals and possibly domestic animals serve as reservoir hosts, personal hygiene, improved sanitary measures, and safe drinking water are considerations. Iodine has been recommended as an effective disinfectant for drinking water. Filtration systems have been recommended, although they have certain drawbacks, such as clogging.

Treatment

In most cases, treatment is not necessary, because infections are self-limiting; however, treatment will decrease the duration and prevent transmission to others. The treatments of choice include metronidazole, nitazoxanide, or tinidazole.

Chilomastix mesnili

General Characteristics

C. mesnili has both trophozoite and cyst stages and is somewhat more easily identified than are some of the smaller flagellates, such as *E. hominis* and *R. intestinalis* (Tables 47.3, 47.4 and Figs. 47.18 and 47.21). The *C. mesnili* trophozoite is pear-shaped, measuring 6 to 24 µm long and 4 to 8 µm wide. It has a single nucleus and a distinct oral groove, or **cytostome** (mouth), close to the nucleus. Flagella are difficult to see without obvious motility in a direct wet preparation. The morphology can be seen on the permanent stained smear; the cytostome may be visible in some trophozoites. The cysts are pear- or lemon-shaped and range from 6 to 10 µm long and 4 to 6 µm wide (Figs. 47.21 and 47.22). They have a single nucleus and a typical curved cytostomal fibril, called the **shepherd's crook.** The cyst's definitive morphology can be seen on a permanent stain.

Epidemiology

C. mesnili tends to have a cosmopolitan distribution, although it is found more commonly in warm climates. Transmission occurs through ingestion of infective cysts.

Pathogenesis and Spectrum of Disease

C. mesnili is considered nonpathogenic and does not cause disease.

Laboratory Diagnosis

Although cysts sometimes can be seen in a wet preparation, definitive identification of *C. mesnili* relies on examination of permanent stained smears.

Therapy

Specific treatment is not recommended for *C. mesnili.* Because these nonpathogenic organisms are acquired through fecal-oral contamination, both pathogens and nonpathogens can be found in the same patient. If few organisms are present, extended microscopic examination and multiple organism measurements are required for definitive identification. It is always important to report pathogens and nonpathogens, because they are acquired the same way.

Prevention

Prevention depends on adequate disposal of human excreta and improved personal hygiene, preventive measures that apply to most of the intestinal protozoa.

Dientamoeba fragilis

General Characteristics

D. fragilis has a worldwide distribution, and surveys report incidence rates of 1.4% to 19%. Much higher incidence figures have been reported for patients in mental institutions, missionaries, and Native Americans in Arizona. *D. fragilis* tends to be common in some pediatric populations, and the incidence is higher for patients younger than 20 years in some studies. Some speculate that *D. fragilis* may be infrequently recovered and identified; a low incidence or absence from survey studies may be a result of poor laboratory techniques and a general lack of knowledge about the organism.

The *D. fragilis* trophozoite is characterized as having one nucleus (20% to 40%) or two nuclei (60% to 80%). The nuclear chromatin usually is fragmented into three to five granules, and normally no peripheral chromatin is seen on the nuclear membrane. In some organisms, the nuclear chromatin tends to mimic that of *E. nana, E. hartmanni,* or even *C. mesnili,* particularly if the organisms are overstained with trichrome or iron-hematoxylin stain. The cytoplasm is usually vacuolated and may contain ingested debris and some large, uniform granules. The cytoplasm can also appear uniform and clean with few inclusions. Size and shape vary considerably among organisms, even on a single smear. The cyst has a distinct cell wall with a clear zone around the cyst that includes an axostyle, flagellar axonemes, and a costa. Cysts generally contain two nucleic with a large central karyosome. A precystic stage exists that is a compact spherical structure about half the size of a trophozoite. The cysts are rarely found in clinical samples.

Epidemiology

The transmission of *D. fragilis* has been postulated as associated with helminth eggs (e.g., *Ascaris* and *Enterobius* spp.) (Figs. 47.23–47.25). A cyst stage has been identified, although rarely present in clinical samples, and indicates that fecal-oral transmission occurs (Tables 47.3 and 47.4).

Pathogenesis and Spectrum of Disease

D. fragilis has been associated with a wide range of symptoms. Case reports of children infected with *D. fragilis* reveal a number of symptoms, including intermittent diarrhea, abdominal pain, nausea, anorexia, malaise, fatigue, poor weight gain, and unexplained eosinophilia. The most common symptoms in patients infected with this parasite appear to be intermittent diarrhea and fatigue. In some patients, both the organism and the symptoms persist or reappear until appropriate treatment is initiated.

Laboratory Diagnosis

Routine Methods

Diagnosis of *D. fragilis* infections depends on proper collection and processing techniques (a minimum of three fecal specimens). Although the survival time for this parasite has been reported as 24 to 48 hours in the trophozoite form, the survival time in terms of morphology is limited, and stool specimens must be examined immediately or preserved in a suitable fixative soon after defecation. It is particularly important to examine permanent stained smears of stool with an oil immersion objective (×100). The trophozoites have been recovered in formed stool; therefore, a permanent stained smear must be prepared for every stool sample submitted for examination. Organisms seen in direct wet mounts may appear as refractile, round forms that may actually represent the cysts or precystic forms; the nuclear structure cannot be seen without examination of the permanent stained smear.

Antigen Detection

Although fecal immunoassays for antigen detection are not yet available commercially, they have been developed using several test formats. Detection of deoxyribonucleic acid (DNA) from feces is being used in some laboratories.

Antibody Detection

On indirect immunofluorescence assay, serum samples from patients with confirmed *D. fragilis* infections showed positive titers, and all matched controls had positive titers ranging from 20 to 160. However, these tests are not routinely used, nor are the reagents commercially available.

Therapy

Although treatment is not generally recommended for infections with nonpathogenic flagellates, clinical improvement has been seen in adults receiving tetracycline, and symptomatic relief has been observed in children receiving diiodohydroxyquin, metronidazole, or tetracycline. Current recommendations include iodoquinol, paromomycin, or tetracycline. Although limited studies have been undertaken on the efficacy of various therapies, information continues to support the finding that elimination of this organism from symptomatic patients leads to clinical improvement. Treatment of *D. fragilis* infection with iodoquinol, paromomycin, or combination therapy results in eradication of the parasite and complete resolution of symptoms.

Prevention

Fecal-oral transmission has been documented. Therefore, transmission from ingestion of certain helminth eggs, or the fecal-oral route, indicate that the appropriate hygiene and sanitary measures to prevent contamination with fecal material are useful for the prevention of infection with *D. fragilis*, as with other intestinal parasites.

Pentatrichomonas hominis

P. hominis is probably the most commonly identified flagellate, other than *G. duodenalis* and *D. fragilis. P. hominis* has been recovered from all parts of the world, in both warm and temperate climates, and is considered nonpathogenic and noninvasive. It is not known to have a cyst stage (Fig. 47.18). *P. hominis* trophozoites live in the cecum and feed on bacteria. The trophozoite measures 5 to 15 µm long and 7 to 10 µm wide. It has a pyriform shape and has both an **axostyle** and an undulating membrane, which aid identification of the organism. The undulating membrane extends the entire length of the body, in contrast to that seen in the pathogen *T. vaginalis* (on which the membrane extends halfway down the body).

Epidemiology

Because *P. hominis* is not known to have a cyst stage, transmission probably occurs in the trophic form. If ingested in a substance such as milk, these organisms apparently can survive passage through the stomach and small intestine in patients with achlorhydria. *P. hominis* cannot be transplanted into the vagina, the natural habitat of *T. vaginalis.* The incidence of this organism is relatively low, but it tends to be recovered more often than *E. hominis* or *R. intestinalis,* two small nonpathogenic flagellates that are rarely seen and extremely difficult to identify (Fig. 47.18).

Pathogenesis and Spectrum of Disease

P. hominis is considered nonpathogenic and does not cause disease.

Laboratory Diagnosis

P. hominis trophozoites can sometimes be seen on a permanent stained smear, but definitive identification can be difficult. However, it is important to report the presence of the organism if seen.

Therapy

Specific treatment is not recommended for this nonpathogen.

Prevention

Prevention depends on adequate disposal of human excreta and improved personal hygiene, preventive measures that apply to most of the intestinal protozoa.

Retortamonas intestinalis

Retortamonas intestinalis is a small oval to elongated pyriform trophozoite. The trophozoite has a cystome that may not be evident, and the cyst stage is pear shaped. Both life cycle stages have a single nucleus. The organism is transmitted by the fecal-oral route; however, it is considered nonpathogenic, and therefore treatment is not warranted.

Ciliates

The class Ciliata, or ciliates, include species that move by means of **cilia,** or short extensions of cytoplasm that cover the surface of the organism. The ciliates also have two different types of nuclei, one **macronucleus** and one or more **micronuclei.** This group includes only one organism that infects humans, *Neobalantidium coli,* which infects the intestinal tract and may produce severe symptoms. Using current molecular techniques, the classification of this organism has been revised, although there seems to be discrepancy in the literature listing the organism as *Balantidium, Neobalantidium,* or *Balanitides coli.* An extensive molecular analysis was completed by Pomajbíková et al. (2013) which supports the new taxonomic designation of *Neobalantidium coli* (previously *Balantidium coli*).

Neobalantidium coli

General Characteristics

The life cycle of *N. coli* includes both the trophozoite and cyst stages (Fig. 47.26). The cyst form is the infective stage. After ingestion of the cysts and excystation, trophozoites secrete hyaluronidase, which aids the invasion of the colonic tissue.

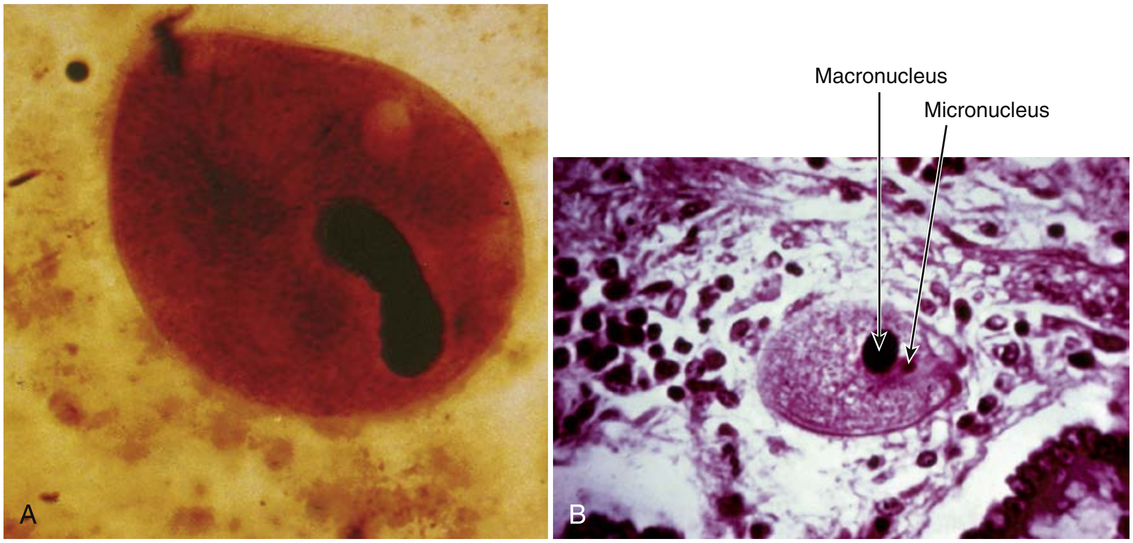
The trophozoite is quite large, oval, and covered with short cilia. It measures approximately 50 to 150 µm long and 40 to 70 µm wide. The organism can be seen in a wet preparation on lower power. The anterior end is somewhat pointed and has a cytostome (primitive mouth opening); in contrast, the posterior end is broadly rounded. The cytoplasm contains many vacuoles with ingested bacteria and debris. The trophozoite has two nuclei: one very large, bean-shaped macronucleus and a smaller, round micronucleus. The organisms live in the large intestine. The trophozoites have a rapid, rotatory, boring motion because of the movement of the cilia. The cyst is formed as the trophozoite moves down the intestine. Nuclear division does not occur in the cyst; therefore, only two nuclei are present, the macronucleus and the micronucleus. The cysts measure 50 to 70 µm in diameter (Table 47.5).

Epidemiology

N. coli is widely distributed in hogs, particularly in warm and temperate climates, and in monkeys in the tropics. Human infection is found in warmer climates, sporadically in cooler areas, and in institutionalized groups with low levels of personal hygiene.

Pathogenesis and Spectrum of Disease

Some individuals with *N. coli* infection are asymptomatic, whereas others have severe dysentery, similar to that seen in patients with amebiasis. Symptoms include diarrhea or dysentery, tenesmus, nausea, vomiting, anorexia, and headache. Insomnia, muscular weakness, and weight loss have been reported. Diarrhea may persist for weeks to months, with or without subsequent development of dysentery. Tremendous fluid loss may occur, with diarrhea similar to that seen in cholera or in some coccidial or microsporidial infections.



• **Fig. 47.26** (A) *Neobalantidium coli* trophozoite. (B) *N. coli* trophozoite. (B, Courtesy Dr. Henry Travers, Sioux Falls, SD.)

N. coli can invade tissue. It may penetrate the mucosa on contact, with cellular infiltration in the area of the developing ulcer. Some of the abscess formations may extend to the muscular layer. The ulcers may vary in shape, and the ulcer bed may be full of pus and necrotic debris. The organism has been reported to migrate from the intestine to the lungs causing a pneumonia-like illness in immunocompromised patients. Although the number of cases is small, extraintestinal disease (peritonitis, urinary tract infection, and inflammatory vaginitis) has been reported.

Laboratory Diagnosis

Routine stool examinations, particularly direct wet preparation examinations of fresh and concentrated material, demonstrate the presence of organisms. Organism recognition and identification on a permanent stained smear is usually difficult. These protozoa are large and stain very darkly, which obscures any internal morphology. *N. coli* organisms may be confused with helminth eggs or debris because of their size, particularly when the cilia are not visible. Recovery of *N. coli* from specimens in the United States is rare. However, laboratories should be able to identify these organisms in proficiency testing specimens.

Results Reporting

As previously noted, the organism is rarely identified, and care should be taken to not confuse the parasite with contaminating debris.

Therapy

Tetracycline is the drug of choice for treating *N. coli* infection, although it is considered investigational for this infection. Iodoquinol or metronidazole may be used as an alternative. Nitazoxanide, a broad-spectrum antiparasitic drug, may be another alternative.

Prevention

In areas where pigs are raised, the incidence of human infection can be quite high in pig farmers and slaughterhouse workers. Human infection is fairly rare in temperate areas, although infections can develop into an epidemic, particularly in areas of poor environmental sanitation and personal hygiene. This situation has been seen in mental hospitals in the United States. Preventive measures involve increased attention to personal hygiene and sanitation measures, because the mode of transmission is ingestion of infective cysts through contaminated food or water.

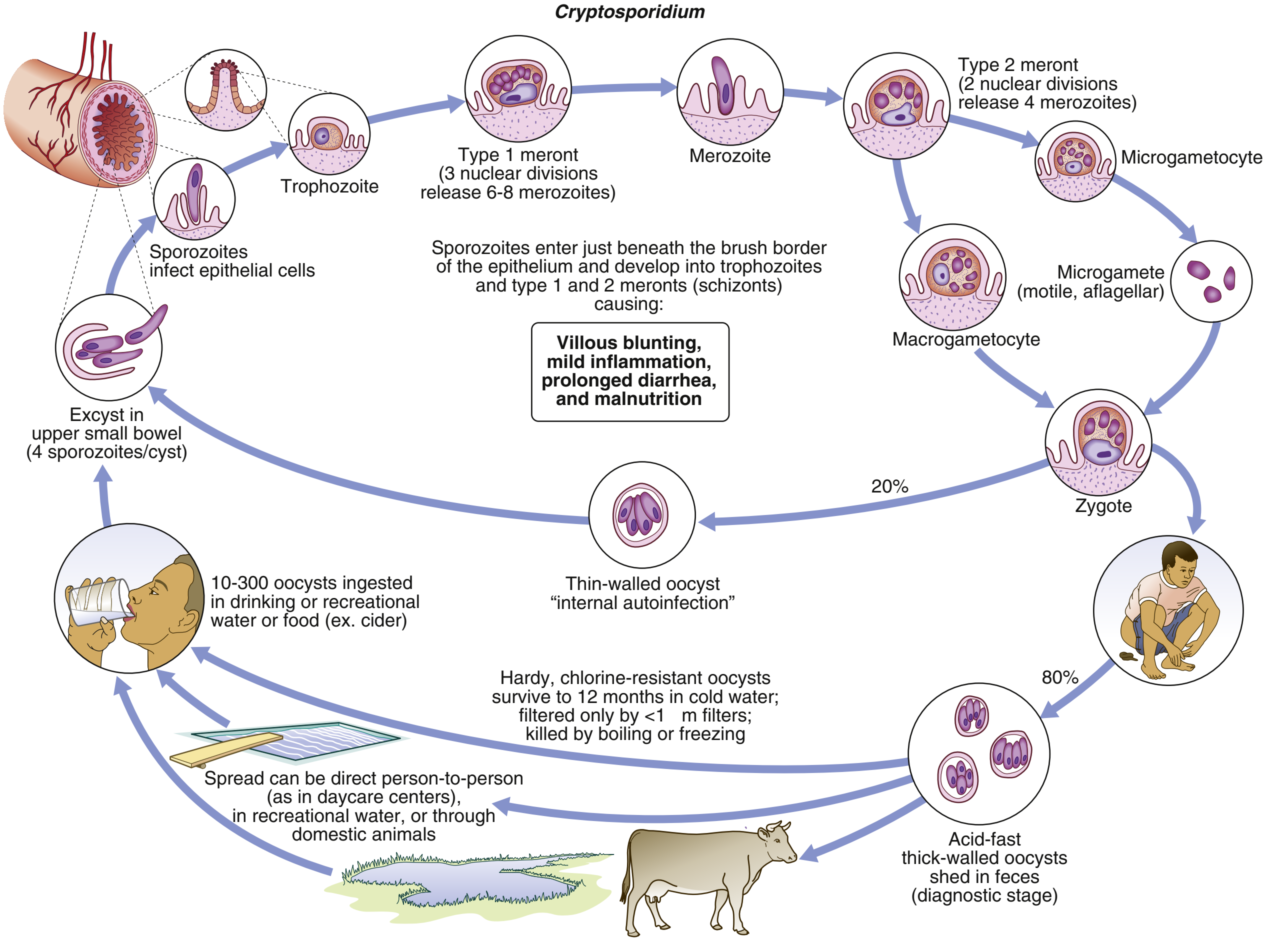
Sporozoa (Apicomplexa)

All the Apicomplexa are unicellular and have an **apical complex.** These structures can be seen in electron microscopy (EM) studies and are used to help classify the various organisms. Genera that develop in the gastrointestinal tract of vertebrates throughout their entire life cycle include *Cystoisospora, Cyclospora,* and *Cryptosporidium.* Genera capable of or requiring extraintestinal development are referred to as **cyst-forming coccidia;** they include *Sarcocystis* and *Toxoplasma* spp. The genera that cause disease in humans include *Cryptosporidium, Cyclospora, Cystoisospora, Sarcocystis,* and *Toxoplasma* (see Chapter 49 for a discussion of *Toxoplasma*).

Cryptosporidium spp.

General Characteristics

Cryptosporidium spp. are intracellular parasites that primarily infect epithelial cells of the stomach, intestine, and biliary ducts. The organism previously called *Cryptosporidium parvum,* thought to be the primary *Cryptosporidium* species infecting humans, now is classified as two species, *C. parvum* (mammals, including humans) and *Cryptosporidium hominis* (primarily humans) (Figs. 47.27 and 47.28, and



Cryptosporidium
Trophozoite
Type 1 meront

• **Fig. 47.28** *Cryptosporidium*. (A) Oocysts recovered from a Sheather’s sugar flotation; organisms measure 4 to 6 μm. (B) Scanning electron microscopy view of organisms at brush border of epithelial cells. (From Garcia LS, Bruckner DA. *Diagnostic Medical Parasitology*. Washington, DC: ASM Press; 1993.)

Table 47.6). Differentiation of these two species based on oocyst morphology is not possible. Currently, more than 20 established *Cryptosporidium* spp. have been reported in humans in immunocompetent and immunocompromised individuals.

Cryptosporidium infections begin with ingestion of viable oocysts (Fig. 47.27). Upon contact with gastric and duodenal fluid, each **oocyst** releases four **sporozoites,** which invade the epithelial cells and develop into trophozoites surrounded by a **parasitophorous vacuole** (layers of endoplasmic reticulum around an intracellular parasite). In the epithelial cells, trophozoites undergo two or three generations of asexual amplification, called **merogony,** leading to the formation of different types of **meronts** containing four to eight **merozoites.** The merozoites differentiate into sexually distinct stages in a process called **gametogony.** New oocysts are formed in the epithelial cells in a process called **sporogony.** About 20% of the oocysts are thin-walled and may excyst in the digestive tract of the host, leading to the infection of new cells (**autoinfection**). The remaining 80% of the oocysts are excreted into the environment; are resistant to low temperature, high salinity, and most disinfectants; and can initiate infection in a new host. *Cryptosporidium* oocysts in humans measure 4 to 6 μm in diameter.

Epidemiology

Humans can acquire cryptosporidiosis through several transmission routes, such as direct contact with infected people or animals or consumption of contaminated water (drinking or recreational) or food. The interval between ingestion of infective oocysts to completion of the life cycle and excretion of new oocysts usually is 4 to 10 days. The only extracellular stage in the *Cryptosporidium* life cycle is the oocysts; these are the environmental stage of the parasite and are immediately infectious when passed in the stool (Fig. 47.28).

Cryptosporidium spp. have a worldwide distribution, and the oocysts are ubiquitous in the environment. In developing countries, human *Cryptosporidium* infection occurs mostly in children younger than 5 years, with peak occurrence of infections and diarrhea in children younger than 2 years. In developed countries, pediatric cryptosporidiosis occurs in older children, probably because, due to better hygiene, exposure to contaminated environments occurs later. Cryptosporidiosis is also common in the elderly in nursing homes, where person-to-person transmission occurs. In the general population, sporadic infections occur in all age groups in the United States and the United Kingdom, and traveling to developing countries and consumption of contaminated food and water can lead to infection. Cryptosporidiosis is common in immunocompromised individuals, such as those with AIDS or primary immunodeficiency and cancer and transplant patients undergoing immunosuppressive therapy.

Calves and perhaps other animals serve as potential sources of human infection. Contact with these animals may be an unrecognized cause of gastroenteritis in humans in both rural and urban settings. Direct person-to-person transmission is also likely and may occur through direct or indirect contact with stool material. Direct transmission may occur during sexual practices involving oral-anal contact. Nucleic acid sequence analyses of the *gp60* (glycoprotein) gene for epidemiologic determination has indicated that human infections of *C. parvum* are not zoonotic. There are two major subtypes, IIa and IIc. The first subtype has been identified in humans and ruminants, therefore suggesting potential zoonotic transmission. The latter, IIc, has only been identified in humans and is therefore limited as a human (**anthroponotic**) pathogen. Subtype infection rates in humans varies geographically. Both IIa and IIc have been identified in human cases in developing countries; a third subtype, IId, has been identified in humans in the Middle Eastern countries. Indirect transmission may occur through exposure to positive specimens in a laboratory setting or from contaminated surfaces, food, or water.

Pathogenesis and Spectrum of Disease

Immunocompetent Individuals

In immunocompetent people with sporadic cryptosporidiosis in industrialized nations, the most common symptom is diarrhea. Clinical symptoms include nausea; low-grade fever; abdominal cramps; anorexia; and 5 to 10 watery, frothy bowel movements per day, which may be followed by constipation. Some patients may have diarrhea, and others may have few symptoms, particularly later in the course of the infection. In patients with the typical watery diarrhea, the stool contains mainly water and mucus. Often the organisms are entrapped in the mucus, and diagnostic procedures are performed accordingly. Generally, a patient with a normal immune system has a self-limited infection; however, patients who are immunocompromised may have a chronic infection with a wide range of symptoms. The illness usually lasts 9 to 21 days and may require hospitalization in up to 20% of those infected. Patients infected with *C. hominis* are more likely to have joint pain, eye pain, recurrent headache, dizziness, and fatigue than those infected with *C. parvum.*

Immunocompromised Individuals

Hemodialysis patients with chronic renal failure and renal transplant patients with cryptosporidiosis can have chronic, life-threatening diarrhea. In individuals infected with the human immunodeficiency virus (HIV), cryptosporidiosis increases as the CD4+ lymphocyte count falls, especially below 200 cells/μL. Sclerosing cholangitis and other biliary involvement are also seen in AIDS patients with cryptosporidiosis. The combination of AIDS and cryptosporidiosis often leads to increased mortality. In these patients, *Cryptosporidium* infections are not always confined to the gastrointestinal tract; additional symptoms (respiratory problems, cholecystitis, hepatitis, and pancreatitis) have been associated with extraintestinal infections. Although the clinical features of sclerosing cholangitis secondary to opportunistic infections of the biliary tree in patients with AIDS are well known, the mechanisms by which pathogens such as *Cryptosporidium* spp. cause disease are unclear.

Laboratory Diagnosis

Routine Methods

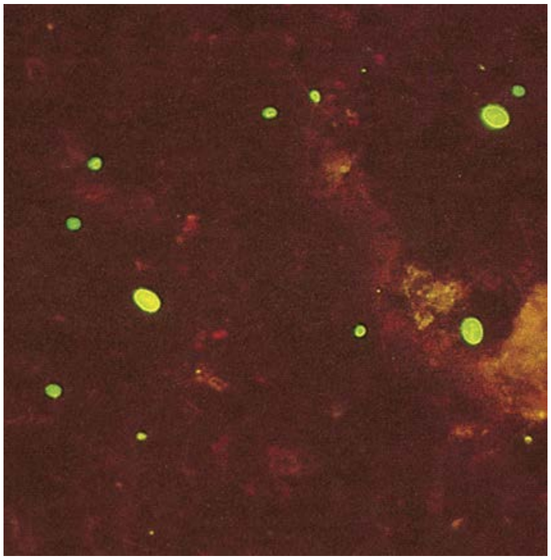
Oocysts in clinical specimens are difficult to see without special staining techniques, such as the modified acid-fast, Ziehl-Neelsen or Kinyoun's, or Giemsa method, or the newer immunoassay methods. Oocysts appear bright red to purple against a blue or green background when stained using a modified acid-fast stain. The four sporozoites may be seen in the oocyst in some of the organisms, although they are not always visible in freshly passed specimens.

Antigen Detection

Immunoassays are very helpful, because they are a more sensitive method of detecting organisms in stool specimens. A direct fluorescent antigen (FA) procedure with excellent specificity and sensitivity has been developed and results in a significantly increased detection rate over conventional staining and microscopy methods. Some of these reagents, particularly the combination direct FA product used to identify both *Giardia* spp. cysts and *Cryptosporidium* spp. oocysts, are being widely used in water testing and outbreak situations (Fig. 47.29). Most antibodies in commercial direct fluorescent antibody (DFA) kits react with oocysts of almost all *Cryptosporidium* species, making identification to the species level impossible. EIA tests also provide excellent specificity and sensitivity for laboratories using this approach, as do the immunochromatographic cartridge rapid test formats. However, high false-positive rates have been reported in rapid diagnostic tests. It is important to remember that if a patient is in the carrier state or undergoing self-cure, the number of oocysts may drop below the sensitivity levels of these kits. The inability to detect other *Cryptosporidium* spp. other than *C. hominis* and *C. parvum* may thus produce a false-negative result. Positive rapid diagnostic tests should be confirmed with additional testing and negative tests should be interpreted with caution and correlated with the patient's clinical presentation.

Nucleic Acid Detection

Molecular techniques, especially PCR and PCR-related methods, have been used to detect and differentiate *Cryptosporidium* spp., and a few of the PCR assays are commercially available. Several genus-specific PCR-restriction fragment length polymorphism–based genotyping tools have been developed for detecting and differentiating *Cryptosporidium* organisms at the species level. Other genotyping techniques are designed mostly for differentiation of *C. parvum* and *C. hominis* and cannot detect and differentiate other *Cryptosporidium* spp. or genotypes. Currently, three FDA-approved assays are available for the detection of *Cryptosporidium* in the United States: the xTAG Gastrointestinal Pathogen Panel, the FilmArray System GI Panel (BioFire Diagnostics, Salt Lake City, UT) and the BD MAX enteric parasite panel (Becton Dickinson Company, Sparks, MD) as previously noted.



• Fig. 47.29 *Cryptosporidium* oocysts and *Giardia* cysts stained with monoclonal antibody–conjugated fluorescent reagent. (Courtesy Merifluor, Meridian Diagnostics, Cincinnati, OH.)

Antibody Detection

In the United States, drinking untreated surface water has been identified as a risk factor for cryptosporidiosis; residents living in cities with surface-derived drinking water generally have higher antibody levels against *Cryptosporidium* spp. in their blood than those living in cities with ground water as drinking water. However, antibody detection is not available on a routine basis and currently is not used in the diagnosis of cryptosporidiosis.

Histology

In the examination of histologic preparations, developmental stages (sporozoites, trophozoites, merozoites, and oocysts) in the life cycle of *Cryptosporidium* spp. can be found at all levels of the intestinal tract, with the jejunum being the most heavily infected site. Routine hematoxylin and eosin staining is sufficient to demonstrate these parasites. Under regular light microscopy, the organisms are visible as small, round structures (about 1 to 3 μm in diameter) aligned along the brush border. They are intracellular but extracytoplasmic and are found in parasitophorous vacuoles. Developmental stages are more difficult to identify without a transmission electron microscope. It also is important to remember that in severely compromised patients, *Cryptosporidium* spp. have been found in other body sites, primarily the lungs, as a disseminated infection.

Results Reporting

Cryptosporidiosis is a reportable disease in the United States. An increase in reported cases may indicate an outbreak. Identification of oocysts in a patient's stool should be reported as *Cryptosporidium* positive. A positive antigen test should be reported as *Cryptosporidium*-presumptive with additional follow-up testing. Positive diagnosis should be referred to the appropriate public health laboratory for confirmation.

Therapy

Oral or intravenous rehydration and antimotility drugs are used whenever severe diarrhea is associated with cryptosporidiosis. Nitazoxanide is the only drug approved by the FDA for the treatment of cryptosporidiosis in immunocompetent individuals. This drug can shorten the clinical disease and reduce the number of parasites present. However, nitazoxanide is not effective in treating cryptosporidiosis in immunodeficient patients; paromomycin and spiramycin have been used in these individuals.

In industrialized nations, the most effective prophylaxis and treatment for cryptosporidiosis in patients with AIDS is highly active antiretroviral therapy (HAART). Eradication and prevention of the infection are related to replenishment of CD4+ cells in treated individuals and the antiparasitic activities of the protease inhibitors used in HAART. Relapse of cryptosporidiosis is common in patients with AIDS who have stopped HAART.

Prevention

Effective concentrations of most substances used for disinfection are not practical outside the laboratory, and high concentrations that significantly reduce oocyst infectivity are either very expensive or quite toxic. *Cryptosporidium* oocysts are highly resistant to most commercial disinfectants, including iodine water purification tablets. Although chlorine and related compounds can dramatically reduce the ability of oocysts to excyst or infect, high concentrations and long exposure times are required, making this approach impractical.

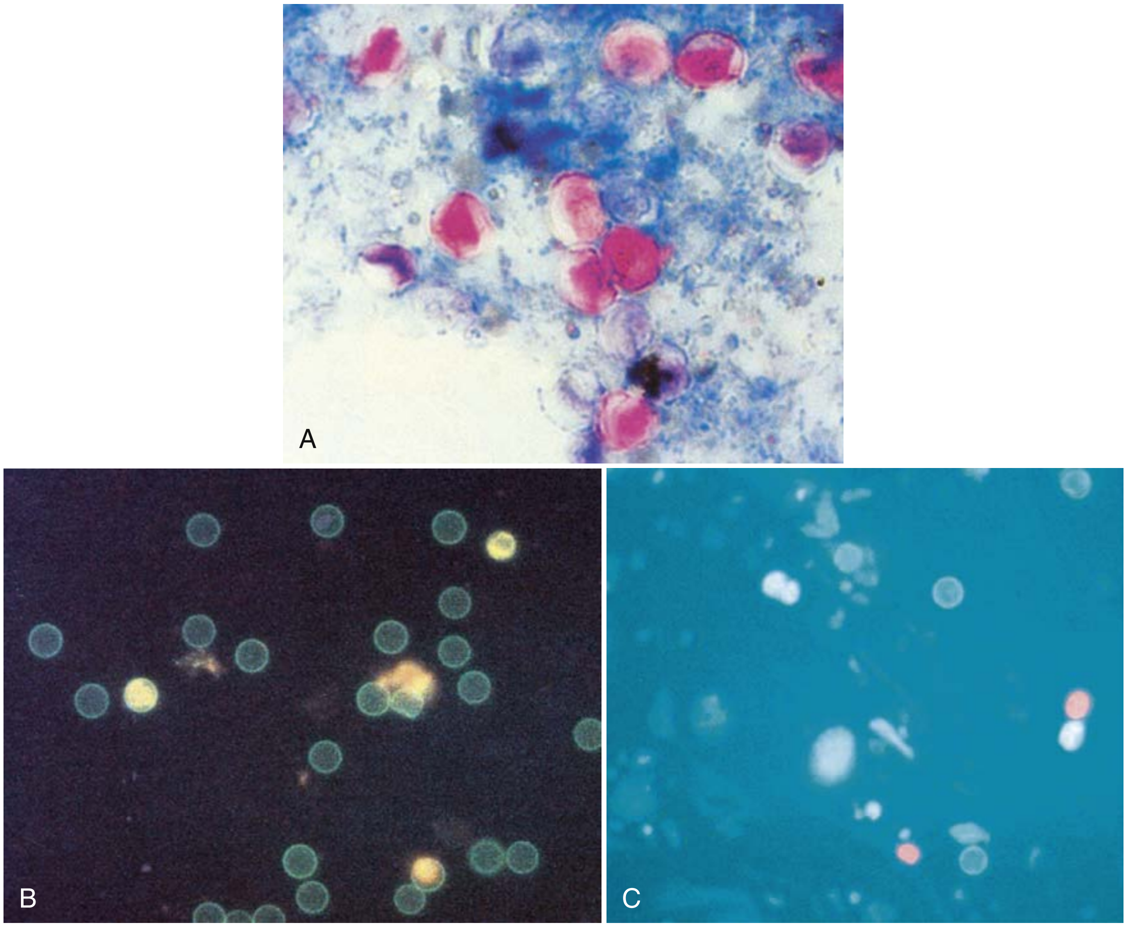
Cyclospora cayetanensis

General Characteristics

During the past few years, a number of outbreaks of diarrhea associated with *Cyclospora cayetanensis* have occurred; the distribution is worldwide (United States, Caribbean, Central and South America, Southeast Asia, Eastern Europe, Australia, Nepal). These organisms are acid-fast variable and have been found in the feces of immunocompetent travelers to developing countries, immunocompetent individuals with no travel history, and patients with AIDS.

The life cycle of *C. cayetanensis* involves only humans as hosts. Oocysts are passed in the feces unsporulated (Fig. 47.30A). At room temperature (23°C to 25°C), small numbers of oocysts may sporulate within 10 to 12 days.

In clean wet mounts, *Cyclospora* organisms are seen as nonrefractile spheres, which are difficult to recognize as parasites. Unless a high number of oocysts are present, they may easily be mistaken for artifacts. They are acid-fast variable with the modified acid-fast stain; those that are unstained appear as glassy, wrinkled spheres (wrinkled cellophane). The oocysts are twice the size of those of *Cryptosporidium* spp. and measure 8 to 10 µm in diameter. Because it takes 10 days to 2 weeks for the oocysts to sporulate, no internal structures are visible (sporozoites), as can be seen in *Cryptosporidium* organisms.



• **Fig. 47.30** (A) *Cyclospora cayetanensis* oocysts after modified acid-fast staining. Note the variability in the intensity of the stain. These oocysts measure 8 to 10 µm, twice the size of *Cryptosporidium* spp. (oil immersion, ×1000). (B and C) *Cyclospora cayetanensis* oocysts exhibiting autofluorescence (high dry power, ×400). (A and B, Courtesy Charles R. Sterling, University of Arizona. C, Courtesy E. Long, Centers for Disease Control and Prevention, Atlanta, GA.)

Epidemiology

Transmission of *C. cayetanensis* is by the fecal-oral route and often correlated with the ingestion of contaminated fruits and vegetables. However, direct person-to-person transmission has not been well documented and may not be a factor, because sporulation takes a number of days. Information on reservoir hosts is not well defined; however, in some areas humans appear to be the only host.

C. cayetanensis is endemic in Central and South America, the Caribbean, Mexico, Indonesia, Asia, Nepal, Africa, India, Southern Europe, and the Middle East. In endemic areas, contact with soil and water increases the risk of *Cyclospora* infection. Infections in most temperate areas correlate with the consumption of imported contaminated fruits and vegetables.

Pathogenesis and Spectrum of Disease

Although some patients are asymptomatic, others report a flulike illness, marked by nausea, vomiting, anorexia, weight loss, and explosive diarrhea lasting 1 to 3 weeks. The incubation period is not yet known. However, the onset of symptoms after infection generally averages 7 to 8 days, and the symptoms last 2 to 3 weeks. Oocyst shedding in the feces is highly variable and may range from 7 days to several months. Indigenous infections are confined primarily to tropical, subtropical, or warm temperate regions of the world. Outbreaks occur in other areas of the world as a result of contaminated foodstuffs.

In immunocompromised and immunocompetent patients, *C. cayetanensis* infection can be associated with biliary disease. With light and transmission EM, developmental stages have been seen in the gallbladder epithelium of AIDS patients with acalculous cholecystitis. In addition, oocysts have been seen in the bile of patients with active biliary disease.

Laboratory Diagnosis

C. cayetanensis oocysts do not routinely stain with the trichrome fecal stain; special methods are required for identification. The oocysts can be concentrated using routine methods; special stains can then be used to enhance morphology. A single negative stool specimen is not conclusive in the examination of stools for coccidia; three stool specimens collected on subsequent days must be examined before infection can be ruled out.

Special Stains

With modified acid-fast stains, the oocysts appear light pink to deep red, and some contain granules or have a bubbly appearance (described as wrinkled cellophane). It is very important to be aware of these organisms when the modified acid-fast stain is used, because *Cryptosporidium* spp. and other similar but larger structures (approximately twice the size of *Cryptosporidium* oocysts [8 to 10 μm]) are seen in the stained smear. Laboratories need to measure all acid-fast oocysts, particularly if they appear to be somewhat larger than *Cryptosporidium* spp. Variations on the safranin staining technique stain *C. cayetanensis* oocysts orange or pinkish orange. Heating and other treatments have been used to increase the staining frequency of oocysts. The oocysts autofluoresce green (450 to 490 DM excitation filter) or blue (365 DM excitation filter) under ultraviolet (UV) epifluorescence (Fig. 47.30B and C). It is strongly recommended that during concentration (formalin ethyl acetate) of stool specimens, centrifugation be carried out for 10 minutes at 500× *g*. The concentration sediment can then be stained, enhancing the sensitivity of the microscopy examinations.

Nucleic Acid Detection and Serologic Tests

Several nucleic acid–based tests have been developed in research laboratories that detect a variety of organism-specific genes, including the 18S rRNA, 28S rRNA, and the cytochrome oxidase 1 sequence. Commercially available multiplex panels are also available for the detection of *C. cayetanensis* including the BioFire FilmArray Gastrointestinal panel, previously described. No antibody or antigen tests are available for the diagnosis of *C. cayetanensis* infection.

Results and Reporting

C. cayetanensis is reportable to both the local public health authorities and the Centers for Disease Control and Prevention. The organism has been associated with human outbreaks and contamination of food sources. Quantitation is not required. If a negative result is indicated, it is important to note that three samples have been examined before a negative is reported.

Therapy

Patients have been treated symptomatically with antidiarrheal preparations and have obtained some relief; however, the disease appears to be self-limiting within a few weeks. TMP-SMX, currently the drug of choice, is given orally twice daily for 7 days. Elimination of parasites, a decrease in diarrhea, and diminished abdominal pain occur within 2 to 3 days after treatment. Patients with AIDS may need higher doses and long-term maintenance treatment. However, more than 40% of patients have a recurrence of symptoms in 1 to 3 months after treatment. Patients who are allergic to sulfonamides have been effectively treated with ciprofloxacin.

Prevention

Individuals in endemic areas should wear gloves when gardening to prevent exposure to oocysts of *C. cayetanensis.* Thorough washing of produce may help remove oocysts. Most of the produce items implicated in the transmission of *C. cayetanensis* are consumed raw; thus cooking as a means of prevention is not relevant.

Cystoisospora belli

General Characteristics

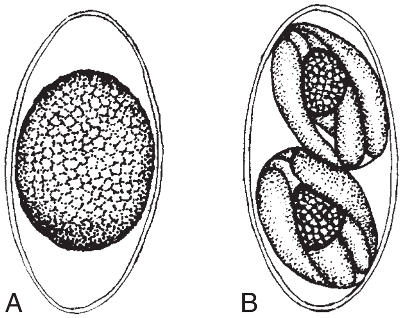
Although *Cystoisospora belli* is found worldwide, certain tropical areas in the Western Hemisphere have specific locations where endemic infections occur. These organisms infect both adults and children, and intestinal involvement and symptoms are generally transient unless the patient is immunocompromised. *C. belli* has also been implicated in traveler's diarrhea. However, unlike with *Cryptosporidium* spp. and *C. cayetanensis,* large outbreaks have not been reported (Table 47.6).

C. belli oocysts are passed in the stool. They are long and oval, measuring 20 to 33 µm long by 10 to 19 µm wide. Usually the oocyst contains one immature **sporont,** but two may be present. Continued development occurs outside the body, with the development of two mature **sporocysts,** each containing four sporozoites, which can be recovered from the fecal specimen. The sporulated oocyst is the infective stage that excysts in the small intestine, releasing the sporozoites, which penetrate the mucosal cells and initiate the life cycle.

Epidemiology

C. belli oocysts are passed in the feces unsporulated or partially sporulated (Fig. 47.31). Oocysts complete sporulation within 72 hours, although it may take longer, depending on the temperature. The time required for unsporulated oocysts to appear in the feces after ingestion of sporulated oocysts is 9 to 17 days. Oocyst shedding is variable and depends on the immune status of the infected individual. Oocysts can be found for 30 to 50 days in immunocompetent patients, and immunosuppressed patients may continue to shed oocysts for 6 months or longer. Chronic infections can occur, and oocysts can be shed for months to years. In one particular case, an immunocompetent individual had symptoms for 26 years, and *C. belli* was recovered in stool a number of times over 10 years.

C. belli is thought to be the only species of *Cystoisospora* that infects humans, and no other reservoir hosts are recognized for this infection. However, *C. belli* sporozoites can become dormant as a single-organism-containing tissue cyst in the lymph nodes, liver, or spleen. The existence of these monozoic tissue cysts indicates there may be an unknown transport (paratenic) host in the life cycle of the organism. Transmission occurs through ingestion of water or food contaminated with mature, sporulated oocysts and possibly from the ingestion of tissue from the unknown paratenic host. Sexual transmission by direct oral contact with the anus or perineum also occurs, although this mode of transmission is probably much less common. The oocysts are very resistant to environmental conditions and may remain viable for months if kept cool and moist; oocysts usually mature within 48 hours after stool passage and are then infectious.



• **Fig. 47.31** (A) Immature oocyst of *Cystoisospora belli*. (B) Mature oocyst of *C. belli*. (Illustration by Nobuko Kitamura.)

Pathogenesis and Spectrum of Disease

Symptoms include diarrhea (most common), weight loss, abdominal colic, and fever. Stools (usually 6 to 10 per day) are watery to soft, foamy, and offensive smelling, suggesting a malabsorption process. Many patients have eosinophilia, recurrences are quite common, and the disease is more severe in infants and young children.

Patients who are immunosuppressed, particularly those with AIDS, often present with profuse diarrhea associated with weakness, anorexia, and weight loss. Biopsies reveal an abnormal mucosa with short villi, hypertrophied crypts, and infiltration of the lamina propria with eosinophils, neutrophils, and round cells. Physicians should consider *C. belli* in AIDS patients with diarrhea who have immigrated from or traveled to Latin America, are Hispanics born in the United States, are young adults, or who have not received prophylaxis with TMP-SMX for *Pneumocystis* infection. It has also been recommended that patients with AIDS traveling to Latin America and other developing countries be advised of the waterborne and foodborne transmission of *C. belli* and that chemoprophylaxis should be considered.

Extraintestinal infections in immunocompromised patients have been reported. At autopsy, microscopic findings associated with *C. belli* infection were seen in the lymph nodes and walls of the small and large intestines, mesenteric and mediastinal lymph nodes, lymphatic channels, liver, and spleen. *C. belli* infections in the gallbladder epithelium and endometrial epithelium have also been reported, and oocysts have been recovered in bile specimens.

Laboratory Diagnosis

Examination of fresh material, either as a direct wet prep or as concentrated material, is recommended, rather than a permanent stained smear. The oocysts are very pale and transparent and can easily be overlooked. The light level of the microscope should be reduced, and additional contrast through staining may be required for optimal visualization. On the permanent stained smear, the organisms may take up excess stain and resemble helminth eggs or artifacts.

It is possible to have a positive biopsy specimen but not recover the oocysts in the stool because of the small numbers of organisms present. The oocysts are acid-fast and can also be demonstrated by using auramine rhodamine stains. Organisms tentatively identified using auramine rhodamine stains should be confirmed by wet prep examination or acid-fast stains, particularly if the stool contains other cells or excess artifact material (more normal stool consistency).

Nucleic Acid Detection

Currently, there are no commercially available nucleic acid–based methods for the detection of *C. belli.* However, PCR assays have been developed for the detection of the organism in stool samples.

Histology

Developmental stages of *C. belli* have been reported for intestinal biopsy specimens of the duodenum, jejunum, and occasionally ileum. Intestinal development tends to occur in epithelial cells, although developing stages are occasionally reported from the lamina propria or submucosa. Extraintestinal infections in immunocompromised patients have been reported; the organisms become dormant as cysts in a variety of tissues, including the intestine, mesenteric lymph nodes, liver, and spleen; these cysts are called monozoic tissue **cysts**. In histologic sections, these cysts are thick-walled and measure 12 to 22 µm × 8 to 10 µm, and each contains a single dormant sporozoite or merozoite of about 8 to 10 µm × 5 µm. As immunity declines, these cysts can reactivate patient infections.

Results and Reporting

C. belli is typically easily identified in human stool specimens. Quantitation is not required. If a negative result is indicated, it is important to note that three samples have been examined before a negative is reported.

Therapy

The drug of choice to treat *C. belli* infection is TMP-SMX, which is given two to four times a day for 10 to 14 days. With this approach, the parasites are eliminated, the diarrhea stops, and the abdominal pain decreases within a few days. There is no standardized treatment for patients who are allergic or cannot tolerate sulfonamides. Pyrimethamine has been used as an effective alternate treatment.

Prevention

Because transmission occurs through the infective oocysts, prevention includes improved personal hygiene measures and sanitary conditions to eliminate possible fecal-oral transmission from contaminated food, water, and possibly environmental surfaces.

Sarcocystis spp.

General Characteristics

Two well-described *Sarcocystis* spp. include *Sarcocystis hominis* and *Sarcocystis suihominis*. Humans are the definitive host for both species, and the intermediate hosts are either cattle (*S. hominis*) or pigs (*S. suihominis*). When uncooked meat from these infected animals is ingested by humans, **gamogony** (fission resulting in the production of sporozoan gametes) can occur in the intestinal cells, with eventual production of the sporocysts in stool.

Sarcocystis spp. have an obligatory two-host life cycle. Intermediate hosts (herbivores and omnivores) become infected through ingestion of sporocysts excreted in the feces of the definitive hosts (carnivores and omnivores). The definitive hosts become infected through ingestion of mature cysts found in the muscles of the intermediate hosts. In some intermediate hosts, such as cattle and sheep, all adult animals may be infected. Extraintestinal human sarcocystosis is rare, with a much lower incidence than is seen with the intestinal infection. Humans who have ingested meat containing the mature sarcocysts serve as the definitive hosts. Fever, severe diarrhea, abdominal pain, and weight loss have been reported in immunocompromised hosts, although the number of patients with these symptoms has been quite small.

The sporocysts found in the stool are broadly oval and slightly tapered at the ends. They measure 9 to 16 µm long and contain four mature sporozoites and the **residual body** (Table 47.6). Normally, the oocyst contains two sporocysts (similar to *C. belli*); however, in *Sarcocystis* infections, the sporocysts are released from the oocyst and normally are seen singly. These sporocysts tend to be larger than *Cryptosporidium* oocysts that contain four sporozoites. The oocysts are fully sporulated when passed in the stool.

Pathogenesis and Spectrum of Disease

When humans (intermediate host) ingest oocysts from other animal stool sources, the **sarcocysts** that develop in human muscle are 7 to 16 µm long and cause few, if any, problems. No inflammatory response to these organisms occurs in the muscle, and no evidence of pathogenicity is seen. Patients demonstrate symptoms related to the disintegration of the sarcocysts and death of **intracystic bradyzoites.** Painful muscle swellings measuring 1 to 3 cm in diameter are associated with erythema of the overlying skin; these occur periodically and last 2 days to 2 weeks. Symptoms also include fever, diffuse myalgia, muscle tenderness, weakness, eosinophilia, and bronchospasm. Different types of skeletal and cardiac muscle sarcocysts have been found in humans. No specific therapy is required for this type of infection. Corticosteroids can reduce allergic inflammatory reactions.

Infections in humans can manifest primarily as intestinal disease if infected meat is ingested or as muscular disease if sporocysts are ingested. Intestinal disease occurs within a few hours after consumption of infected meat and is characterized by nausea, abdominal pain, and diarrhea. However, in both situations patients may be infected and asymptomatic.

Laboratory Diagnosis

A presumptive diagnosis of intestinal disease may be based on the patient's symptoms, particularly with documented ingestion of raw or poorly cooked meat. Confirmation of the diagnosis may depend on finding human fecal specimens containing sporocysts, which are passed in the stool 11 to 18 days after ingestion of beef or pork. Sporocysts of the two *Sarcocystis* spp. are very difficult to differentiate.

A muscle biopsy is appropriate for suspected symptomatic intramuscular infection in a patient with a history of travel to or residence in a tropical location. Sarcocysts in biopsy specimens can be identified by microscopy on routine histologic sections stained with hematoxylin and eosin. Most sarcocysts in humans have been found in skeletal and cardiac muscle; however, muscles in the larynx, pharynx, and upper esophagus have also been involved.

Nucleic Acid Detection

No molecular assays are currently available for the detection of sarcocystis in humans. Laboratory developed tests have used PCR to detect *Sarcocystis* spp. DNA in human stool and muscle biopsy tissue.

Results and Reporting

Identification of *Sarcocystis* spp. is very rare. However, it is not possible to differentiate the two species based on morphologic characteristics of the sporocysts. It is recommended that potential identification be confirmed by a reference laboratory and should be included in the final patient report.

Therapy

No known treatment or prophylaxis is available for intestinal infection, myositis, vasculitis, or related lesions caused by human sarcocystosis. Supportive therapy for patients with severe diarrhea is indicated. It is also unclear whether immunosuppressives are effective at reducing the inflammatory reactions seen in vasculitis or myositis. Without more definitive data, no course of therapy can be recommended.

Prevention

Cooking meat to an internal temperature higher than 67°C kills *Toxoplasma gondii* tissue cysts in meat; this temperature should also kill *Sarcocystis* tissue cysts in meat. Preventing cattle, buffalo, and swine from consuming human feces shedding infective oocysts also prevents animal infection. Most cases of human muscular *Sarcocystis* infection have been reported from the Far East. When humans are intermediate hosts, preventive measures involve careful disposal of animal feces that may contain the infective sporocysts. This may be impossible in wilderness areas, where wild animals may serve as reservoir hosts for many *Sarcocystis* spp.

Microsporidia

Microsporidia are obligate intracellular, spore-forming parasites. More than 200 microsporidial genera and 1500 species have been identified. Nine genera (*Anncaliia, Encephalitozoon, Endoreticulatus, Enterocytozoon, Nosema, Pleistophora, Vittaforma, Tubulinosema,* and *Trachipleistophora*) and unclassified microsporidia *(Microsporidium)* have been identified as causing human infections.

Although the microsporidia are true eukaryotes, they also have molecular and cytologic characteristics of prokaryotes. Microsporidia evolved from the fungi. Features shared with fungi include the presence of chitin and trehalose, similarities in cell cycles, and certain gene organizations. Microsporidia are considered highly derived fungi that underwent genetic and functional losses, resulting in one of the smallest eukaryotic genomes known. However, the life cycle of microsporidia is unique and unlike that of any fungal species. At this point, clinical and diagnostic issues and responsibilities often remain with the parasitologists.

General Characteristics

Human microsporidial infections have been documented worldwide. The spore, the only life cycle stage able to survive outside the host cell, is the infective stage (Fig. 47.32 and Table 47.7). Infection occurs with ingestion or inhalation of the infective spores, from which the infective **sporoplasm** (spore protoplasm) enters the host cell through the **polar tubule** (Fig. 47.33). The microsporidia multiply extensively in the host cell cytoplasm; the life cycle includes repeated divisions by binary fission (merogony) or multiple fission (schizogony) and spore production (sporogony). Both merogony and sporogony can occur in the same cell at the same time. During sporogony, a thick spore wall is formed, providing environmental protection for the spore.

Microsporidial spores measure 0.7 to about 4 μm in diameter. Mature spores contain a tubular extrusion apparatus (polar tube or tubule) for injecting infective spore contents (sporoplasm) into the host cell.

Epidemiology

Transmission possibilities include human-to-human and animal-to-human routes. Many questions relating to reservoir hosts and possible congenital infections are still unanswered. Primary infection occurs through inhalation or ingestion of spores from environmental sources or by zoonotic transmission. The presence of *Encephalitozoon intestinalis* has been confirmed in tertiary sewage effluent, surface water, and groundwater; *Enterocytozoon bieneusi* has been confirmed in surface water; and *Vittaforma corneae* has been confirmed in tertiary effluent. Ingestion or inhalation of the environmentally highly resistant spores is probably the normal mode of transmission. Direct contact with contaminated water or other infected animals including humans may also serve as a route of transmission.

E. bieneusi, an intestinal pathogen, serves as an example of infection potential. The spores are released into the intestinal lumen and are passed in the stool (Fig. 47.34). These spores are environmentally resistant and can be ingested by other hosts. Zoonotic transmission of microsporidia infecting humans has not been verified.

Pathogenesis and Spectrum of Disease

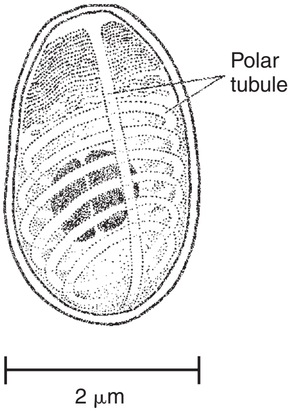
Microsporidia were recognized as causing disease in animals as early as the 1920s but were not recognized as agents of human disease until the AIDS pandemic began in the mid-1980s.

Enterocytozoon bieneusi

A number of cases of *E. bieneusi* infection have been reported in patients with AIDS. Chronic intractable diarrhea, fever, malaise, and weight loss are symptoms of *E. bieneusi* infections, and these symptoms mimic those seen with cryptosporidiosis or isosporiasis. Often these patients have four to eight watery, nonbloody stools each day, accompanied by nausea and anorexia. Dehydration and D-xylose and fat malabsorption also may develop. These patients tend to be severely immunodeficient, with a CD4+ count usually below 200 cells/mm^3 and often below 100 cells/mm^3. Mixed infections with *E. bieneusi* and *E. intestinalis* have been reported. *E. bieneusi* infection has been implicated in AIDS-related sclerosing cholangitis. However, demonstration of *E. bieneusi* spores in extraepithelial tissues does not always appear to be associated with subsequent development of systemic infection.

E. bieneusi spores have been identified in sputum and bronchoalveolar lavage fluid in addition to stool specimens. *E. bieneusi* can colonize the respiratory tract, and clinical specimens from these sources may reveal the presence of spores. Multiorgan microsporidiosis caused by *E. bieneusi* has been diagnosed in patients infected with HIV; organisms have been recovered in stools, duodenal biopsy specimens, nasal discharge, and sputum.

Infection with *E. bieneusi* has been reported in immunocompetent individuals; symptoms were self-limited, and diarrheal disease resolved within 2 weeks. *E. bieneusi* may be more commonly associated with sporadic diarrheal disease than was previously suspected, and the immune system may play a role in the control of this intestinal infection. It is possible that *E. bieneusi* may persist as an asymptomatic infection in immunocompetent individuals.



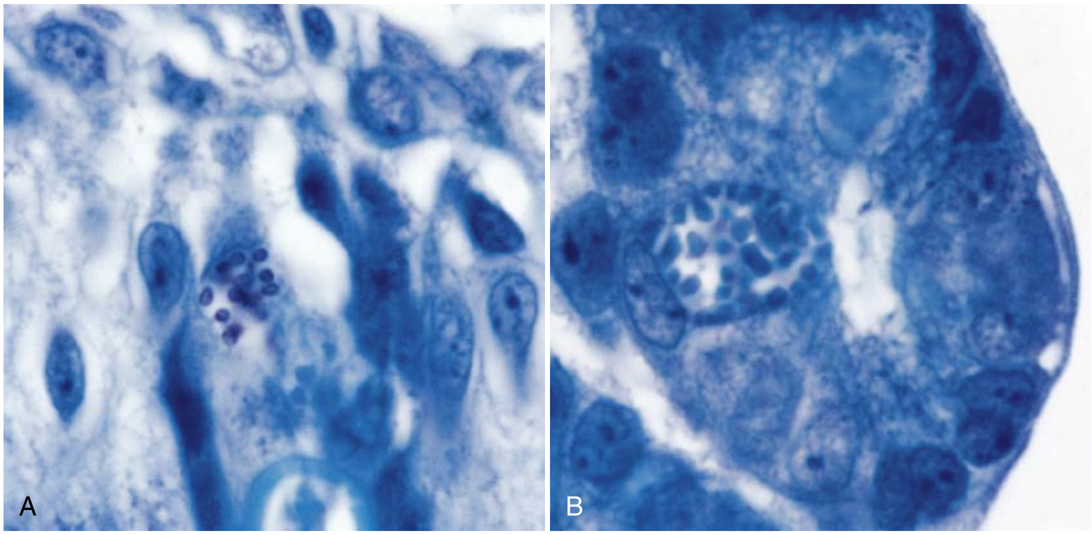
• Fig. 47.33 Diagram illustrating the polar tubule in a microsporidian spore.

Encephalitozoon spp.

Both *Encephalitozoon cuniculi* and *Encephalitozoon hellem* have been isolated from human infections. The spectrum of disease in patients with AIDS, organ transplant recipients, and otherwise immunocompromised patients includes keratoconjunctivitis, intraocular infection, sinusitis, bronchiolitis, pneumonitis, nephritis, ureteritis, cystitis, prostatitis, urethritis, hepatitis, sclerosing cholangitis, peritonitis, diarrhea, and encephalitis. Clinical manifestations may vary, ranging from an asymptomatic carrier state to organ failure.

Encephalitozoon intestinalis

Encephalitozoon intestinalis infects primarily small intestinal enterocytes, but infection does not remain



• Fig. 47.34 Routine histology micrograph of microsporidian spores in enterocytes (Giemsa stain). (A) Note the fully formed spores. (B) These spores are not fully mature.

confined to epithelial cells. *E. intestinalis* is also found in lamina propria macrophages, fibroblasts, and endothelial cells. Dissemination to the kidneys, lower airways, and biliary tract appears to occur through infected macrophages. Fortunately, these infections tend to respond to therapy with albendazole, unlike infections caused by *E. bieneusi.*

Other Microsporidia

Different microsporidial species have been isolated from immunocompetent individuals who presented with keratoconjunctivitis, severe keratitis, or corneal ulcers. In addition, keratoconjunctivitis has been found in an immunocompetent contact lens wearer.

In immunocompromised patients, myositis has been seen in infections caused by *Pleistophora* spp., *Pleistophora ronneafiei, Trichomonas hominis, Anncaliia vesicularum,* and *Anncaliia algerae. Trachipleistophora anthropophthera* has been identified in cerebral, cardiac, renal, pancreatic, thyroid, hepatic, splenic, lymphoid, and bone marrow tissue. Disseminated infection caused by *Anncaliia connori* has also been identified.

Laboratory Diagnosis

The most commonly used stains are chromotrope-based stains (modified trichrome) and chemofluorescent optical brightening agents, including calcofluor white and other chemofluorescent stains. Regardless of the staining technique selected, the use of positive control material is highly recommended. Detection of the small microsporidial spores requires adequate illumination and magnification (i.e., magnification using the oil immersion objective [×100] for a total magnification of ×1000). Microsporidial spores may be identified in a variety of specimens including unconcentrated stool, body fluids (duodenal aspirates, bile, biliary aspirates, urine, bronchoalveolar lavage, cerebral spinal fluid, sputum, and nasal discharge), conjunctival specimens, and corneal scrapings.

Antigen Detection

Antigen detection tests have been developed, but the reagents are not widely available commercially.

Antibody Detection

Although the detection of antibody using a number of methods has been documented, cross-reactivity among the genera may occur. Currently, this approach is not commonly used.

Nucleic Acid Detection

Molecular techniques have been quite successful in identifying a number of the microsporidia; however, this approach is not yet widely used in clinical laboratories. These laboratory-developed tests include PCR, real-time PCR, loop-mediated isothermal amplification technique (LAMP), and *in situ* hybridization for tissue biopsies. These tests can be universal panmicrosporidian or genus and species–specific assays.

Histology

Microsporidia do not tend to stain predictably, if at all, in tissues. However, spores occasionally can be seen very well with use of the PAS stain, silver stains, or acid-fast stains. Modified Gram stains also have proved sensitive. The spore has a small, PAS-positive posterior body; the spore coat stains with silver, and the spores are acid-fast variable. Tissue examination by EM techniques is still considered the best approach for differentiation of genera; however, this option is not available to all laboratories, and the sensitivity of EM may not be equal to that of other methods when examining stool or urine.

Results and Reporting

Immunocompetent patients may not produce significant numbers of microsporidia for identification. However, as a predominantly opportunistic pathogen in immunocompromised patients, stool examination along with additional body fluid or tissue specimens should be performed to properly assess the patient's condition if a microsporidia infection is suspected.

Therapy

Albendazole therapy can result in clinical cure of HIV-associated infection with *Encephalitozoon* spp., along with elimination of spore shedding. Albendazole is not effective for *Enterocytozoon* infections, although clinical improvement occurs in some patients. Oral purified fumagillin, nikkomycin Z, and fluoroquinolones have been shown to inhibit sporulation and eradicate *E. bieneusi* and *Vittaforma.* Antiretroviral combination therapy results in complete clinical response with elimination of intestinal microsporidia.

Prevention

The presence of infective spores in human clinical specimens suggests that taking precautions when handling body fluids and following personal hygiene measures, such as hand washing, may be important in preventing primary infections in the health care setting. However, the establishment of comprehensive guidelines for disease prevention requires more definitive information about sources of infection and modes of transmission.

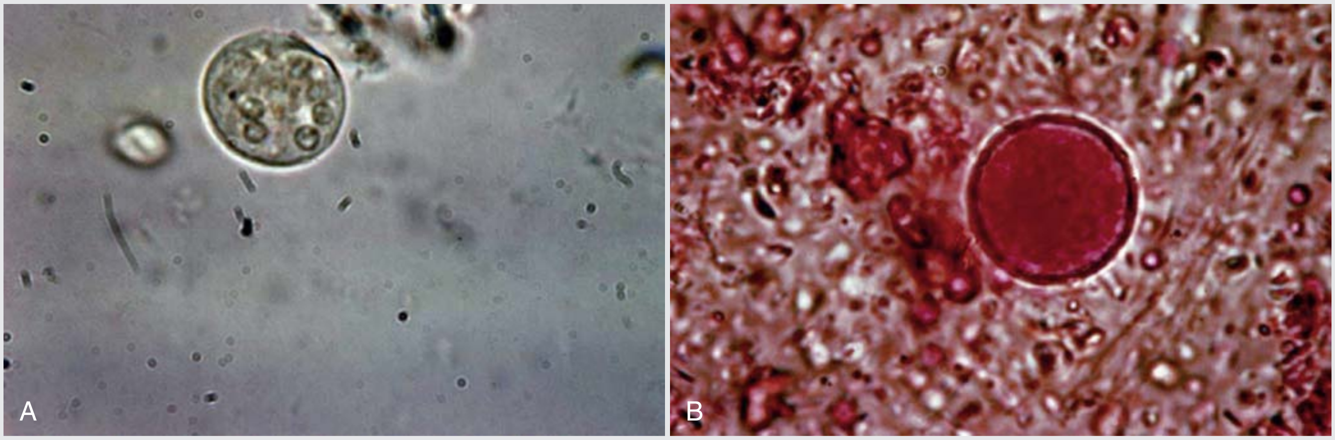
CASE STUDY 47.1

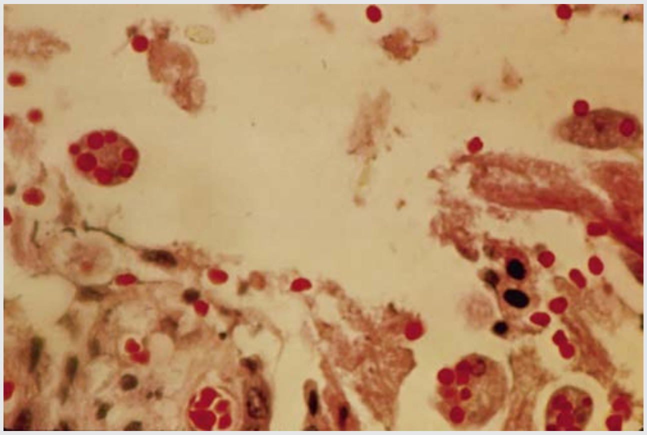
A 34-year-old male presents to the emergency department with crampy abdominal pain and bloody diarrhea. The patient states that the symptoms have come and gone over approximately 14 days. During that time, he also has experienced a significant weight loss (approximately 6 pounds). Stool specimens are collected for routine ova and parasite (O&P) examination. Two cysts are identified in the samples (Fig. 47.35). In addition, during the physical examination, the physician discovers a small rectal lesion. The biopsy specimen (Fig. 47.36) indicates the presence of a significant parasite.

Questions

1. What technique or techniques may be used to identify the infecting organism definitively?
2. The cysts identified in the stool specimens represent two species. What are the organisms and should the mixed infection cause any significant concern?
3. What treatment would be recommended for this individual?



• **Fig. 47.35** (A and B) Cysts identified in stool specimens. (Courtesy Dr. Henry Travers, Sioux Falls, SD.)



• **Fig. 47.36** Rectal biopsy. (Courtesy Dr. Henry Travers, Sioux Falls, SD.)

Chapter Review

1. Which of the following is the best technique for identifying *Dientamoeba fragilis* in stool?
   - **a.** Formalin concentrate
   - **b.** Trichrome-stained smear
   - **c.** Modified acid-fast–stained smear
   - **d.** Giemsa stain
   - **e.** Fluorescent stain
2. Which of the following protozoan organisms has been widely implicated in waterborne and foodborne outbreaks in the United States?
   - **a.** *Pentatrichomonas hominis*
   - **b.** *Dientamoeba fragilis*
   - **c.** *Giardia duodenalis*
   - **d.** *Neobalantidium coli*
   - **e.** *Entamoeba coli*
3. An *Entamoeba histolytica* trophozoite has which characteristics?
   - **a.** Central karyosome in the nucleus and clear pseudopodia
   - **b.** Ingested RBCs, clear pseudopodia, and uneven chromatin on the nuclear membrane
   - **c.** Ingested RBCs, clear pseudopodia, and large glycogen vacuoles in the cytoplasm
   - **d.** Large blotlike karyosome, ingested white blood cells (WBCs), and granular pseudopods
   - **e.** Uneven karyosome, no peripheral chromatin, granular pseudopods
4. *Entamoeba dispar* is most easily confused morphologically with:
   - **a.** *Entamoeba coli*
   - **b.** *Entamoeba hartmanni*
   - **c.** *Dientamoeba fragilis*
   - **d.** *Entamoeba histolytica*
   - **e.** *Blastocystis* spp.
5. **True or False**

_____ Microsporidia can cause intestinal symptoms and disease in other tissues, particularly in immunocompromised patients.

_____ Oocysts of *Cryptosporidium* spp. can be detected in stool specimens using the modified acid-fast stain.

_____ Fecal immunoassays for antigen detection have become more commonly used to diagnose infections with *Dientamoeba fragilis* and *Blastocystis* spp.

_____ In the United States, sporadic mini-outbreaks of diarrheal disease have been associated with the ingestion of strawberries, raspberries, fresh basil, mesclun (baby lettuce leaves), and snow peas. The most likely causative agent is *Cryptosporidium* spp.

_____ Although the pathogenicity of *Blastocystis* spp. has been controversial, newer information suggests that numerous strains and species are included in the name, some of which are pathogenic and some nonpathogenic.

6. **Matching:** *Match each term with the correct description.*

_____ ova and parasite examination
_____ *Dientamoeba fragilis*
_____ *Entamoeba histolytica*
_____ *Giardia duodenalis*
_____ Microsporidia
_____ *Cryptosporidium*
_____ fecal immunoassays
_____ *Neobalantidium coli*
_____ *Entamoeba dispar*
_____ *Blastocystis* spp.

a. used for *Giardia, Cryptosporidium* spp.
b. immunocompromised patients
c. immediately infective oocysts
d. waterborne; traveler's diarrhea
e. nonpathogenic ameba
f. rare in the United States
g. routine examination of stool
h. most common intestinal parasite
i. cause of amebiasis
j. cyst and precystic form

Blood and Tissue Protozoa

OBJECTIVES

1. Explain the general life cycle of *Plasmodium* spp., including both asexual and sexual stages, exoerythrocytic and erythrocytic cycle trophozoites, schizonts, hypnozoites, merozoites, gametocytes, and sporozoites.
2. Describe the distinguishing morphologic characteristics, clinical disease, vectors, stages of infectivity, and laboratory diagnosis for *Plasmodium* spp., *Babesia* spp., and *Trypanosoma* and *Leishmania* spp.
3. Define paroxysm in malarial periodicity.
4. Compare and contrast recrudescence and relapse, including the physiologic basis for each during infection with malaria.
5. Compare and contrast the pathogenesis of infections with *Plasmodium falciparum, Plasmodium malariae, Plasmodium ovale, Plasmodium vivax,* and *Plasmodium knowlesi,* including variation in signs and symptoms.
6. Differentiate intracellular forms of *Babesia* spp. from *Plasmodium* spp.
7. Define and describe the life cycle stages of *Trypanosoma* and *Leishmania* spp., including amastigotes, promastigotes, trypomastigotes, epimastigotes, and metacyclic trypanosome forms when appropriate.
8. Compare and contrast the efficacy of various detection and diagnostic methods for blood and tissue parasites.

PARASITES TO BE CONSIDERED

Protozoa

Sporozoa, Flagellates (Blood, Tissue)
Sporozoa (Malaria and Babesiosis)

- *Plasmodium vivax*
- *Plasmodium ovale*
- *Plasmodium malariae*
- *Plasmodium falciparum*
- *Plasmodium knowlesi*
- *Babesia* spp.

Flagellates (Leishmaniae, Trypanosomes)

- *Leishmania tropica* complex
- *Leishmania major* complex
- *Leishmania mexicana* complex
- *Leishmania braziliensis* complex
- *Leishmania donovani* complex
- *Leishmania enrietti* complex
- *Leishmania guyanensis* complex
- *Leishmania peruviana*
- *Trypanosoma brucei gambiense*
- *Trypanosoma brucei rhodesiense*
- *Trypanosoma cruzi*
- *Trypanosoma rangeli*

Plasmodium spp.

Malaria has been well documented as an ancient disease in Egyptian and Chinese writing beginning in 2700 BCE. By 200 BCE, malaria was identified in Rome; it spread throughout Europe during the 12th century and arrived in England by the 14th century. By the early 1800s, malaria was found worldwide.

Malaria has played a tremendous role in world history, influencing the outcome of wars, the movement of populations, and the development and decline of various nations. Before the American Civil War, malaria was found as far north as southern Canada, but it was no longer endemic within the United States by the 1950s.

In 2018, the World Health Organization (WHO) estimated that 228 million individuals worldwide were infected with *Plasmodium* spp. As many as 405,000 people die each year of malaria, more than 67% (272,000) of whom are children. This is a significant decrease from previous years in part due to better access to testing and treatment, as well as improvements in prevention and surveillance, but we still have a long way to go. Approximately 1700 cases of malaria are diagnosed in the United States each year, primarily from individuals who traveled to endemic areas. Malaria is endemic in more than 90 countries, impacting a population of 2400 million people, representing 40% of the world's population. More than 90% of deaths caused by malaria occur in Africa, and another 5% occur in Southeast Asia. *Plasmodium falciparum* is the major species associated with deadly infections throughout the world. Unfortunately, prevention remains a complex problem, and no drug is universally effective for all *Plasmodium* species.

There are approximately 250 species of *Plasmodium.* However, only five species infect humans. Of the species that cause human disease, *Plasmodium vivax* and *P. falciparum* cause 95% of infections. *P. vivax* may be responsible for 80% of the remaining infections, because this species has the widest distribution in the tropics, subtropics, and temperate zones. *P. falciparum* is generally confined to the tropics, *Plasmodium malariae* is sporadically distributed, and *Plasmodium ovale* is confined mainly to central West Africa and some South Pacific islands. The fifth human malaria, *Plasmodium knowlesi,* a malaria parasite of long-tailed macaque monkeys, has been confirmed in human cases from Malaysian Borneo, Thailand, Myanmar, and the Philippines.

• **Fig. 48.1** Life cycle of *Plasmodium*. (Courtesy Division of Parasitic Diseases/Centers for Disease Control and Prevention.)

The vector for malaria is the female *Anopheles* mosquito. When the vector takes a blood meal, **sporozoites** contained in the salivary glands of the mosquito are discharged into the puncture wound (Fig. 48.1). Within an hour, these infective sporozoites are carried via the blood to the liver, where they penetrate hepatocytes and begin to grow, initiating the **preerythrocytic** or **primary exoerythrocytic** cycle. The sporozoites become round or oval and begin dividing repeatedly. **Schizogony** results in large numbers of exoerythrocytic **merozoites.** Once these merozoites leave the liver, they invade the red blood cells (RBCs), initiating the **erythrocytic cycle.** A dormant schizogony may occur in *P. vivax* and *P. ovale* organisms, which remain quiescent in the liver. These resting stages are known as **hypnozoites** and lead to a true relapse, often within 1 year or up to more than 5 years later. Delayed schizogony does not occur in *P. falciparum, P. malariae,* or *P. knowlesi.*

Once the RBCs and reticulocytes have been invaded, the parasites grow and feed on hemoglobin and other proteins inside the cells. Within the RBC, the merozoite (or young trophozoite) is vacuolated, ring-shaped, more or less amoeboid, and uninucleate. The excess protein and hematin present from the metabolism of hemoglobin combine to form malarial pigment. Once the nucleus begins to divide, the trophozoite is called a developing **schizont.** The mature schizont contains merozoites (the number depends on the species), which are released into the bloodstream. Many of the merozoites are destroyed by the immune system, but others invade RBCs and initiate a new cycle of **erythrocytic schizogony.** After several erythrocytic generations, some of the merozoites begin to undergo development into the male and female **gametocytes.**

Although malaria is often associated with travelers to endemic areas, other situations resulting in infection include blood transfusions, use of contaminated hypodermic needles, bone marrow transplantation, congenital infection, and transmission within the United States by indigenous mosquitoes that acquired the parasites from imported infections.

Plasmodium vivax (Benign Tertian Malaria)

General Characteristics

P. vivax infects only the reticulocytes; thus the parasitemia is limited to approximately 2% to 5% of the available RBCs in an otherwise healthy host (Tables 48.1–48.3 and Figs. 48.2–48.4 during the first few weeks of infection. The spleen will

TABLE 48.1 ***Plasmodium* spp.: Clinical Characteristics of the Five Human Infections**

Infection	Incubation Period	Prodromal Symptoms Severity Initial Fever Pattern	Symptom Periodicity	Initial Paroxysm Severity Mean Duration	Duration of Untreated Primary Attack	Duration of Untreated Infection	Parasitemia Limitations	Anemia	CNS Involvement	Nephrotic Syndrome
Plasmodium vivax	8–17 days	Mild to moderate Irregular (48 h)	48 h	Moderate to severe 10 h	3–8+weeks	5–7 years	Young RBCs	Mild to moderate	Rare	Possible
Plasmodium ovale	10–17 days	Mild Irregular (48 h)	48 h	Mild 10 h	2–3 weeks	12 months	Young RBCs	Mild	Possible	Rare
Plasmodium malariae	18–40 days	Mild to moderate Regular (72 h)	72 h	Moderate to severe 11 h	3–24 weeks	20+ years	Old RBCs	Mild to moderate	Rare	Very common
Plasmodium falciparum	8–11 days	Mild Continuous remittent	36–48 h	Severe 16–36 h	2–3 weeks	6–17 months	All RBCs	Severe	Very common	Rare
Plasmodium knowlesi	9–12 days	Mild to moderate Regular (24 h)	24–27 h	Moderate to severe Not available	Not available	Not available	All RBCs	Moderate to severe	Possible	Probably common
Comments	All may be extended for months to years.	All may mimic influenza symptoms. Early symptoms may reflect lack of regular periodicity.		*P. knowlesi* can be as dangerous as *P. falciparum.*				*P. knowlesi* can be as dangerous as *P. falciparum.*

TABLE 48.2

Plasmodia in Giemsa-Stained Thin Blood Smears

	Persistence of Exoerythrocytic Cycle	Relapses	Time of Cycle	Appearance of Parasitized RBCs; Size and Shape	Schüffner Dots (Eosinophilic Stippling)	Color of Cytoplasm	Multiple Rings/Cell	All Developmental Stages Present in Peripheral Blood	Appearance of Parasite; Young Trophozoite (Early Ring Form)
Plasmodium vivax	Yes	Yes	44–48 h	1.5–2 times larger than normal; oval to normal; may be normal size until ring fills half of cell.	Usually present in all cells except early ring forms.	Decolorized, pale	Occasional	All stages present	Ring is ⅓ diameter of cell, cytoplasmic circle around vacuole; heavy chromatin dot.
Plasmodium malariae	No	No, but long-term recrudescence is recognized	72 h	Normal shape; size may be normal or slightly smaller.	None	Normal	Rare	Few ring forms, because ring stage is brief; mostly growing and mature trophozoites and schizonts	Ring often smaller than in *P. vivax,* occupying ⅛ of cell; heavy chromatin dot; vacuole at times "filled in"; pigment forms early.
Plasmodium falciparum	No	No long-term relapses	36–48 h	Both normal.	None; occasionally comma-like red dots are present (Maurer dots).	Normal, bluish tinge at times	Common	Young ring forms and no older stages; few gametocytes	Delicate, small ring with small chromatin dot (often 2); scanty cytoplasm around small vacuoles; sometimes at edge of red cell (appliqué form) or filamentous slender form; may have multiple rings per cell.
Plasmodium ovale	Yes	Possible, but usually spontaneous recovery	48 h	60% of cells larger than normal and oval; 20% have irregular, frayed edges.	Present in all stages including early ring forms; dots may be larger and darker than in *P. vivax*.	Decolorized, pale	Occasional	All stages present	Ring is larger and more amoeboid than in *P. vivax*; otherwise similar to *P. vivax*.
Plasmodium knowlesi	No	No	24 h	Normal shape, size.	No true stippling; occasional faint dots.	Normal	Common	All stages present	Rings ⅓ to ½ diameter of RBC; double chromatin dots; appliqué forms rare; multiple rings per RBC.

RBC, Red blood cell.

This pa

Growing Trophozoite	Mature Trophozoite	Schizont (Presegmenter)	Mature Schizont	Macrogametocyte	Microgametocyte	Main Criteria
Multishaped irregular amoeboid parasite; streamers of cytoplasm close to large chromatin dot; vacuole retained until close to maturity; increasing amounts of brown pigment.	Irregular amoeboid mass; 1 or more small vacuoles retained until schizont stage; fills almost entire cell; fine brown pigment.	Progressive chromatin division; cytoplasmic bands containing clumps of brown pigment.	16 (12–24) merozoites, each with chromatin and cytoplasm, filling entire red cell, which can hardly be seen	Rounded or oval homogeneous cytoplasm; diffuse delicate light brown pigment throughout parasite; eccentric compact chromatin	Large pink to purple chromatin mass surrounded by pale or colorless halo; evenly distributed pigment	Large pale red cell; trophozoite irregular; pigment usually present; Schüffner dots not always present; several phases of growth seen in one smear; gametocytes appear as early as third day.
Nonamoeboid rounded or band-shaped solid forms; chromatin may be hidden by coarse dark brown pigment.	Vacuoles disappear early; cytoplasm compact, oval, band shaped, or nearly round and almost filling cell; chromatin may be hidden by peripheral coarse dark brown pigment.	Similar to *P. vivax* except smaller; darker, larger pigment granules, peripheral or central.	8 (6–12) merozoites in rosettes or irregular clusters filling normal-sized cells, which can hardly be seen; central arrangement of brown-green pigment	Similar to *P. vivax,* but fewer in number; pigment darker and more coarse	Similar to *P. vivax,* but fewer in number; pigment darker and more coarse	Red cell normal in size and color; trophozoites compact, stain usually intense, band forms not always seen; coarse pigment; no stippling of red cells; gametocytes appear after a few weeks.
Heavy ring forms; fine pigment grains.	Not seen in peripheral blood (except in severe infections); development of all phases after ring form occurs in capillaries of viscera.	Not seen in peripheral blood (see previous entries).	Not seen in peripheral blood	Gender differentiation difficult; “crescent” or “sausage” shapes characteristic; may appear in “showers” with black pigment near chromatin dot, which is often central	Same as macrogametocyte (described in previous entries)	Development after ring stage takes place in blood vessels of internal organs; delicate ring forms and crescent-shaped gametocytes are only forms normally seen in peripheral blood; gametocytes appear after 7–10 days.
Ring shape maintained until late in development; nonamoeboid compared with *P. vivax*.	Compact; vacuoles disappear; pigment dark brown, less than in *P. malariae*.	Smaller and more compact than *P. vivax*.	¾ of cells occupied by 8 (8–12) merozoites in rosettes or irregular clusters	Smaller than *P. vivax*	Smaller than *P. vivax*	Red cell enlarged, oval, with fimbriated edges; Schüffner dots seen in all stages; gametocytes appear after 4 days or as late as 18 days.
Slightly amoeboid and irregular; band forms seen; very little pigment.	Denser cytoplasm (slightly amoeboid) band forms seen; little to no malaria pigment (scattered, fine brown grains).	Between 2 and 5 divided nuclear chromatin masses; abundant pigment granules occupy ⅔ of RBCs.	RBCs normal size; distorted/fimbriated RBCs very rare; occupy whole RBC; maximum of 16 merozoites; no rosettes; grapelike clusters	Occupy most of RBC; bluish cytoplasm; dense pink chromatin at periphery of parasite	Occupy most of RBC; cytoplasm pinkish purple; early forms similar to mature trophozoite	Ring forms compact; single/double chromatin dots, appliqué forms, multiple rings/RBC (mimic *P. falciparum*); overall RBCs not enlarged; developing stages mimic *P. malariae* (band forms, 16 merozoites in mature schizont, but no rosettes).

TABLE 48.3 **Malaria Characteristics With Fresh Blood or Blood Collected Using EDTA With No Extended Lag Time**

Type of Malaria	Characteristics
Plasmodium vivax (benign tertian malaria)	1 48-h cycle 2 Tends to infect young cells 3 Enlarged RBCs 4 Schüffner dots (true stippling) after 8–10 h 5 Delicate ring 6 Very amoeboid trophozoite 7 Mature schizont contains 12–24 merozoites
Plasmodium malariae (quartan malaria)	1 72-h cycle (long incubation period) 2 Tends to infect old cells 3 Normal size RBCs 4 No stippling 5 Thick ring, large nucleus 6 Trophozoite tends to form “bands” across the cell 7 Mature schizont contains 6–12 merozoites
Plasmodium ovale	1 48-h cycle 2 Tends to infect young cells 3 Enlarged RBCs with fimbriated edges (oval) 4 Schüffner dots appear in the beginning (in RBCs with very young ring forms, in contrast to *P. vivax*) 5 Smaller ring than *P. vivax* 6 Trophozoite less amoeboid than that of *P. vivax* 7 Mature schizont contains an average of 8 merozoites
Plasmodium falciparum (malignant tertian malaria)	1 36–48–h cycle 2 Tends to infect any cell regardless of age, thus very heavy infection may result 3 All sizes of RBCs 4 No Schüffner dots (Maurer dots: may be larger, single dots, bluish) 5 Multiple rings/cell (only young rings, gametocytes, and occasional mature schizonts are seen in peripheral blood) 6 Delicate rings, may have two dots of chromatin/ring, appliqué or accolé forms 7 Crescent-shaped gametocytes
Plasmodium knowlesi (simian malaria)[a]	1 24-h cycle 2 Tends to infect any cell regardless of age; thus very heavy infection may result 3 All sizes of RBCs, but most tend to be normal size 4 No Schüffner dots (faint, clumpy dots later in cycle) 5 Multiple rings/cell (may have 2–3) 6 Delicate rings, may have 2 or 3 dots of chromatin/ring, appliqué forms 7 Band form trophozoites commonly seen 8 Mature schizont contains 16 merozoites, no rosettes 9 Gametocytes round, tend to fill the cell 10 Early stages mimic *P. falciparum;* later stages mimic *P. malariae*

EDTA, Ethylenediaminetetraacetic acid; *RBC*, red blood cell.

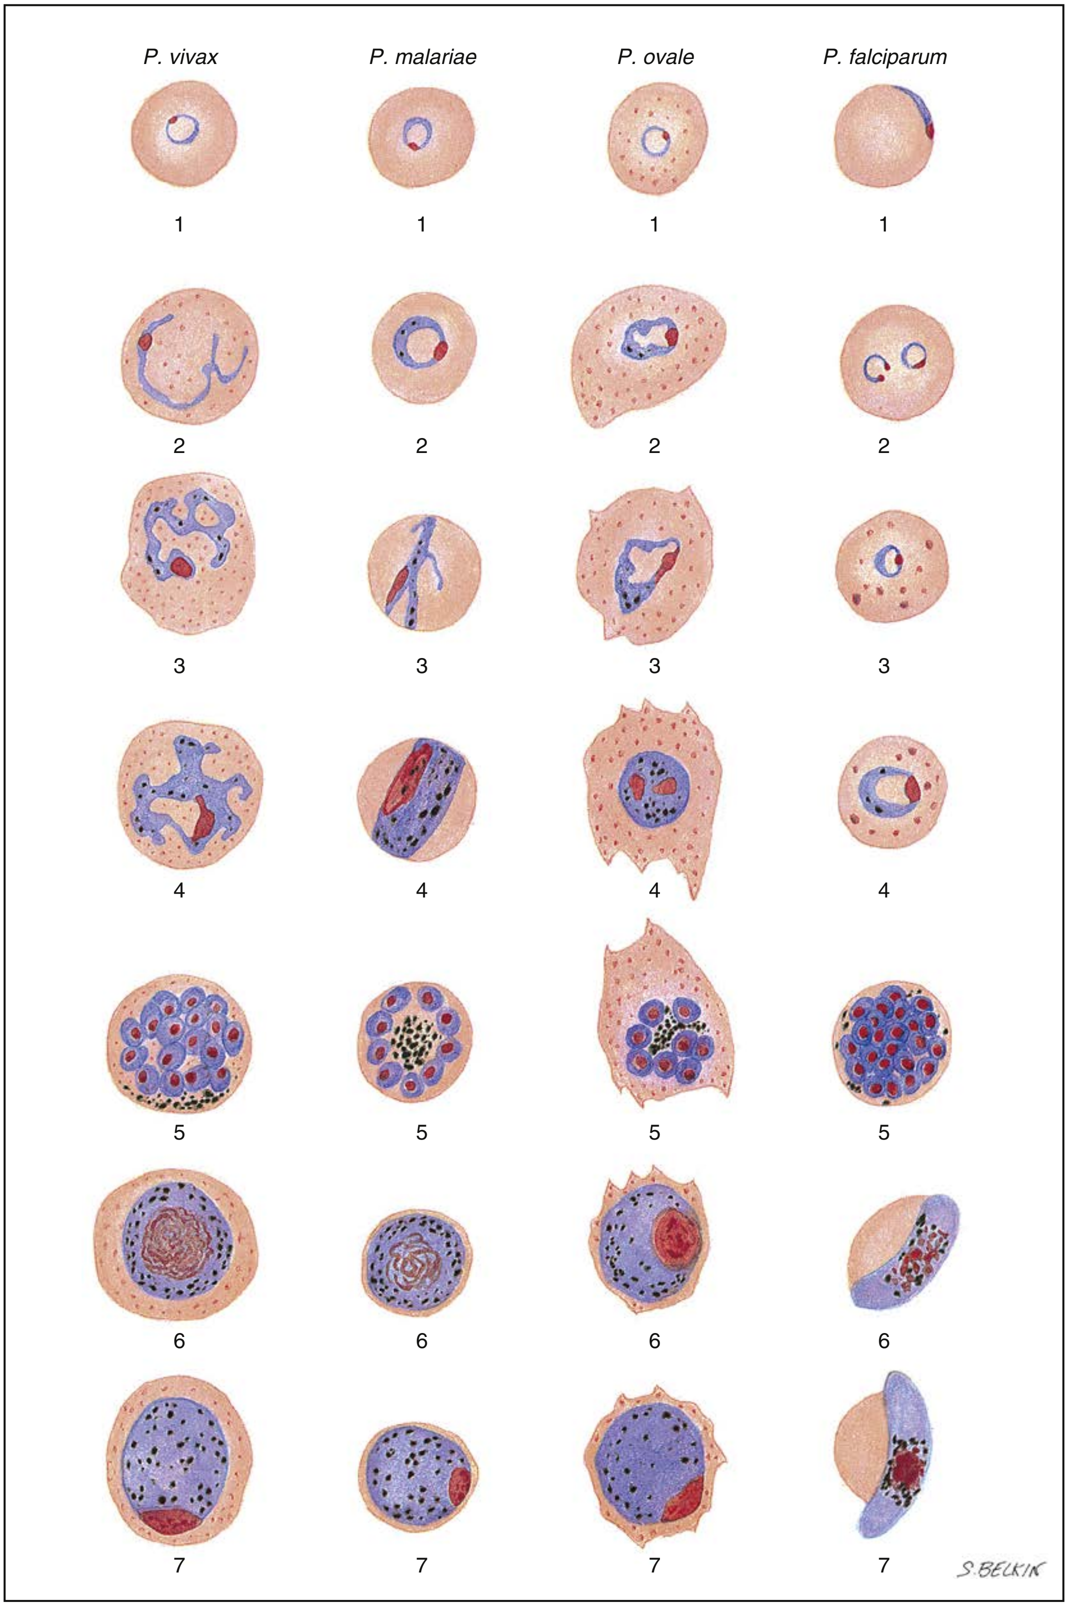
[a] Preparation of thick and thin blood films within 60 min of collection.

progress from being soft and palpable to hard, with continued enlargement during a chronic infection. If the infection is treated during the early phases, the spleen will return to its normal size. A secondary or dormant schizogony occurs in *P. vivax* and *P. ovale,* which remain quiescent in the liver as hypnozoites.

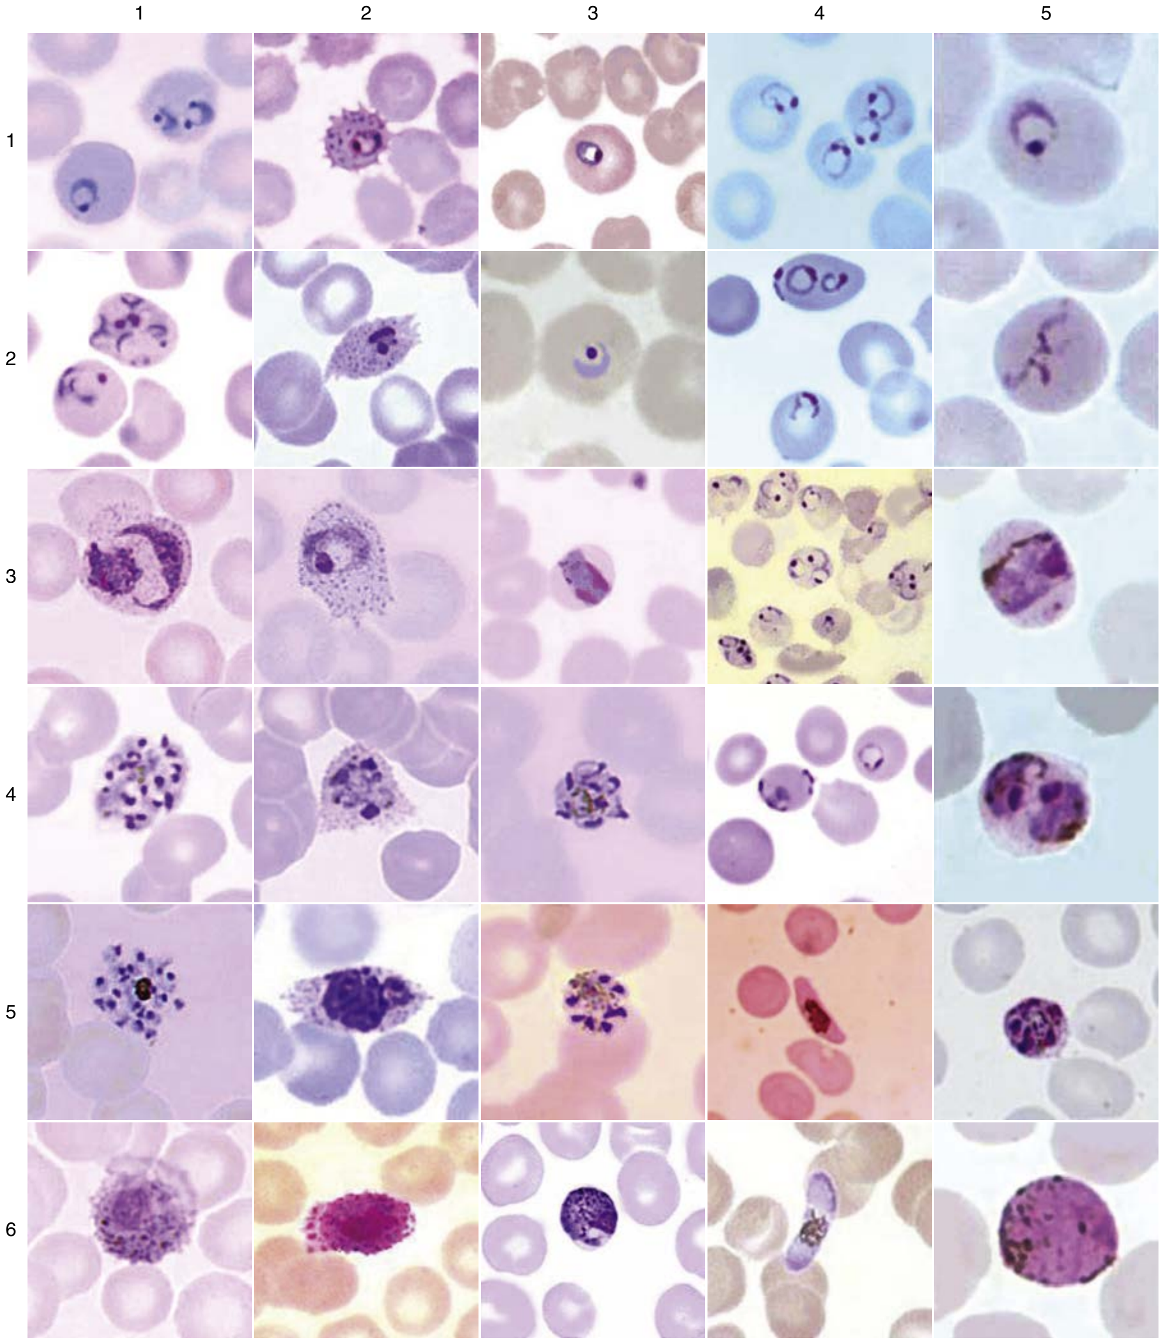
After a few days of irregular periodicity, a regular 48-hour cycle is established. An untreated primary attack may last from 3 weeks to 2 months or longer. Over time, the **paroxysms** (symptomatic period) become less severe and more irregular in frequency and then cease altogether. In approximately 50% of patients infected with *P. vivax,* relapses occur after weeks, months, or even after 5 years or more. The RBCs tend to be enlarged (young RBCs), there may be **Schüffner dots,** which are small, round, red granulations (exclusively found in *P. vivax* and *P. ovale*) after 8 to 10 hours, and the developing rings are amoeboid and very actively (Fig. 48.5B) motile; hence the name vivax or lively. The mature schizont contains 12 to 24 merozoites, a key identification factor (Fig. 48.5A).

Pathogenesis and Spectrum of Disease

In patients who have never been exposed to malaria, symptoms such as headache, photophobia, muscle aches, anorexia, nausea, and sometimes vomiting may occur before organisms can be detected in the bloodstream. In other patients with prior exposure to the malaria, the parasites can be found in the bloodstream several days before symptoms appear.



• **Fig. 48.2** Morphology of malaria parasites. *Plasmodium vivax: 1,* Early trophozoite (ring form). *2,* Late trophozoite with Schüffner dots (note enlarged red blood cell). *3,* Late trophozoite with amoeboid cytoplasm (very typical of *P. vivax*). *4,* Late trophozoite with amoeboid cytoplasm. *5,* Mature schizont with merozoites (18) and clumped pigment. *6,* Microgametocyte with dispersed chromatin. *7,* Macrogametocyte with compact chromatin. *Plasmodium malariae: 1,* Early trophozoite (ring form). *2,* Early trophozoite with thick cytoplasm. *3,* Early trophozoite (band form). *4,* Late trophozoite (band form) with heavy pigment. *5,* Mature schizont with merozoites (9) arranged in rosette. *6,* Microgametocyte with dispersed chromatin. *7,* Macrogametocyte with compact chromatin. *Plasmodium ovale: 1,* Early trophozoite (ring form) with Schüffner dots. *2,* Early trophozoite (note enlarged red blood cell). *3,* Late trophozoite in red blood cell with fimbriated edges. *4,* Developing schizont with irregularly shaped red blood cell. *5,* Mature schizont with merozoites (8) arranged irregularly. *6,* Microgametocyte with dispersed chromatin. *7,* Macrogametocyte with compact chromatin. *Plasmodium falciparum: 1,* Early trophozoite (accolé or appliqué form). *2,* Early trophozoite (one ring is in headphone configuration/double chromatin dots). *3,* Early trophozoite with Maurer dots. *4,* Late trophozoite with larger ring and Maurer dots. *5,* Mature schizont with merozoites (24). *6,* Microgametocyte with dispersed chromatin. *7,* Macrogametocyte with compact chromatin. Note: Without the appliqué form, Schüffner dots, multiple rings/cell, and other developing stages, differentiation among the species can be difficult. It is obvious that the early rings of all four species can mimic one another very easily. *One set of negative blood films cannot rule out a malarial infection.* (Reprinted by permission of the publisher from Garcia LS. *Diagnostic Medical Parasitology.* 5th ed. Washington, DC: ASM; 2007. Copyright by American Society for Microbiology.)



• **Fig. 48.3** Morphology of malaria parasites. *Column 1: Plasmodium vivax* (note enlarged infected red blood cells [RBCs]). (1) Early trophozoite (ring form) (note one RBC contains two rings—not that uncommon); (2) older ring, note ameboid nature of rings; (3) late trophozoite with Schüffner dots (note enlarged RBC); (4) developing schizont; (5) mature schizont with 18 merozoites and clumped pigment; (6) microgametocyte with dispersed chromatin. *Column 2: Plasmodium ovale* (note enlarged infected RBCs). (1) Early trophozoite (ring form) with Schüffner dots (RBC has fimbriated edges); (2) early trophozoite (note enlarged RBC, Schüffner dots, and RBC oval in shape); (3) late trophozoite in RBC with fimbriated edges; (4) developing schizont with irregular-shaped RBC; (5) mature schizont with eight merozoites arranged irregularly; (6) microgametocyte with dispersed chromatin. *Column 3: Plasmodium malariae* (note normal or smaller than normal infected RBCs). (1) Early trophozoite (ring form); (2) early trophozoite with thick cytoplasm; (3) late trophozoite (band form); (4) developing schizont; (5) mature schizont with nine merozoites arranged in a rosette; (6) microgametocyte with compact chromatin. *Column 4: Plasmodium falciparum.* (1) Early trophozoites (the rings are in the headphone configuration with double chromatin dots); (2) early trophozoite (accolé or appliqué form); (3) early trophozoites (note the multiple rings/cell); (4) late trophozoite with larger ring (accolé or appliqué form); (5) crescent-shaped gametocyte; (6) crescent-shaped gametocyte. *Column 5: Plasmodium knowlesi*—with the exception of image 5, these were photographed at a higher magnification (note normal or smaller than normal infected RBCs). (1) Early trophozoite (ring form); (2) early trophozoite with slim band form; (3) late trophozoite (band form); (4) developing schizont; (5) mature schizont with merozoites arranged in a rosette; (6) microgametocyte with dispersed chromatin. **Note:** Without the appliqué form, Schüffner dots, multiple rings per cell, and other developing stages, differentiation among the species can be very difficult. It is obvious that the early rings of all five species can mimic one another very easily. *Remember: One set of negative blood films cannot rule out a malaria infection.* (From Garcia LS. *Malaria Clin Lab Med* 30:93–129, 2010, with permission. Column 5 courtesy Centers for Disease Control and Prevention.)

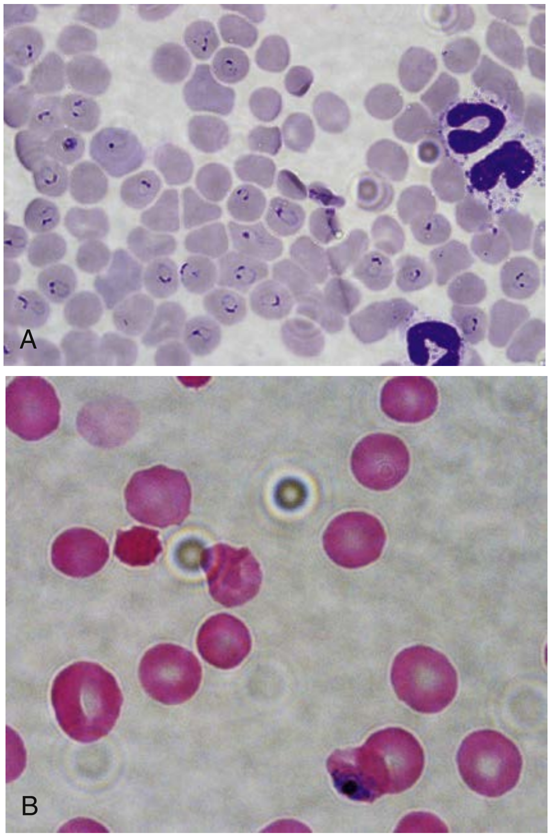
Malaria Identification Rubric

1. How many ring forms are seen per cell?
    a. More than 1 ring form per cell → ***Plasmodium falciparum***
        i. Look for applique ring forms
        ii. Banana-shaped gametocytes
        iii. Typically only ring forms and gametocytes seen in peripheral blood
        iv. Schizonts have up to 24 merozoites (nuclei)
        v. Black Water Fever – Heme pigments in urine
    b. Only 1 ring form per cell → Go to next question

2. Are the infected RBCs larger than the noninfected RBC?
    a. Infected RBCs not enlarged → probably ***Plasmodium malariae*** or ***P. knowlesi***
        i. Difficult to distinguish without PCR
        ii. RBC may look smaller due to rounding
        iii. Look for band form trophozoites
        iv. Compact ring with large chromatin dot
        v. *P. malariae*
            1. Every 3rd day paroxysm (quartan)
            2. Schizonts have 6 – 12 merozoites (nuclei) – may rosette
        vi. *P. knowlesi*
            1. Every day paroxysm (quotidian)
            2. Schizonts have 8 – 10 merozoites (nuclei) – may rosette
    b. Infected RBCs larger than noninfected → Go to next question

3. Are the infected cells oval in shape?
    a. Yes, some cells oval → most likely ***Plasmodium ovale***
        i. No Schüffner's dots
        ii. RBCs may have rough edge – "comet cells"
        iii. Schizonts have 4 – 12 merozoites (nuclei)
    b. Not oval → ***Plasmodium vivax***
        i. Schüffner's dots (best seen with Giemsa stain)
        ii. Large spread-out or small ring forms
        iii. May see full array of stages
        iv. Schizonts have 12 – 24 merozoites (nuclei)

• **Fig. 48.4** Malaria identification rubric: This rubric is used for the identification and characterization of *Plasmodium* spp. from Giemsa-stained peripheral blood thin smears. All laboratory reports should include the body form of the parasite present in the smear, along with the genus and species when possible. (Developed by Janice Conway-Klaassen, University of Minnesota.)



• Fig. 48.5 (A) *Plasmodium falciparum.* Ring forms (trophozoites) (100× oil immersion). (B) *P. falciparum* microgametocyte appliqué form (100× oil immersion).

Severe complications are uncommon in *P. vivax* infections, although coma and sudden death or other symptoms of cerebral involvement have been reported, particularly in patients whose disease is caused by primaquine-resistant organisms. These patients can exhibit cerebral malaria, renal failure, circulatory collapse, severe anemia, hemoglobinuria, abnormal bleeding, acute respiratory distress syndrome, and jaundice. Acute cerebral malaria involves changes in mental status and if untreated may result in fatality within 3 days.

Plasmodium ovale

General Characteristics

P. ovale was first described in 1922 where the distinctive oval-shaped cells with ragged edges distinguish it from *P. vivax*. Although *P. ovale* and *P. vivax* infections are clinically similar, *P. ovale* malaria is usually less severe, tends to relapse less frequently, and usually ends with spontaneous recovery, often after no more than 6 to 10 paroxysms (Tables 48.1–48.3 and Figs. 48.2 and 48.3). Like *P. vivax, P. ovale* infects only the reticulocytes, so the parasitemia is limited to approximately 2% to 5% of the available RBCs in otherwise healthy individuals. For many years, the literature has stated that, as with *P. vivax,* a secondary or dormant schizogony occurs in *P. ovale,* which remain quiescent in the liver. However, newer findings indicate that hypnozoites have never been demonstrated in naturally occurring cases.

After a few days of irregular periodicity, a regular 48-hour cycle is established. Over time, the paroxysms become less severe and more irregular in frequency and then stop altogether. In some patients infected with *P. ovale,* relapses occur after weeks, months, or up to 1 year or more. The RBCs tend to be enlarged (young RBCs), Schüffner dots (also known as **James stippling**) are present from the beginning of the cycle, the developing rings are less amoeboid than those of *P. vivax,* and the mature schizont contains an average of eight merozoites.

Pathogenesis and Spectrum of Disease

The incubation period is similar to that for *P. vivax* malaria, but the frequency and severity of the symptoms are much less, with a lower fever and a lack of typical rigors. The geographic range is usually described as being limited to tropical Africa, the Middle East, Papua New Guinea, and Irian Jaya in Indonesia. However, *P. ovale* infections in Southeast Asia may cause benign and relapsing malaria in this area. Sequences of small subunit ribosomal RNA have identified two subtypes, *P. ovale curtisi* (classic type) and *P. ovale wallikeri* (variant type) which are morphologically indistinguishable. Human infections with variant-type *P. ovale* are associated with a higher level of parasitemia.

Plasmodium malariae (Quartan Malaria)

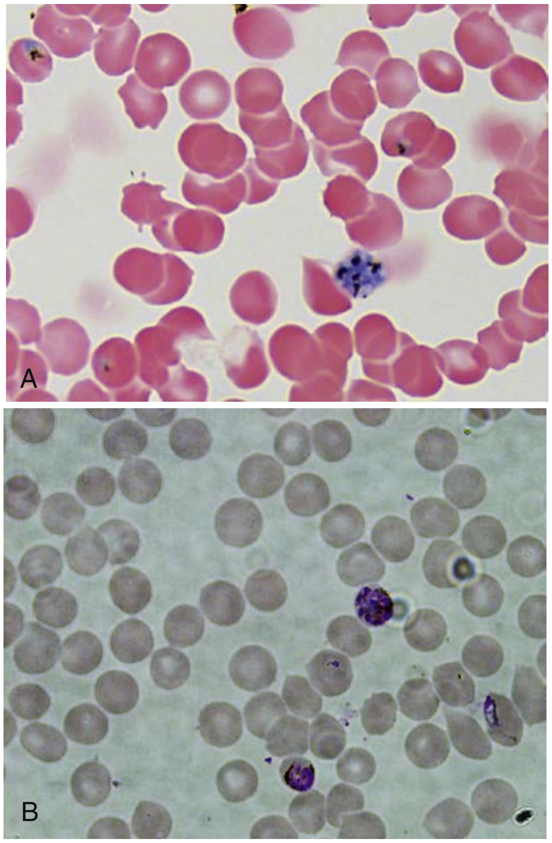
General Characteristics

P. malariae invades primarily the older RBCs, limiting the number of infected cells (Tables 48.1–48.3 and Figs. 48.2 and 48.3). The incubation period between infection and symptoms may be much longer than that for *P. vivax* or *P. ovale* malaria, ranging from approximately 27 to 40 days. A regular periodicity is seen from the beginning, with a more severe paroxysm, including a longer cold stage and more severe symptoms during the hot stage. Collapse during the sweating phase is not uncommon.

A regular periodicity of 72 hours is seen from the beginning of the erythrocytic cycle. The infection may end with spontaneous recovery, or there may be a **recrudescence** (recurrence of symptoms) or series of recrudescence over many years. These patients are left with a latent infection and persisting low-grade parasitemia for many, many years. The RBCs tend to be normal to small (old RBCs), there is no true stippling, the RBCs may have fimbriated edges, the developing rings tend to demonstrate "band" forms, and the mature schizont contains an average of 6 to 12 merozoites (Fig. 48.6).

Pathogenesis and Spectrum of Disease

Proteinuria is common in *P. malariae* infections and may be associated with clinical signs of nephrotic syndrome. With a chronic infection, kidney problems result from deposition within the glomeruli of circulating antigen-antibody complexes. A membrane proliferative type of glomerulonephritis is the most common lesion seen in quartan malaria. Because chronic glomerular disease associated with *P. malariae* infections is usually not reversible with therapy, genetic



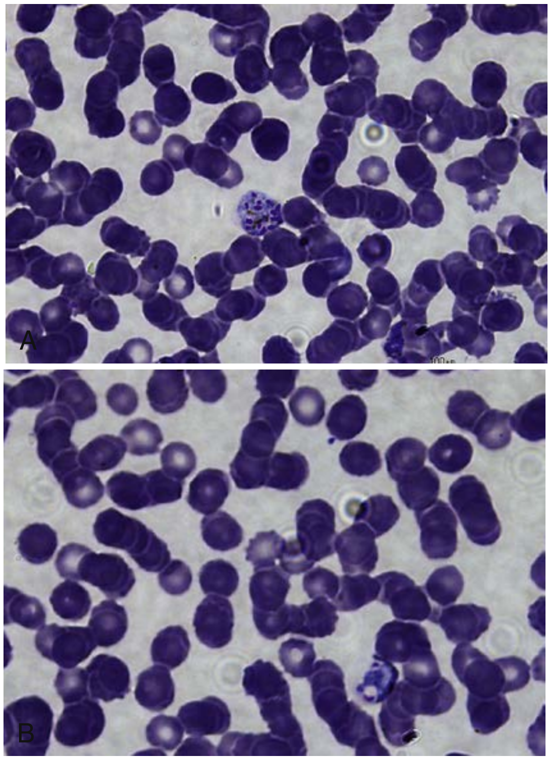
• **Fig. 48.6** (A) *Plasmodium malariae* schizont (100× oil immersion). (B) *P. malariae* schizont and developing trophozoite (100× oil immersion).

and environmental factors may play a role in the disease, as well. The patient may have a spontaneous recovery, or there may be a recrudescence or series of recrudescence over many years (>50 years). In these cases, patients are left with a latent infection and persisting low-grade parasitemia.

Plasmodium falciparum (Malignant Tertian Malaria)

General Characteristics

P. falciparum invades all ages of RBCs, and the number of infected cells may exceed 50% (Fig. 48.7; Tables 48.1–48.3 and Figs. 48.2 and 48.3). Schizogony occurs in the spleen, liver, and bone marrow rather than in the circulating blood. Ischemia caused by the obstruction of vessels within these organs by parasitized RBCs will produce various symptoms, depending on the organ involved. A decrease in the ability of the RBCs to change shape when passing through capillaries or the splenic filter may lead to plugging of the vessels. In addition, *P. falciparum* causes **cytoadherence,** allowing the parasites to bind to the surface of RBC and to vascular endothelial cells, a feature that is associated with severe malaria.



• **Fig. 48.7** (A) *Plasmodium vivax* schizont with late trophozoite and Schüffner dots. (B) *P. vivax* late trophozoite (100× oil immersion).

The asexual and sexual forms circulate in the bloodstream during infections by four of the *Plasmodium* species. However, as the parasite matures in *P. falciparum* infections, the RBC membrane becomes sticky and the cells adhere to the endothelial lining of the capillaries of the internal organs. Thus, only the ring forms and the gametocytes (occasionally mature schizonts) normally appear in the peripheral blood. Periodicity of the cycle will not be established during the early stages, and the presumptive diagnosis may be totally unrelated to a possible malaria infection. If the fever demonstrates a synchronous cycle, it is usually a cycle of 36 to 48 hours. Because *P. falciparum* infects young and old RBCs, very heavy parasitemia can occur. The RBCs are all sizes; there is no true stippling, but **Maurer dots** (coarse granulation in the cytoplasm of RBCs) are sometimes present. A unique characteristic of *P. falciparum* is multiple parasite infections per cells, and therefore multiple rings may be seen. The rings are delicate and often have two dots of chromatin. Infected RBCs may show **appliqué** or **accolé** forms—ring forms located on the surface or marginal regions of the erythrocytes (Fig. 48.5B). The gametocytes of *P. falciparum* are crescent shaped, whereas other species are round.

Pathogenesis and Spectrum of Disease

The onset of a *P. falciparum* malaria attack occurs 8 to 12 days after infection and is characterized by 3 to 4 days of vague symptoms such as aches, pains, headache, fatigue, anorexia, or nausea. This stage is followed by fever, a more severe headache, and nausea and vomiting, with occasional severe epigastric pain. At the onset of fever, there may be a feeling of chilliness. As with the other *Plasmodium* spp., periodicity of the cycle will not be established during the early stages.

Severe or fatal complications can occur at any time and are related to the obstruction of vessels in the internal organs (liver, intestinal tract, adrenal glands, intravascular hemolysis/blackwater fever, and kidneys). **Blackwater fever** is a complication of malaria that is a result of RBC lysis, releasing hemoglobin into the bloodstream and urine, causing discoloration. The severity of the complications may not correlate with the peripheral blood parasitemia, particularly in *P. falciparum* infections in a patient who has never been exposed to malaria before (immunologically naïve).

Disseminated intravascular coagulation (DIC) is a rare complication and is seen with a high parasitemia, pulmonary edema, anemia, and cerebral and renal complications. Vascular endothelial damage from endotoxins and bound parasitized blood cells may lead to clot formation in small vessels. Cerebral malaria is more common in *P. falciparum* infections but can also occur in the other species. If the onset is gradual, the patient becomes disoriented or violent or may develop severe headaches and pass into coma. However, some patients, including those with no prior symptoms, may suddenly become comatose. Physical signs of central nervous system (CNS) involvement vary, and there is no correlation between the severity of the symptoms and the level of parasitemia.

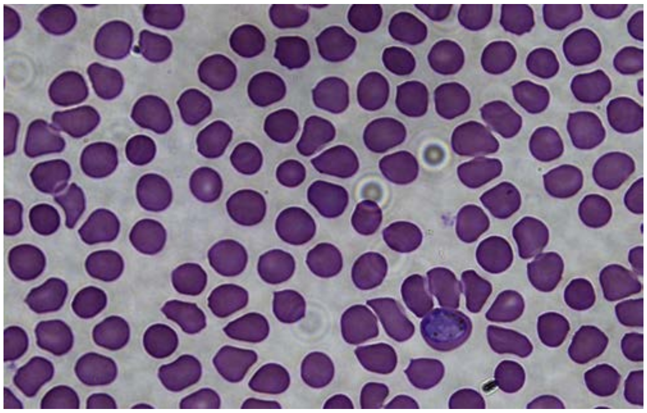
Extreme fevers, 41.7°C (107°F) or higher, may occur in an uncomplicated malaria attack or in cases of cerebral malaria. Without vigorous therapy, the patient usually dies. Cerebral malaria is considered the most serious complication and the major cause of death with *P. falciparum;* it occurs in up to 10% of all *P. falciparum* patients admitted to the hospital and is responsible for 80% of fatal cases.

Plasmodium knowlesi (Simian Malaria, The Fifth Human Malaria)

General Characteristics

P. knowlesi invades all ages of RBCs, and the number of infected cells can be significantly more than are seen in *P. vivax, P. ovale,* and *P. malariae. P. knowlesi* infection should be considered in patients with a travel history to forested areas of Southeast Asia, especially if *P. malariae* is diagnosed, unusual forms are seen with microscopy, or if a mixed infection with *P. falciparum* and *P. malariae* is diagnosed. Because the disease is potentially fatal, proper identification to the species level is critical.

The early blood stages of *P. knowlesi* resemble those of *P. falciparum;* whereas the mature blood stages and gametocytes resemble those of *P. malariae* (Tables 48.1–48.3 and Figs. 48.2–48.4). Unfortunately, these infections are often misdiagnosed as the relatively benign *P. malariae*; however, infections with *P. knowlesi* can be fatal. The RBCs are all sizes, there is no true stippling (fine, granular, blue stippling in RBCs stained with Wright's stain or red when using eosin hematoxylin (Fig. 48.8), often there are multiple rings per RBC (there may be two to three rings), the rings are delicate and often have two to three dots of chromatin, band forms are typically seen with the developing trophozoites, and the mature schizont contains 16 merozoites. The early stages mimic *P. falciparum,* whereas the later stages mimic *P. malariae.*



• **Fig. 48.8** *Plasmodium knowlesi* microgametocyte (100× oil immersion).

Because of different levels of parasitemia, low organism densities, and confusion among various morphologic criteria for identification, detection of mixed infections can be quite difficult. Even if a mixed infection is suspected, identification to the species level may not be possible using routine microscopy methods. However, using polymerase chain reaction (PCR) methods, it is likely that higher detection and identification rates of chronic and mixed malarial infections will be possible.

Pathogenesis and Spectrum of Disease

Patients exhibit chills, minor headaches, and daily low-grade fever. Patients who have been diagnosed with high numbers of *P. malariae* organisms by microscopy should receive intensive management as appropriate for severe *P. falciparum* malaria, assuming the infection is actually caused by *P. knowlesi.* Overall, these infections can be as severe as those caused by *P. falciparum,* with fatal outcomes.

Laboratory Diagnosis (All Species)

Routine Methods

Malaria is considered to be immediately life threatening, and a patient with the diagnosis of *P. falciparum* or *P. knowlesi* malaria should be considered a medical emergency because the disease can be rapidly fatal. This approach to the patient is recommended in situations in which *P. falciparum* or *P. knowlesi* cannot be ruled out as a possible diagnosis. Any laboratory providing the expertise to identify malarial parasites should do so on a 24-hour basis, 7 days a week.

Examination of a single blood specimen is not sufficient to exclude the diagnosis of malaria, especially when the patient has received partial prophylaxis or therapy and has a low number of organisms in the blood. Patients with a relapse case or an early primary case may also have few organisms in the blood smear. Regardless of the presence or absence of any fever periodicity, both thick and thin blood films should be prepared immediately, and at least 200 to 300 oil immersion fields should be examined on both films before a negative report is issued. If the initial specimen is negative, additional blood specimens should be examined over a 36-hour time frame. Although Giemsa stain is recommended for all parasitic blood work, the organisms can be seen with other bloodstains, such as Wright's stain, Wright-Giemsa, or the rapid Field's stain. Using any of the bloodstains, the white blood cells (WBCs) serve as the built-in quality control; if the WBCs look good, any parasites present will be more easily visualized. Fig. 48.7 compares the multinucleated stages (schizont) of *P. malariae* and *P. vivax*. Fluorescent nucleic acid stains, such as acridine orange, may also be used to identify organisms in infected RBCs. However, this may be more difficult to interpret because of the presence of WBC nuclei or RBC **Howell-Jolly bodies**. Acridine orange may be used in the **quantitative buffy coat (QBC)** (QBC Diagnostics, Becton Dickinson, Port Matilda, PA) method. The method provides a rapid screening tool (results are available in 15 minutes) that is technically simple. The test uses a 50-μL tube that contains all the reagents (anticoagulant) and stain (acridine orange) needed for completion of the assay. The microhematocrit tube can be used to collect either capillary or venous blood. The tube also contains a plastic float that is inserted in the tube after phlebotomy. The float is designed to separate specific layers of blood during centrifugation that allows a clear separation of RBCs, WBCs, and what is termed the **malaria detection zone**. Once the tube is centrifuged, it is examined under a fluorescent microscope, permitting rapid detection of stained malaria organisms.

For thin- and thick-smear microscopic films, blood collected using ethylenediaminetetraacetic acid (EDTA) anticoagulant is preferred; however, if the blood remains in the tube for any length of time before blood film preparation, Schüffner dots may not be visible after staining (e.g., *P. vivax*), and other morphologic changes in the parasites will be seen. In addition, the proper ratio between blood and anticoagulant is required to maintain organism morphology, so each collection tube should be filled to the top. Finger-stick blood is recommended, particularly when the volume of blood required is minimal (i.e., when no other hematologic procedures have been ordered). The blood should be free flowing when taken for smear preparation and should not be contaminated with alcohol used to clean the finger before the stick. However, the use of finger-stick blood is currently much less common, and venipuncture blood is the normal specimen collected for the laboratory. Identification to the species level is highly desirable because this information determines the recommended drug therapy. Patients with early *P. falciparum* infections may not have the crescent-shaped gametocytes in the blood. In addition, low parasitemia with the delicate ring forms may be missed; consequently, oil immersion examination at 1000× is mandatory.

Antigen-Based Tests

Several rapid diagnostic tests (RDTs) for malaria are now commercially available, some of which use monoclonal antibodies against the histidine-rich protein 2 (HRP2) or *Plasmodium* aldolase, whereas others detect species-specific parasite lactate dehydrogenase (pLDH). These procedures are based on an antigen capture approach in dipstick or cartridge formats of immuno-chromatographic antigen-detection tests. The BinaxNOW rapid malaria test (Alere, Waltham, MA) is US Food and Drug Administration (FDA) approved for use within the United States. The kit is designed to detect primarily *P. falciparum* and a panmalarial antigen common to the four primary malaria species that infect humans. However, because of sensitivity limitations in patients with a low parasitemia, the "gold standard" is still considered the examination of thick and thin blood films. Given the limitations associated with the rapid tests, it is recommended that results be confirmed using the standard thick and thin blood films. If the rapid test is negative, the thick and thin blood films must be examined on a STAT basis.

Nucleic Acid Detection

Other methods include direct detection of the five species by using a specific DNA probe after PCR amplification of target DNA sequences. Some laboratories are now using PCR for detection of malaria; the high sensitivity, rapidity, and simplicity of some of the methods are becoming much more relevant for diagnosis. Detection is possible for as few as 5 or 10 parasites per microliter of blood; thus, PCR detects many more cases of low-level parasitemia than do thick blood films. This approach is also valuable when the determination of species is questionable by microscopy or when mixed infections are suspected. Although these tests are more sensitive than the traditional blood films, they are primarily available as laboratory-developed tests and are not FDA approved. When a positive result is obtained using a nucleic acid–based test, it is still recommended that a thin and thick blood smear be completed to quantitate the level of parasitemia. Nucleic acid–based quantitation does not correlate with manual quantitation, because the assays are unable to differentiate the reproductive and extracellular forms from the organisms infecting the RBCs.

Automated Instruments

Using automated flow cytometry hematology instruments, there are potential limitations related to the diagnosis of blood parasite infections. *Plasmodium* spp. and *Babesia* spp. infections have been completely missed using such instrumentation. Failure to detect a light parasitemia is highly likely. Unfortunately, failure to make the diagnosis in many of these patients has resulted in delayed therapy. Although most of these instruments are not designed to detect intracellular blood parasites, the inability of the automated systems to discriminate between uninfected RBCs and those infected with parasites may pose serious diagnostic problems in situations in which the parasitemia is 0.5% or less.

Serologic Tests

Serologic tests have little to no clinical utility. This is primarily because of their inability to detect antibodies at the presentation of symptoms. It is also extremely difficult to differentiate a previous from an acute malaria infection. Serology is primarily used to screen donor blood units and for epidemiologic studies.

Results Reporting

In addition to reporting the species of *Plasmodium* identified, it is also important to quantify the level of parasitemia. This will help to guide and monitor the patient's treatment and potentially provide prognostic information to the clinician. Quantitation in the thick film may be reported based on the number of WBCs per microliter of blood in comparison to the number of organisms. If quantitation is completed on the thin smear, the parasitemia is reported as the percentage of infected RBCs in total erythrocytes; extracellular parasites are not included in the count. In addition, *Plasmodium* spp. gametocytes should not be included in the quantitation because they are not considered infectious and are not affected by antimalarial medications. Failure to exclude the reproductive forms of the parasite may result in erroneous changes in treatment due to either falsely elevated or depressed results.

Therapy

Malaria is serious health problem, both in residents of endemic areas and in travelers returning to nonendemic areas. Therapy has become more complex as a result of increased resistance of *P. falciparum* to a variety of drugs, resistance problems with *P. vivax,* and the need to treat severe disease complications. Antimalarial drugs are classified according to the stage of malaria against which they are targeted. These drugs are referred to as **tissue schizonticides** (which kill tissue schizonts), **blood schizonticides** (which kill blood schizonts), **gametocytocides** (which kill gametocytes), and **sporonticides** (which prevent formation of sporozoites within the mosquito). It is important for the clinician to know the species of *Plasmodium* involved in the infection, the estimated parasitemia, and the patient's travel history to assess the possibility of drug resistance related to the organism and geographic area.

Chloroquine-resistant *P. falciparum* is present in almost all endemic areas other than Central America and the Caribbean. Increasing resistance to sulfadoxine-pyrimethamine and mefloquine has been identified in *P. falciparum.* Therefore treatment with **artemisinin combination therapy (ACT)**—including artesunate-mefloquine, artemether-lumefantrine (Coartem), and artesunate-amodiaquine—has been instituted against *P. falciparum.* However, resistance to artesunate-mefloquine has already appeared in Southeast Asia. Current information on the distribution of drug-resistant *P. falciparum* is available from the Centers for Disease Control and Prevention (CDC) malaria hotline in Atlanta, Georgia (phone: 770-488-7788). Therapy for chloroquine-resistant *P. falciparum* remains very complex with continual changes; thus, consultation with an infectious disease specialist is highly recommended. Chloroquine resistance continues to evolve and spread. Primaquine tolerance has been documented. Current CDC treatment guidelines are available at https://www.cdc.gov/malaria/diagnosis_treatment/index.html.

Molecular detection of specific single nucleotide polymorphisms associated with antimalarial resistance has been used successfully to identify resistance to sulfadoxine-pyrimethamine, chloroquine, mefloquine, quinine, and artemisinin. Methods are available that use PCR and DNA microarray formats, but they are primarily for reference and research laboratory use.

Babesia spp.

The genus *Babesia* includes approximately 100 species transmitted by ticks of the genus *Ixodes.* In addition to humans, these blood parasites infect a variety of wild and domestic animals. Cases of babesiosis have been documented worldwide, and several outbreaks in humans have occurred in the northeastern United States, particularly in Long Island, Cape Cod, and the islands off the East Coast (Homer). Although there are many species of *Babesia, Babesia microti* is the cause of most human infections in the United States. *Babesia duncani* and *B. duncani*–like organisms have also been reported associated with infections across Canada and in Washington, Oregon, and California. *Babesia divergens* tends to be more common in Europe, is often found in splenectomized patients, and causes a more serious form of the disease.

General Characteristics

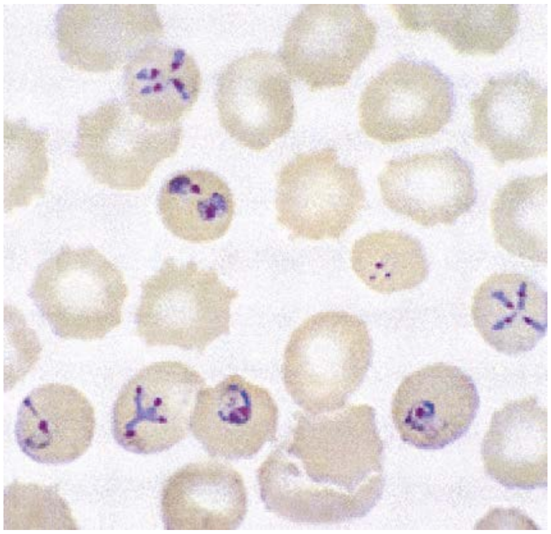
Organism

Although the life cycle of *Babesia* spp. is similar to that of *Plasmodium* spp., no exoerythrocytic stage has been described; in addition, sporozoites injected by the bite of an infected tick (*Ixodes scapularis–B. microti* and *Ixodes ricinus–B. divergens*) invade erythrocytes directly. The specific vector for the transmission of *B. duncani* and *B. duncani*–like organisms has not been identified. Once inside the erythrocytes, the trophozoites reproduce by binary fission rather than schizogony. Once the tick begins to take a blood meal, the sporozoites are injected into the host with the tick's saliva.

The trophozoites of *Babesia* can mimic *P. falciparum* rings; however, there are differences that can help to differentiate the two organisms (Fig. 48.9). *Babesia* trophozoites vary in size from 1 to 5 µm; the smallest are smaller than *P. falciparum* rings. In addition, ring forms outside of the RBCs and two to three rings per RBC are much more common in *Babesia.* The ring forms of *Babesia* tend to be very pleomorphic and range in size, even within a single RBC. The diagnostic tetrads, the Maltese cross, although not seen in every specimen or species, may be present (Fig. 48.6).

Pathogenesis and Spectrum of Disease

Babesiosis caused by *B. microti* and *B. duncani* or *B. duncani*–like parasites may be mild to severe. Mild disease



• **Fig. 48.9** *Babesia* in red blood cells.

resembles influenza-like illness, whereas severe disease is clinically similar to malaria, and symptoms include high fever, myalgias, malaise, fatigue, hepatosplenomegaly, and anemia. Usually, *B. microti* infections in the United States occur in nonsplenectomized individuals and are relatively mild. Infections with some of the other *Babesia* spp. from the United States and with *B. divergens* in Europe occur in splenectomized or immunocompromised individuals and are clinically more serious. A recent study found infections with *B. duncani* across Canada, not just in the Pacific Northwest region. Mortality among symptomatic cases of *B. microti* infection in the United States is 5%, whereas that in *B. divergens* infection in Europe is approximately 40%. In both areas, risk factors for severe disease include increasing age, splenectomy, and a compromised immune system. Infections with *Babesia* species from California, Washington, and other Western states tend to be more serious and can mimic the symptoms seen in *B. divergens.*

Laboratory Diagnosis

Routine Methods

The diagnosis of babesiosis should be considered for a patient with typical symptoms and a travel history including endemic areas, exposure to ticks, or recent blood transfusion. Examination of thick- and thin-stained blood films is the most direct approach to diagnosis. It is important to remember that the parasitemia may be low, and these organisms tend to be routinely missed using automated hematology instruments. Similar to malaria infections, the level of parasitemia should be reported to assist in the therapy and patient management in splenectomized or immunocompromised individuals.

Nucleic Acid Detection

Molecular methods such as PCR are available in some laboratories. Nucleic acid amplification acids have demonstrated increased sensitivity in cases of low parasitemia in comparison to identification on blood films. Assays are available for *B. microti* and *B. divergens*; however, none are FDA approved/cleared.

Serologic Tests

Serologic testing has little use in the diagnosis of acute infections. Antibodies to *B. microti* typically appear within 2 weeks after the development of symptoms and persist for many years after infection. An indirect immunofluorescent test is available in the United States for the detection of antibodies in response to infection with *B. microti* (Imugen, Norwood, MA). Seroconversion in a paired acute versus convalescent or a fourfold rise in titer is indicative of a recent infection.

Results Reporting

Identification of *B. microti* organisms in the thin or thick smear should be immediately reported to the clinician. Quantitation is recommended. Serial smears should be completed if the initial smears are negative, because a negative single smear does not rule out a diagnosis of babesiosis.

Therapy

Mild cases caused by *B. microti* usually resolve spontaneously, and in more serious cases, treatment with clindamycin and quinine or atovaquone and azithromycin is used. In very severe cases of *B. microti* infection and in splenectomized or immunosuppressed patients with *B. divergens*, exchange transfusion can be used in addition to antimicrobials.

Prevention

Personal protective measures, such as long pants, long-sleeved shirts, and insect repellant, may reduce the risk of infection when outdoors in endemic areas for the tick vectors.

Trypanosoma spp.

Trypanosoma spp. are hemoflagellate protozoa that live in the blood and tissue of the human host belonging to the Class Kinetoplastea and Family Trypanosomatidae (Tables 48.4 and 48.5 and Fig. 48.10). African trypanosomiasis (sleeping sickness) is caused by *Trypanosoma brucei gambiense* and *T. brucei rhodesiense* species and is confined to the central belt of Africa. American trypanosomiasis (Chagas disease) is produced by *Trypanosoma cruzi* (Fig. 48.11A) and is confined to the Americas. *Trypanosoma rangeli* infects a wide range of mammals in South and Central America and produces an asymptomatic infection in humans. African trypanosomes and *T. rangeli* are transmitted directly into the bite wound by salivary secretions from the insect vector, whereas *T. cruzi* is transmitted through contamination of the bite wound with the feces from the reduviid bug.

TABLE 48.4 Characteristics of American Trypanosomiasis

Characteristic	Causative Organism	
	Trypanosoma cruzi	*Trypanosoma rangeli*
Vector	Reduviid bug	Reduviid bug
Primary reservoirs	Opossums, dogs, cats, wild rodents	Wild rodents
Illness	Symptomatic (acute, chronic)	Asymptomatic
Diagnostic stage Blood Tissue	Trypomastigote Amastigote	Trypomastigote None
Recommended specimens	Blood, lymph node aspirate, chagoma	Blood

African Trypanosomiasis

The primary area of endemic infection with *T. brucei gambiense* (West African trypanosomiasis) coincides with the vector tsetse fly belt through the heart of Africa, where 300,000 to 500,000 people may be infected in Western and Central Africa. *T. brucei rhodesiense* (which causes Rhodesian trypanosomiasis or East African sleeping sickness) is more limited in distribution than *T. brucei gambiense,* found only in central East Africa, where the disease has been responsible for some of the most serious obstacles to economic and social development of Africa. Within this area, the tsetse flies prefer animal blood, which therefore limits the raising of livestock. The infection in humans has a greater morbidity and mortality than does *T. brucei gambiense* infection, and game animals, such as the bushbuck, and cattle are the natural reservoir hosts.

A unique feature of African trypanosomes is their ability to change the antigenic surface coat of the outer membrane of the **trypomastigote,** helping to evade the host immune response. The trypomastigote surface is covered with a dense coat of **variant surface glycoprotein (VSG).** There are approximately 100 to 1000 genes in the genome, responsible for encoding as many as 1000 different VSGs. More than 100 serotypes have been detected in a single infection. It is postulated that the trypomastigote changes its antigenic coat approximately every 5 to 7 days (antigenic variation). This change is responsible for successive waves of parasitemia every 7 to 14 days and allows the parasite to evade the host humoral immune response. Each time the antigenic coat changes, the host does not recognize the organism and must mount a new immunologic response. The sustained high immunoglobulin M (IgM) levels are a result of the parasite producing variable antigen types, and in an immunocompetent host, the absence of elevated IgM levels in serum rules out trypanosomiasis.

General Characteristics

Trypanosomal forms are ingested by the tsetse fly (*Glossina* spp.) when a blood meal is taken. The organisms multiply in the lumen of the midgut and hindgut of the fly. After approximately 2 weeks, the organisms migrate back to salivary glands where the organisms attach to the epithelial cells of the salivary ducts and then transform to their **epimastigote** forms. Multiplication continues within the salivary gland, and **metacyclic** (infective) **forms** develop from the epimastigotes in 2 to 5 days. While feeding, the fly introduces the metacyclic trypanosomal forms into the next victim in saliva injected into the puncture wound. The entire developmental cycle in the fly takes approximately 3 weeks, and once infected, the tsetse fly remains infected for life.

In fresh blood, the trypanosomes move rapidly among the RBCs. An undulating membrane and flagellum may be seen with slower-moving organisms. The trypomastigote forms are 14 to 33 μm long and 1.5 to 3.5 μm wide (Table 48.5, and Fig. 48.11B). With a bloodstain, the granular cytoplasm stains pale blue. The centrally located nucleus stains reddish. At the posterior end of the organism is the **kinetoplast,** which also stains reddish, and the remaining intracytoplasmic flagellum (axoneme), which may not be noticeable. The flagellum arises from the kinetoplast, as does the undulating membrane. The flagellum runs along the edge of the undulating membrane until the undulating membrane merges with the trypanosome body at the anterior end of the organism. At this point, the flagellum becomes free to extend beyond the body.

Pathogenesis and Spectrum of Disease

Trypanosoma brucei gambiense

African trypanosomiasis caused by *T. brucei gambiense* (West African sleeping sickness) has a long, mild, chronic course that ends in death with CNS involvement after several years. This is unlike the disease caused by *T. brucei rhodesiense* (East African sleeping sickness), which has an acute, short course and ends fatally within 1 year.

After the host is bitten by an infected tsetse fly, a nodule or chancre at the site may develop after a few days. Usually, this primary lesion will resolve spontaneously within 1 to 2 weeks, and is rarely seen in patients living in an endemic area. Trypomastigotes may be detected in fluid aspirated from the ulcer. The trypomastigotes enter the bloodstream, causing a low-grade parasitemia that may continue for months with the patient remaining asymptomatic. This is considered **stage I disease,** where the patient can have systemic trypanosomiasis without CNS involvement. During this time, the parasites may be difficult to detect, even by thick blood film examinations. The infection may self-cure during this period without development of symptoms or lymph node invasion.

Symptoms may occur months to years after infection. When the lymph nodes are invaded, the first symptoms appear and include remittent, irregular fevers with night sweats. Headaches, malaise, and anorexia may also be present. The febrile periods of up to 1 week alternate with afebrile periods of variable duration. Many trypomastigotes may be found in the circulating blood during fevers, but few are seen during afebrile periods. Lymphadenopathy is a consistent feature of Gambian trypanosomiasis, and the enlarged lymph nodes are soft and painless. In addition to lymph node involvement, the spleen and liver become enlarged. With Gambian trypanosomiasis, the blood lymphatic stage may last for years before the sleeping sickness syndrome occurs.

When the organisms finally invade the CNS, the sleeping sickness stage of the infection is initiated (**stage II disease**). Behavioral and personality changes are seen during CNS invasion. This stage of the disease is characterized by steady progressive meningoencephalitis, apathy, confusion, fatigue, loss of coordination, and **somnolence** (state of drowsiness). In the terminal phase of the disease, the patient becomes emaciated and progresses to profound coma and death, usually from secondary infection. The typical signs of true sleeping sickness are seen in patients with Gambian disease.

Trypanosoma brucei rhodesiense

T. brucei rhodesiense produces a more rapid, fulminating disease than does *T. brucei gambiense.* Fever, severe headaches, irritability, extreme fatigue, swollen lymph nodes, and aching muscles and joints are typical symptoms. Progressive confusion, personality changes, slurred speech, seizures, and difficulty in walking and talking occur as the organisms invade the CNS. The early stages of the infection are like those of *T. brucei gambiense* infections. However, CNS invasion occurs early, the disease progresses more rapidly, and death may occur before there is extensive CNS involvement. The incubation period is short, often within 1 to 4 weeks, with trypomastigotes being more numerous and appearing earlier in the blood. Lymph node involvement is less pronounced. Febrile episodes are more common, and the patients are more anemic and more likely to develop myocarditis or jaundice. Some patients may develop persistent tachycardia, and death may result from arrhythmia and congestive heart failure. Myocarditis may develop in patients with Gambian trypanosomiasis but is more common and severe with the Rhodesian form.

Laboratory Diagnosis (All Species)

Routine Methods

Blood can be collected from either finger stick or venipuncture (use EDTA anticoagulant). Multiple thick and thin blood films should be made for examination, and multiple blood examinations should be completed before trypanosomiasis is ruled out. Parasites will be found in large numbers in the blood during the febrile period and in small numbers when the patient is afebrile. In addition to thin and thick blood films, a QBC concentration method is recommended to detect the parasites. Parasites can be detected on thin blood films with a detection limit at approximately 1 parasite/200 microscopic fields (high dry power magnification, ×400) and thick blood smears when the numbers are greater than 2000/mL, and when they are greater than 100/mL with hematocrit capillary tube concentration

Nucleic Acid Detection

Reference laboratories have used nucleic acid–based tests to detect infections and differentiate species, but these methods are not routinely used in the field. The PCR-based methods have not been standardized, and validation studies have not been performed. Few studies have compared the various PCR methods used for diagnostic purposes. In general, these tests are not available in the routine laboratory.

Antigen Detection

A simple and rapid test, the card indirect agglutination trypanosomiasis test (CATT), and LATEX/*T.b. gambiense* are available, primarily in areas of endemic infection, for the detection of circulating antigens in persons with African trypanosomiasis. These tests are not available for use in the United States. The sensitivity of the test (95.8% for *T. brucei gambiense* and 97.7% for *T. brucei rhodesiense*) is significantly higher than those for lymph node puncture, microhematocrit centrifugation, and cerebrospinal fluid (CSF) examination after single and double centrifugation. Its specificity is excellent, and it has a high positive predictive value.

Antibody Detection

Serologic techniques that have been widely used for epidemiologic screening include indirect fluorescent antibody assays (IFA), enzyme-linked immunosorbent assays (ELISAs), the indirect hemagglutination test, and the card agglutination trypanosomiasis test. A major problem in endemic areas is that individuals have elevated antibody levels attributable to exposure to animal trypanosomes that are noninfectious to humans. Serum and CSF IgM concentrations are of diagnostic value. CSF antibody titers should be interpreted with caution because of the lack of reference values and the possibility that the CSF will contain serum as the result of a traumatic tap. In addition, antibodies to galactocerebrosides and neurofilaments along with elevated interleukin-10 may also indicate CNS involvement if present in the CSF.

Therapy

All drugs used in the therapy of African trypanosomiasis are toxic and require prolonged administration. Treatment should be started as soon as possible, and the antiparasitic drug selected depends on whether the CNS is involved. Suramin or pentamidine isethionate can be used when the CNS is not involved. Melarsoprol, a toxic trivalent arsenic derivative, is effective for both blood and CNS stages but is recommended for treatment of late-stage sleeping sickness. Eflornithine (DL-alpha-difluoromethylornithine; DFMO) has been used for more than 10 years for melarsoprol-resistant *T. brucei gambiense* infection with or without CNS involvement. Any individual treated for African trypanosomiasis should be monitored for 2 years after completion of therapy.

American Trypanosomiasis

American trypanosomiasis (Chagas disease) is a zoonosis occurring throughout the American continent and involves reduviid bugs/kissing bugs (vectors) living in close association with human reservoirs (dogs, cats, armadillos, opossums, raccoons, and rodents). Sylvatic cycles of *T. cruzi* transmission extend from southern Argentina and Chile to northern California. Transmission to humans depends on the defecation habits of the insect vector. In areas where the local species of reduviid bug does not ordinarily defecate while feeding, there are no human infections. This may explain why there are few human infections in the United States, even though sylvatic infections are known to occur in the southern states. A number of **autochthonous** (indigenous) cases have been reported in the United States, in both Texas and California. The reduviid species involved in transmitting the infection to humans vary with the geographic area. A very serious problem is disease acquisition through blood transfusion and organ transplantation.

A large number of patients with positive serologic results can remain asymptomatic. Patients can present with either acute or chronic disease.

Trypanosoma cruzi

General Characteristics

Trypomastigotes (Table 48.4) are ingested by the reduviid bug (triatomids, kissing bugs, or conenose bugs) as it obtains a blood meal. The trypomastigotes transform into epimastigotes (Fig. 48.10) that multiply in the posterior portion of the bug's midgut. After 8 to 10 days, trypomastigotes develop from the epimastigotes. Humans contract Chagas disease when the reduviid bug defecates while taking a blood meal and the parasites in the feces are rubbed or scratched into the bite wound or onto mucosal surfaces.

In humans, *T. cruzi* is found in two forms: **amastigotes** and trypomastigotes (Fig. 48.10). The trypomastigote form is present in the blood and infects the host cells. The amastigote form multiplies within the cell, eventually destroying the cell, and both amastigotes and trypomastigotes are released into the blood.

The trypomastigote (Fig. 48.11A) is approximately 20 µm long, and it usually assumes a C or U shape in stained blood films. Trypomastigotes occur in the blood in two forms: a long slender form and a short stubby one. The nucleus is situated in the center of the body, with a large oval kinetoplast located at the posterior extremity. A flagellum arises from the kinetoplast and extends along the outer edge of an undulating membrane until it reaches the anterior end of the body, where it projects as a free flagellum. When the trypomastigotes are stained with any of the blood stains, the cytoplasm stains blue and the nucleus, kinetoplast, and flagellum stain red or violet.

When the trypomastigote penetrates a cell, it loses its flagellum and undulating membrane and divides by binary fission to form an amastigote (Fig. 48.9). The amastigote continues to divide and eventually fills and destroys the infected cell. Both amastigote and trypomastigote forms are released from the cell. The amastigote is indistinguishable from those found in leishmanial infections. It is 2 to 6 µm in diameter and contains a large nucleus and rod-shaped kinetoplast that stains red or violet with bloodstains. The cytoplasm stains blue. Only the trypomastigotes are found free in the peripheral blood.

Pathogenesis and Spectrum of Disease

The clinical stages associated with Chagas disease are categorized as acute, indeterminate, and chronic. The acute stage represents the initial encounter of the patient with the parasite, whereas the chronic phase is the result of late sequelae. In children younger than the age of 5 years, the disease is seen in its acute form, whereas in older children and adults, the disease is milder and is commonly diagnosed in the subacute or chronic form. The incubation period in humans is approximately 7 to 14 days but is somewhat longer in some patients.

Acute symptoms occur 2 to 3 weeks after infection and include high fevers, enlarged spleen and liver, myalgia, erythematous rash, acute myocarditis, lymphadenopathy, keratitis, and subcutaneous edema of the face, legs, and feet. There may be symptoms of CNS involvement, which carry a very poor prognosis. Myocarditis is confirmed by electrocardiographic changes, tachycardia, chest pain, and weakness. Amastigotes proliferate within the cardiac muscle cells and destroy them, leading to conduction defects and a loss of heart contractility (Fig. 48.9). Death may result from myocardial insufficiency or cardiac arrest. In infants and very young children, fatal swelling of the brain can develop.

The chronic stage may be initially asymptomatic (indeterminate stage), and even though parasites are rarely seen in blood films, transmission by blood transfusion is a serious problem in endemic areas.

Chronic Chagas disease may develop years after undetected infection or after the diagnosis of acute disease. Approximately 30% of patients may develop chronic Chagas disease, including cardiac changes and enlargement of the colon and esophagus. Megacolon results in constipation, abdominal pain, and the inability to discharge feces. There may be acute obstruction leading to perforation, septicemia, and death. However, the most common clinical signs of chronic Chagas disease involve the heart, where enlargement of the heart and conduction changes are commonly seen.

Laboratory Diagnosis

Routine Methods. Trypomastigotes may be detected in blood by using thick and thin blood films or the buffy coat concentration technique (QBC). Any of the blood stains can be used for both amastigote and trypomastigote stages.

Nucleic Acid Detection. Referral laboratories have used molecular methods to detect infections with as few as one trypomastigote in 20 mL of blood, but these methods are not routinely used in the field. The PCR-based methods have not been standardized, and validation studies have not been performed. PCR-based methods have been used to monitor parasite load and therapy. As with African trypanosomiasis, there have been few studies that have compared the various PCR methods used for diagnostic purposes. In general, these tests are not available in the routine laboratory.

Xenodiagnosis. In endemic areas where reduviid bugs are readily available, xenodiagnosis can be used to detect light infections; this technique is helpful in the diagnosis of chronic infections when there are few trypomastigotes in the blood. Trypanosome-free bugs are allowed to feed on individuals suspected of having Chagas disease. If organisms are ingested in the blood meal, the parasites will multiply and be detected in the bug's intestinal contents, which should be examined monthly for flagellated forms over a period of 3 months.

Antigen Detection. Immunoassays have been used to detect antigens in urine and sera in patients with congenital infections and those with chronic Chagas disease. Antigen detection can also be valuable for early diagnosis and for diagnosis of chronic cases in patients with conflicting serologic test results.

Serologic Tests. Serologic tests for antibody detection include complement fixation, IFA, indirect hemagglutination tests, and ELISA. The use of synthetic peptides and recombinant antigens has improved the sensitivity and specificity of these tests. However, depending on the antigens used, cross-reactions have been noted to occur in patients with *T. rangeli* infection, leishmaniasis, toxoplasmosis, and hepatitis. The sensitivity and specificity of serologic tests for screening blood donors has improved; single-assay screening may be acceptable rather than the two-assay screening methods previously recommended.

Histology. In tissue, amastigotes can be differentiated from fungal organisms because they will not stain positive with periodic acid-Schiff (PAS), mucicarmine, or silver stains. Although the amastigotes of *T. cruzi* look like those in leishmaniasis, patient history, including geographic and/or travel history, and confirmation of organisms in striated muscle rather than reticuloendothelial tissues are very strong evidence for *T. cruzi* rather than *Leishmania donovani* as the causative agent.

Therapy

Nifurtimox (Lampit) and benznidazole (Radamil) reduce the severity of acute Chagas disease. Other drugs, allopurinol, fluconazole, itraconazole, and ketoconazole, have been used to treat a limited number of patients. However, drug therapy has little effect on reducing the progression of chronic Chagas disease. In some cases, surgery has been successfully used to treat cases of chagasic heart disease, megaesophagus, and megacolon.

Leishmania spp.

Leishmaniasis is caused by more than 20 species of the protozoan genus *Leishmania*. Although most laboratories rely on geographic distribution and clinical presentation for the identification of isolates, species differentiation is now based on molecular techniques. Depending on the species involved, infection with *Leishmania* spp. can result in cutaneous, diffuse cutaneous, diffuse, mucocutaneous, or visceral disease. Published disease burden estimates place leishmaniasis second in mortality and fourth in morbidity among all tropical diseases. Leishmaniasis is classified as one of the "most neglected diseases," based on its association with poverty and on the limited resources invested in diagnosis, treatment, and control. The WHO estimates that up to 1 million cases of cutaneous leishmaniasis (CL) and 50,000 to 90,000 cases of visceral leishmaniasis (VL) occur every year in 88 countries. Estimates indicate that approximately 350 million people are at risk for acquiring leishmaniasis, with 12 million currently infected.

Cases of leishmaniasis are seen each year in the United States and can be attributed to immigrants from countries with endemic infection, military personnel, and American travelers. Another concern is the potential for more infections occurring in areas of endemic infection in Texas and Arizona.

General Characteristics

The parasite has two distinct phases in its life cycle: **amastigote** and **promastigote** (Table 48.6, Fig. 48.12). The amastigote form is an intracellular parasite in the cells of the reticuloendothelial system and is oval shaped, measures 1.5 to 5 µm, and contains a nucleus and kinetoplast. *Leishmania* spp. exist as the amastigote in humans and as the promastigote in the insect host. The vector for all forms of human disease is the female phlebotomine sandfly. As the infected sandfly takes a blood meal, promastigotes are introduced into the human host. Depending on the species, the parasites then move from the bite site to the organs within the **reticuloendothelial system** (bone marrow, spleen, liver) or to the macrophages of the skin or mucous membranes.

More than 90% of **cutaneous leishmaniasis** cases occur in Afghanistan, Algeria, Iran, Iraq, Saudi Arabia, Syria, Brazil, and Peru. There has been an increase in the number of cases among military personnel deployed in Afghanistan, Iraq, and Kuwait. Autochthonous (native to origin) human infections have been described in Texas. Most of the cases of **mucocutaneous leishmaniasis** occur in Bolivia, Brazil, and Peru. More than 90% of the cases of **visceral leishmaniasis** are found in Brazil, East Africa, and South-East Asia.

In endemic areas with leishmaniasis, coinfection with human immunodeficiency virus (HIV)-positive patients is common. If coinfected patients are severely immunocompromised, up to 25% will die shortly after being diagnosed.

Pathogenesis and Spectrum of Disease

The first sign of cutaneous disease is a lesion (generally a firm, painless papule) at the bite site. Although a single lesion may appear insignificant, multiple lesions or disfiguring facial lesions may be devastating for the patient. Usually, the secondary lesions will have a similar appearance and will progress at the same speed. The original lesion may remain as a flattened plaque or may progress to a shallow ulcer. As the ulcer enlarges, it produces exudate and often becomes secondarily infected with bacteria or other organisms.

In mucocutaneous leishmaniasis, the primary lesions are similar to those found in CL. Untreated primary cutaneous lesions may develop into the mucocutaneous form in up to 80% of the cases. Dissemination to the nasal or oral mucosa may occur from the active primary lesion or may occur years later after the original lesion has healed. These mucosal lesions do not heal spontaneously, and secondary bacterial infections are common and may be fatal. The mucocutaneous form of leishmaniasis is primarily found in Brazil, Bolivia, and Peru.

Diffuse leishmaniasis, including diffuse CL, is characterized as a nodular disease that results in high parasitemia due to an inappropriate antibody response of the infected patient. This is significantly different than disseminated

TABLE 48.6 **Features of Human Leishmanial Infections**[a]

Species	Disease Type	Humoral Antibodies	Delayed Hypersensitivity	Parasite Quantity	Recommended Specimen
Leishmania donovani complex	VL	Abundant	Absent	Absent	Bone marrow, spleen, tissue
	CL, MCL	Variable	Present	Present	Skin or mucosal biopsy
	DL	Variable	Variable	Variable	Skin or tissue biopsy
Leishmania tropica complex	CL, DCL, MCL	Variable	Present	Present	Skin or mucosal biopsy, tissue
Leishmania major complex	CL	Present	Present	Present	Skin biopsy
Leishmania mexicana complex	CL, MCL	Variable	Present	Present	Skin or mucosal biopsy
	DCL	Variable	Absent	Abundant	Skin or mucosal biopsy
Leishmania braziliensis complex	CL	Present	Present	Present	Skin biopsy
	MCL	Present	Present	Scant	Skin or mucosal biopsy
Leishmania guyanensis complex	CL, MCL	Present	Present	Present	Skin or mucosal biopsy
Leishmania enrietti complex	CL, DL, VL	ND	ND	ND	Skin or tissue biopsy

CL, Cutaneous leishmaniasis; *DCL*, diffuse cutaneous leishmaniasis; *DL*, diffuse leishmaniasis; *MCL*, mucocutaneous leishmaniasis; *VL*, visceral leishmaniasis; *ND*, no data available.

[a] For culture, specimens must be collected aseptically; in older lesions, the number of parasites may be scant and difficult to recover.

leishmaniasis that demonstrates a very low parasitemia and an inappropriate cell-mediated response by the patient's immune system.

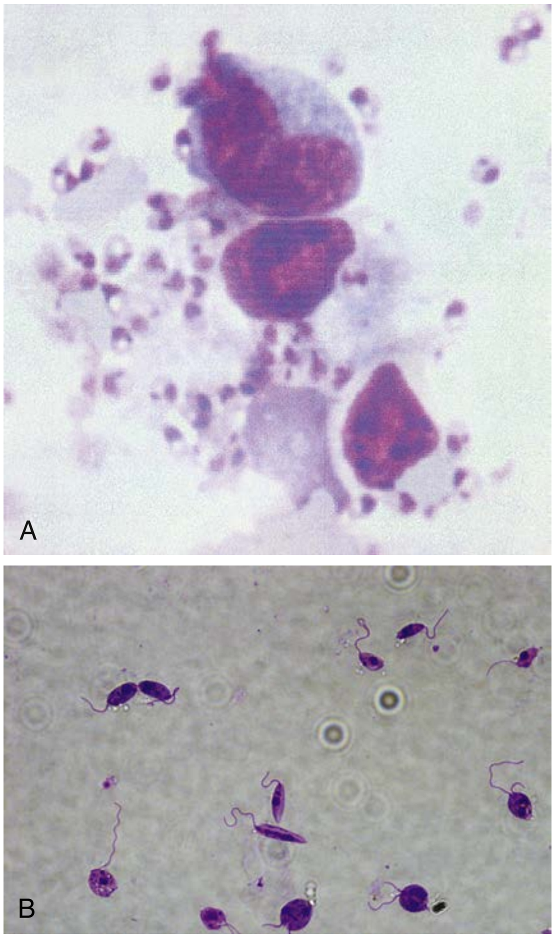
VL, also known as **kala azar**, has an incubation period that ranges from 10 days to 2 years but typically is 2 to 4 months. Common symptoms include fever, anorexia, malaise, weight loss, and, frequently, diarrhea. Clinical signs include nontender enlarged liver and spleen, swollen lymph nodes, and occasional acute abdominal pain. Darkening of facial, hand, foot, and abdominal skin is often seen in light-skinned persons in India. Death may occur after a few weeks or after 2 to 3 years in chronic cases. Most infected individuals will be asymptomatic or have very few or minor symptoms that will resolve without therapy. Since 1990, an increase in leishmaniasis in organ transplant recipients has been documented. Most of these cases have been VL.

Laboratory Diagnosis

After the cutaneous lesion exudate is removed, these lesions should be thoroughly cleaned with 70% alcohol. Specimens can be collected from the margin of the lesion by aspiration, scraping, or punch biopsy or by making a slit with a scalpel blade. Smears can be prepared from the material obtained and stained with any of the bloodstains; biopsy specimens should also be submitted for routine histologic examination. Specimens for visceral disease include lymph node aspirates, liver biopsy specimens, bone marrow specimens, and buffy coat preparations of venous blood. Amastigotes within reticuloendothelial cells have been detected in a number of different specimen types from HIV-positive patients. Stained smears can be examined for the presence of the amastigotes. Although the specimens can be cultured using special techniques, these procedures are not routinely available.

Nucleic Acid Detection

A single FDA-approved test for the detection of CL, SMART Leish PCR (Cepheid, Sunnyvale, CA) is available in the United States. Often the level of parasitemia in CL or mucocutaneous leishmaniasis is quite low, making identification difficult microscopically. PCR methods have excellent sensitivity and specificity for direct detection, for identification of causative species, and for assessment of treatment efficacy, although they are not routinely available in most laboratories.



• Fig. 48.12 (A) *Leishmania donovani*. (B) *L. donovani* amastigotes and promastigotes.

Serologic Tests

A rapid immunochromatographic dipstick test using the recombinant K39 antigen has become available for the qualitative detection of total anti–*Leishmania* immunoglobulins.

In patients with severe VL (kala-azar), there is a characteristic hypergammaglobulinemia, including both IgG and IgM. In highly suspect patients for the diagnosis of VL (assuming they are immunocompetent), if hypergammaglobulinemia is not present, this may be used to rule out the original diagnosis. Although serologic testing is available from some reference centers such as the CDC, serologic assays are not very useful for the diagnosis of mucocutaneous and VL.

Therapy

In simple CL, lesions usually heal spontaneously, although treatment options include cryotherapy, heat, photodynamic therapy, surgical excision of lesions, and chemotherapy. Standard therapy consists of injections of antimonial compounds; however, relapse is quite common, and the patient response varies depending on the infecting *Leishmania* species and type of disease.

Patients clinically cured of mucocutaneous infection continue to be PCR positive for many years after therapy; this disease is characterized by chronicity, latency, and metastasis with mucosal membrane involvement.

For many years, pentavalent antimony compounds have been the drugs of choice for the treatment of VL. However, with the first reports of primary treatment failures in the mid-1990s, additional drugs have been used and include lipid-associated amphotericin B for Mediterranean and Indian disease.

Visit the Evolve site for a complete list of procedures, review questions, and case studies.

Chapter Review

1. *Babesia* is an organism that has been implicated in disease from both splenectomized and nonsplenectomized patients. Morphologically, the parasites resemble:
   a. *Plasmodium falciparum* rings
   b. *Leishmania donovani* amastigotes
   c. *Trypanosoma cruzi* trypomastigotes
   d. *Plasmodium vivax* developing rings
   e. *Trypanosoma brucei gambiense* trypomastigotes
2. A 60-year-old Brazilian patient with cardiac irregularities and congestive heart failure suddenly dies. Examination of the myocardium revealed numerous amastigotes, an indication that the cause of death was most likely:
   a. Leishmaniasis with *Leishmania donovani*
   b. Leishmaniasis with *Leishmania braziliensis*
   c. Trypanosomiasis with *Trypanosoma brucei gambiense*
   d. Trypanosomiasis with *Trypanosoma cruzi*
   e. Any of the above
3. *Plasmodium vivax* and *Plasmodium ovale* are similar because they:
   a. Exhibit Schüffner dots and have a true relapse in the life cycle
   b. Have no malarial pigment and multiple rings
   c. Commonly have appliqué forms in the red cells
   d. Have true stippling, do not have a relapse stage, and infect old red cells
   e. Have a 72-hour periodicity cycle in the RBCs
4. Diseases caused by *Trypanosoma brucei gambiense* and *Trypanosoma brucei rhodesiense* have distinct differences, which include:
   a. The morphology of the trypomastigotes, which looks very different
   b. The symptoms and severity of the overall illness
   c. The presence or absence of the undulating membrane in the trypomastigote
   d. The totally different continents in which they appear
   e. The different staining characteristics on a thin blood film
5. **True or False**

   _____ Although Giemsa stain is recommended for staining thick and thin blood films, any of the bloodstains can be used.

   _____ *Trypanosoma cruzi* and *Leishmania* spp. are now endemic within certain areas of the United States.

   _____ The fifth human malaria, *Plasmodium knowlesi,* is considered relatively harmless and can be easily identified and differentiated from the other *Plasmodium* spp.

   _____ Of the American trypanosome or African trypanosome infections, those caused by *Trypanosoma brucei* spp. are known to cause severe problems in tissue transplantation.

   _____ In addition to transmission by insect vectors, transmission of blood parasites can be caused by blood transfusions and shared needles from infected individuals.
6. **Matching:** *Match each term with the correct description.*

_____ "band form" trophozoites
_____ multiple rings per RBC, not endemic in United States
_____ endemic within United States
_____ causes Chagas disease
_____ military returning from Afghanistan and Iraq
_____ considered a STAT procedure
_____ enlarged infected RBC, ameboid trophozoites
_____ mimics both *P. falciparum* and *P. malariae*
_____ one set of malaria blood films
_____ causes cutaneous and visceral disease

a. *Babesia* spp.
b. *Plasmodium malariae*
c. thick, thin blood films
d. *Leishmania* spp.
e. *Plasmodium vivax*
f. *Plasmodium falciparum*
g. *Trypanosoma cruzi*
h. *Leishmania* skin lesions
i. *Plasmodium knowlesi*
j. insufficient for diagnosis

Protozoa From Other Body Sites

OBJECTIVES

1. Describe the distinguishing morphologic characteristics, clinical disease, basics of life cycle (source, stages of infectivity), and laboratory diagnosis for amoebae, flagellates, and coccidia.
2. Compare and contrast the morphologic forms of the *Naegleria* trophozoites, including specimens used for identification.
3. Compare and contrast *Naegleria fowleri, Balamuthia mandrillaris,* and *Acanthamoeba* spp., including routes of transmission, specimens, risk factors, and disease presentation.
4. Compare and contrast the specimen requirements and morphologic characteristics of *Trichomonas vaginalis* and *Trichomonas tenax.*
5. Identify the various morphologic forms of *Toxoplasma gondii* and correlate those with the clinical presentation of the infection (acute, chronic, and congenital).
6. Describe the various individual populations at risk for infection with *Toxoplasma* spp. and the disease symptoms and pathogenesis for each.
7. Define the following terms in relation to the appropriate parasite discussed in this chapter: axostyle, bradyzoite, tachyzoite, ectocyst, mesocyst, endocyst, and oocyst.

PARASITES TO BE CONSIDERED

- Amoebae, flagellates (other body sites)
- Amoebae
  - *Naegleria fowleri*
  - *Acanthamoeba* spp.
  - *Balamuthia mandrillaris*
  - *Paravahlkampfia francinae*
  - *Sappinia pedata*
- Flagellates
  - *Trichomonas vagina lis, Trichomonas tenax*
- Coccidia (other body sites)
- Coccidia
  - *Toxoplasma gondii*

Free-Living Amoebae

Infections caused by small, free-living amoebae belonging to the genera *Naegleria, Acanthamoeba,* and *Balamuthia* are generally not very well-known or recognized clinically but are often fatal in both immunocompetent and immunocompromised patients. In addition, methods for laboratory diagnosis are not routinely offered by most laboratories. However, hundreds of cases of **primary amoebic meningoencephalitis (PAM)** caused by *Naegleria fowleri* and **granulomatous amoebic encephalitis (GAE)** caused by *Acanthamoeba* spp. and *Balamuthia mandrillaris* (including several cases in patients with acquired immunodeficiency syndrome [AIDS]) have been documented. Other infections caused by these organisms result in *Acanthamoeba* keratitis, related primarily to poor lens care in contact lens wearers. Additionally, both *Acanthamoeba* spp. and *B. mandrillaris* can cause cutaneous infections in humans. *Sappinia pedata,* a free-living amoeba normally found in soil contaminated with the feces of elk and buffalo, was identified in an excised brain lesion from a 38-year-old immunocompetent man who developed a frontal headache, blurry vision, and loss of consciousness after a sinus infection. Additionally, *Paravahlkampfia francinae,* a species of the free-living amoeba genus *Paravahlkampfia,* was isolated from the cerebrospinal fluid (CSF) of a patient with a headache, sore throat, and vomiting, symptoms typical of PAM caused by *N. fowleri* from the environment.

Naegleria fowleri

General Characteristics

Although 30 species of *Naegleria* have been recognized based on sequencing data, *N. fowleri* is the only one that has been isolated in cases of amebic meningoencephalitis. There are both trophozoite and cyst stages in the life cycle of *N. fowleri,* with the stage present primarily dependent on environmental conditions. Trophozoites can be found in water or moist soil and can be maintained in tissue culture or other artificial media. The amoebae may enter the nasal cavity by inhalation or aspiration of water, dust, or aerosols containing the trophozoites or cysts. *N. fowleri* is incapable of survival in clean, chlorinated water. After inhalation or aspiration, the organisms then penetrate the nasal mucosa, probably through phagocytosis of the olfactory epithelial cells, and migrate via the olfactory nerves to the brain (Fig. 49.1).

The trophozoites can occur in two forms: amoeboid and flagellate (Table 49.1 and Fig. 49.2). The size ranges from 7 to 35 µm. The diameter of the rounded forms is usually 15 µm. There is a large, central karyosome and no peripheral nuclear chromatin. The cytoplasm is somewhat granular and contains vacuoles. The amoeboid organisms change to the transient pear-shaped flagellate form when transferred from culture or teased from tissue into water and maintained at a temperature of 27°C to 37°C. These flagellate forms do not divide, but when the flagella are lost, the amoeboid forms resume reproduction. Cysts are generally round, measuring 7 to 15 µm with a thick double wall.

Pathogenesis and Spectrum of Disease

PAM caused by *N. fowleri* is an acute, suppurative infection of the brain and meninges (Table 49.1). With extremely rare exceptions, the disease is rapidly fatal in humans. The period between organism contact and onset of symptoms—such as fever, headache, and rhinitis—varies from a few days to 2 weeks. Early symptoms include vague upper respiratory tract distress, headache, lethargy, and occasionally olfactory problems. The acute phase includes sore throat; a stuffy, blocked, or discharging nasal cavity; and severe headache. Progressive symptoms include pyrexia, vomiting, and stiffness of the neck. Mental confusion and coma usually occur approximately 3 to 5 days before death, which is usually caused by cardiorespiratory arrest and pulmonary edema.

PAM resembles acute bacterial meningitis, and these conditions may be difficult to differentiate. Unfortunately, if the CSF Gram stain is interpreted incorrectly as a false positive, the resulting antibacterial therapy does not affect the amoebae and the patient will usually die within a few days.

Laboratory Diagnosis

Routine Methods

Clinical and laboratory data usually cannot be used to differentiate pyogenic meningitis from PAM. A high index of suspicion is often critical for early diagnosis. Most cases are associated with exposure to contaminated water through swimming or bathing. There is normally an incubation period of 1 day to 2 weeks and then a course of 3 to 6 days, most often ending in death.

Analysis of the CSF may demonstrate a normal or decreased glucose level and increased protein concentration. The leukocyte count will range from several hundred to greater than 20,000/mm^3. Although Gram stains and

bacterial cultures of CSF will be negative, serious complications can occur as the result of incorrect therapy if false-positive Gram stains are reported. CSF may include multiple polymorphonuclear (PMN) cells in the absence of bacteria.

A confirmed diagnosis is made by the identification of amoebae in the CSF or in biopsy specimens. CSF should be placed on a slide under a cover slip and observed for motile trophozoites; smears can be stained with any of the blood smear stains. It is important not to mistake leukocytes for actual organisms or vice versa. This type of misidentification often occurs when a counting chamber is used because the amoebae sink to the bottom and round up; hence, the recommendation is to use a regular microscope slide and cover slip. Depending on the temperature and lag time between specimen collection and examination, motility may vary. Microscope slides may be warmed slightly to improve motility. The most important differential characteristic is the spherical nucleus with a large karyosome.

Specimens should never be refrigerated before examination, and CSF should be centrifuged at a slow speed (250 *g*). If *N. fowleri* is the causative agent, only trophozoites are normally seen, whereas cysts and trophozoites may be present with *Acanthamoeba* spp.

Other Methods

Most cases are diagnosed at autopsy; confirmation of tissue findings must include culture and/or special staining with monoclonal reagents in indirect fluorescent antibody procedures. Organisms can be cultured on nonnutrient agar plated with nonmucoid strains of *Klebsiella pneumoniae, Klebsiella aerogenes, Enterobacter cloacae*, and *Escherichia coli*. In tissue, the amoebae can be identified using indirect immunofluorescence and immunoperoxidase techniques. Direct fluorescent antibody staining of CSF smears may assist in the identification of *N. fowleri* in the central nervous system (CNS).

Serologic testing currently has no role in the diagnosis of acute PAM, since the time from exposure to the development of symptoms and death is so rapid the immune response is negligible. Nucleic acid methods are available for tracking contaminated environmental sources but are not available in clinical laboratories. Flow cytometry has been used for the identification and differentiation of *N. fowleri* and *Acanthamoeba* species.

Therapy

Although many antimicrobial and antiparasitic drugs have been screened for activity against *N. fowleri,* only a few patients have recovered after receiving intrathecal (injection into the spinal canal) and intravenous injections of amphotericin B or the latter in combination with miconazole. Unfortunately, delay in diagnosis and the fulminant nature of PAM result in few survivors.

Acanthamoeba spp.

General Characteristics

Unlike *N. fowleri, Acanthamoeba* spp. do not have a flagellate stage in the life cycle, only the trophozoite and cyst. Several species of *Acanthamoeba,* including *A. culbertsoni, A. polyphaga, A. castellanii, A. astronyxis, A. hatchetti, A. rhysodes, A. divionensis, A. lugdunensis, A. quina,* and *A. lenticulata,* are implicated in human disease and are not differentiated clinically. These parasites cause GAE primarily in immunosuppressed, chronically ill, or otherwise debilitated individuals. These patients usually have no relevant history involving freshwater exposure. *Acanthamoeba* spp. also cause amoebic keratitis. It is estimated that the incidence in the United States may be one to two cases per million contact lens users.

Motile organisms have spinelike pseudopods; there is a wide organism size range (25 to 40 µm), with the average diameter of the trophozoites being 30 µm. The nucleus has the typical large karyosome, similar to that found in *N. fowleri.* This morphologic characteristic can be seen on a wet preparation.

The cysts are usually round with a single nucleus; they also have a large karyosome, as in the trophozoite nucleus. The double wall is usually visible, with the slightly wrinkled outer cyst wall and a polyhedral inner cyst wall. This cyst morphology is identifiable in organisms cultured on agar plates.

Pathogenesis and Spectrum of Disease

Granulomatous Amoebic Encephalitis

Meningoencephalitis caused by *Acanthamoeba* spp. may present as an acute suppurative inflammation of the brain and meninges similar to *N. fowleri* infection. The incubation period of GAE is unknown; several weeks or months are probably necessary to establish disease. The clinical course tends to be subacute or chronic and is usually associated with trauma or underlying disease and not with swimming. GAE may present with symptoms of confusion, dizziness, drowsiness, nausea, vomiting, headache, lethargy, stiff neck, seizures, and sometimes **hemiparesis.** Unlike PAM caused by *N. fowleri,* both trophozoites and cysts are found throughout the tissue. In addition, dissemination to other tissues—such as the liver, kidneys, trachea, and adrenals—can occur in immunocompromised individuals; additional unusual sites of dissemination include the ear and necrotic bone from a bone graft of the mandible. Some patients, especially those with AIDS, can develop erythematous nodules, chronic ulcerative skin lesions, or abscesses. Biopsies of these lesions should be examined for the presence of *Acanthamoeba* if GAE is suspected.

Keratitis

Acanthamoeba spp. also cause keratitis, uveitis, and corneal ulceration. Clinicians need to consider acanthamebic infection in the differential diagnosis of eye infections that are not responding to bacterial, fungal, or viral therapy. These infections are often caused by direct exposure of the eyes to contaminated materials or solutions. Use of contact lenses is the leading risk factor for keratitis. The use of homemade saline solutions, poor contact lens hygiene, and corneal abrasions are linked to disease transmission. A contact lens can act as a mechanical vector for transport of amoebae present in the storage case onto the cornea. Subsequent multiplication and invasion of the tissue may occur. The pathogenesis of the *Acanthamoeba* infection is due to the migration and adherence between the mannose-binding protein on the organism and the mannose-containing glycoproteins on the mucosal surfaces of the eye or other tissues. The organism releases oxygen radicals and proteases, which destroy connective tissue. Decreased corneal sensation has contributed to the misdiagnosis of *Acanthamoeba* keratitis as herpes simplex keratitis. *Acanthamoeba* keratitis may be present as a secondary or opportunistic infection in patients with herpes simplex keratitis. Unfortunately, as a result, treatment can be delayed for 2 weeks to 3 months.

Cutaneous Infections

Acanthamoeba spp. skin infections appear as hard erythematous nodules or skin lesions. The condition affects immunocompromised patients more often than immunocompetent individuals. The lesions initially appear as purulent papulonodules that develop into indurated nonhealing ulcers. It is unclear if the ulcers are the primary disease or systemic disease following hematogenous spread of the amoebae. Histologic analysis of the lesions demonstrates extensive tissue necrosis and the presence of both trophozoites and cysts. Cutaneous infections can reach a mortality rate of approximately 75% in the absence of systemic CNS disease.

Laboratory Diagnosis

Routine Methods

The most effective culture approach uses nonnutrient agar plates with Page saline (sodium phosphate, potassium phosphate, sodium chloride, magnesium phosphate, and calcium chloride) and an overlay growth of *Escherichia coli,* on which the amoebae feed. The nonnutrient agar plates and Page saline are available from Hardy Diagnostics, Santa Maria, CA. Amoeba may be detected in as little as 3 days, but negative cultures should be retained for up to 10 days. Amoeba have also been recovered from clinical specimens inoculated to buffered charcoal yeast extract agar (BCYE), tryptic soy agar (TSA) supplemented with 5% horse, rabbit, or sheep blood. Nonnutrient agar overlaid with *Pseudomonas aeruginosa, Klebsiella aerogenes*, or *Stenotrophomonas maltophilia* demonstrates good recovery of both cysts and trophozoites.

Histologic tissue stains are effective. Cysts isolated from cultures can be stained with Gomori silver methenamine, periodic acid–Schiff (PAS), and calcofluor white. Identification of acanthamoebae in ocular samples and other tissues can be difficult, even for trained laboratory professionals; in histologic preparations, the organisms appear similar to keratoplasts as well as neutrophils and monocytes. It has been estimated that up to 70% of clinical *Acanthamoeba* keratitis cases are misdiagnosed as viral keratitis. The average time to diagnosis of keratitis attributable to *Acanthamoeba* infection can average 2.5 weeks longer for noncontact lens wearers than for contact lens users.

Other Methods

CSF or bronchoalveolar lavage (BAL) fluid cytospin preparations can be used to look for amoebae in patients with GAE or respiratory symptoms. The characteristic morphology of the *Acanthamoeba* trophozoites, such as the prominent nucleolus, contractile vacuole, and cytoplasmic vacuoles, can be seen more easily using trichrome or hematoxylin and eosin stains on fixed preparations after cytocentrifugation. The organism may also be cultured on agar plates similarly to *Naegleria* spp. The agar plate should be microscopically examined daily for the presence of amoebae. If an organism is present, the agar should be scraped and inoculated into 1 mL of distilled water and incubated at 37°C and examined periodically for 1 hour. The physician should be informed immediately if an amoeba is present.

In the differential diagnosis of GAE, other space-occupying lesions of the CNS (e.g., toxoplasmosis, tuberculosis, fungal infections, and GAE secondary to *Balamuthia*) must also be considered. Predisposing conditions include Hodgkin disease, diabetes, alcoholism, pregnancy, and corticosteroid therapy. Organisms have also been found in the adrenal gland, brain, eyes, kidneys, liver, pancreas, skin, spleen, thyroid gland, and uterus.

In infections caused by *Acanthamoeba* spp., PAS stains the cyst wall red and methenamine silver stains the cyst black. Normally, *Naegleria* and *Acanthamoeba* isolates are identified to the species level by a reference laboratory, such as the Centers for Disease Control and Prevention (CDC), using indirect fluorescent antibody procedures with a monoclonal or polyclonal antibody.

Therapy

Disseminated Infections

Trophozoites and cysts of *Acanthamoeba* isolates vary in their sensitivity to antimicrobial agents. Successful treatments for keratitis typically consist of a combination of medications. Steroids should not be used to treat cases of GAE, as the medications tend to exacerbate the infection. However, most patients diagnosed with GAE succumb to the infection despite treatment with several drug combinations. *In vitro* testing confirms strain and species differences in sensitivity; however, there is no guarantee that the medications are clinically effective.

Acanthamoeba Keratitis

Prompt treatment of keratitis is essential. Patients should be seen by an ophthalmologist immediately. If the infection is rapidly and properly diagnosed debridement may be sufficient for recovery. If treatment is delayed and the organisms have invaded the cornea or other tissues, therapy may be required for a year or longer. Various prescription eye medications are available.

Balamuthia mandrillaris

General Characteristics

B. mandrillaris is uncommon and was believed to be a harmless soil organism, with no relevance for infecting mammals. Hundreds of cases of human amoebic encephalitis worldwide have been identified, with about half of the cases diagnosed within the United States. Death can occur from a week to several months after the onset of symptoms. Patients eventually die of a massive CNS infection. Genotyping studies indicate that lethal infections caused by *B. mandrillaris* are caused by a single species with a global distribution.

The life cycle is similar to that of *Acanthamoeba* spp.; like *Acanthamoeba* spp., *Balamuthia* does not have a flagellated stage in the life cycle. Both trophozoites and cysts are found in CNS tissue, and their sizes are similar to those of *Acanthamoeba* trophozoites and cysts. It is difficult to differentiate *Balamuthia* from *Acanthamoeba* spp. in tissue sections under a light microscope. The *Balamuthia* trophozoite and cyst is approximately 30 to 120 µm in diameter. Using electron microscopy, the cysts are characterized by three layers in the cyst wall: an outer wrinkled **ectocyst,** a middle structureless **mesocyst,** and an inner thin **endocyst.** Under light microscopy, they appear to have two walls: an outer irregular wall and an inner round wall. In some cases, *Balamuthia* trophozoites in tissue sections appear to have more than one nucleolus in the nucleus. In such cases, it may be possible to distinguish *Balamuthia* amoebae from *Acanthamoeba* organisms based on nuclear morphology, because *Acanthamoeba* trophozoites have only one nucleolus.

Pathogenesis and Spectrum of Disease

The disease is very similar to GAE caused by *Acanthamoeba* spp. The clinical presentation is subacute or chronic and is usually not associated with swimming in freshwater. No characteristic clinical symptoms, laboratory findings, or radiologic indicators have been found to be diagnostic for GAE. The organism produces virulence factors that enhance adhesion to and penetration of the blood-brain barrier. The amoeba causes tissue damage by phagocytosis of cells and the production of toxins and proteases that destroy the extracellular matrices. Whether single or multiple, the lesions in the brain involve mainly the cerebral cortex and subcortical white matter. Generalized symptoms include headache, nausea, vomiting, fever, visual disturbances, dysphagia, seizures, and hemiparesis. The clinical course ranges from a few days to several months. *B. mandrillaris* is larger than human leukocytes, thus making phagocytosis impossible. Instead, in immunocompetent hosts, the immune system attempts to contain them at the portal of entry by mounting a type IV hypersensitivity reaction; however, with rare exceptions, these patients also tend to die with severe CNS disease.

Laboratory Diagnosis

B. mandrillaris does not grow well on *E. coli*–seeded nonnutrient agar plates because, unlike *Naegleria* or *Acanthamoeba*, *B. mandrillaris* does not feed on bacteria. However, these organisms can be cultured in mammalian cell cultures using monkey kidney cells and MRC (human fetal lung fibroblast cells), HEp-2 (human carcinoma cells), and diploid macrophage cell lines. Using human brain microvascular endothelial cells, *B. mandrillaris* has been cultured postmortem from brain and CSF from a case of granulomatous amoebic meningoencephalitis. The organism may be diagnosed by examining blood, CSF, and tissue samples. A cell-free growth medium is also commercially available.

There are two serologic tests that can help confirm the diagnosis of GAE. The indirect immunofluorescence assay (IFA) is a test used to detect antibodies attached to *Balamuthia* amoebae in body tissues. In contrast, immunohistochemistry (IHC) uses specific antibodies against *Balamuthia* to detect the amoebae. Although serum antibodies have been identified in infections, laboratory testing is not routinely available.

Therapy

In vitro studies indicate that *B. mandrillaris* is susceptible to pentamidine isothiocyanate and that patients may benefit from this treatment. Other studies indicate that azithromycin, sulfadiazine, flucytosine, clarithromycin, and miltefosine have amebicidal activity.

Sappinia spp.

Two species of a new free-living amoeba have been identified that may be capable of causing amoebic encephalitis: *S. diploidea* and *S. pedata*. *S. pedata* is the only species that has been clearly associated with human infection. Trophozoites measure approximately 40 to 70 µm and have two nuclei. Cysts have not been identified in human infection but have been visualized in culture. Symptoms of infection may include visual disturbances, headache, and seizures. Computed tomography of the brain may reveal a mass that resembles a tumor. The mass is the site of inflammation and harbors the free-living amoebic trophozoites. Surgical excision followed by antiamebic medications can be used for treatment.

Nucleic Acid Detection (Free-Living Amoebae)

Several isolates for each of the free-living amoebae—*Naegleria, Acanthamoeba,* and *Balamuthia*—have been sequenced. Sequencing of isolates provides information for the development of more specific assays for the identification and treatment of patients with PAM and GAE.

The CDC has developed a real-time polymerase chain reaction (PCR) assay for the simultaneous detection of the three primary free-living amoebae from CSF. This assay has been used successfully to identify amoeba in patient specimens but is not currently available in routine clinical laboratories.

Results Reporting (Free-Living Amoebae)

The presence of any amoebae should be immediately reported to the clinician. Most routine clinical laboratories do not have the technical staff or equipment to identify these organisms and routinely send the specimens to a reference laboratory.

Trichomonas vaginalis

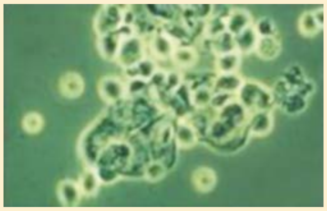
General Characteristics

Infection with *T. vaginalis* is acquired primarily through sexual intercourse, hence the need to diagnose and treat asymptomatic males. The organism is capable of survival for extended periods in a moist environment such as damp towels and underclothes. However, this mode of transmission is thought to be very rare. Infection with *T. vaginalis* occurs worldwide. **Trichomoniasis** is the primary nonviral sexually transmitted disease worldwide, with an estimated annual occurrence of 250 million cases. Infection with *T. vaginalis* has major health consequences for women, including complications in pregnancy, association with cervical cancer, and predisposition to human immunodeficiency virus (HIV) infection.

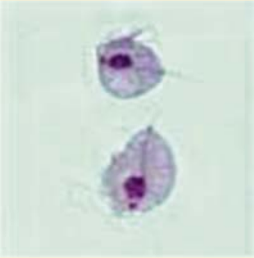
The life cycle of *T. vaginalis* includes a single trophozoite, which is very similar in morphology to other trichomonads (Table 49.2). The trophozoite is 7 to 23 µm long and 5 to 15 µm wide. The **axostyle** is usually obvious and protrudes through the bottom of the organism, whereas the undulating membrane ends halfway down the side of the trophozoite. There are a large number of granules evident along the axostyle.

TABLE 49.2 **Characteristics of *Trichomonas vaginalis***

Shape and size	Pear shaped, 7–23 µm long (average, 13 µm); width, 5–15 µm
Motility	Jerky, rapid
Number of nuclei and visibility	1; not visible in unstained mounts
Number of flagella (usually difficult to see)	3–5 anterior, 1 posterior
Other features	Seen in urine, urethral discharge, and vaginal smears; undulating membrane extends half the length of the body; no free posterior flagellum; axostyle easily seen
Infective stage	Trophozoite
Usual location	Vagina (male, urethra)
Striking clinical findings	Leukorrhea, pruritus vulvae (thin white urethral discharge in male)
Other sites of infection	Urethra (prostate in male)
Stage usually recovered during clinical phase	Trophozoite only—no cyst



Trichomonas, wet mount



Trichomonas, Papanicolaou stain

Pathogenesis and Spectrum of Disease

Growth of the organism results in inflammation and large numbers of trophozoites in the tissues and the secretions. As the acute infection becomes more chronic, the purulent discharge diminishes, with a decrease in the number of organisms. Symptoms such as vaginal or vulval pruritus and discharge are often sudden and occur during or after menstruation because of the increased vaginal acidity. Symptoms include vaginal discharge (42%), odor (50%), and edema or erythema (22% to 37%). Complaints also include dysuria and lower abdominal pain.

Between 25% and 50% of infected females may be asymptomatic; they have a normal vaginal pH of 3.8 to 4.2 and normal vaginal microbiota. Even when the infection is in the carrier form, about 50% of infected females will become symptomatic during the following 6 months.

Although vaginitis is the most common finding in females with trichomoniasis, other complications include distention of a fallopian tube with pus, endometritis, infertility, low birth weight, and cervical erosion. There is also an increased association with HIV transmission and cervical dysplasia.

Dysuria, often the earliest symptom, occurs in about 20% of females with vaginal trichomoniasis. Infected males may be asymptomatic, or the infection may be self-limited, be persistent, or result in recurring urethritis. In nonspecific urethritis, *T. vaginalis* has been detected in 10% to 20% of subjects and in 20% to 30% of those, whose sexual partners had vaginitis. Once established, the infection persists for an extended period in females but for only about 10 days or less in males. *T. vaginalis* is the cause of 11% of all cases of nongonococcal urethritis in males.

Respiratory distress has been reported in a full-term normal male infant with *T. vaginalis* with severe respiratory problems after delivery. A wet preparation of thick white sputum demonstrated a few leukocytes and motile flagellates, which were identified as *T. vaginalis.* This study supports previous data confirming that the organism may cause neonatal pneumonia.

Laboratory Diagnosis

Humans are the only natural host for *T. vaginalis,* and organisms reside in the vagina and prostate; they usually do not survive outside the urogenital tract. The parasites feed on the mucosal surface of the vagina, where bacteria and leukocytes are abundant. The preferred pH for good parasitic growth in females is slightly alkaline or acidic (6.0 to 6.3 optimal), not the normal pH (3.8 to 4.2) of the healthy vagina. The organisms can be recovered in urine, in urethral discharge, or after prostatic massage. Often the organisms are recovered in centrifuged urine sediment from both male and female patients.

Wet Mounts

The identification of *T. vaginalis* is often based on the examination of wet preparations of vaginal and urethral discharges, urine, and prostatic secretions. This examination must be performed within 10 to 20 minutes after sample collection; if delayed, the organisms lose their motility and may be missed. Several specimens may need to be examined for detection of the organisms. The sensitivity associated with wet mount examinations varies between 40% and more than 80%. Often, the percent detection from this procedure is quite low, with limited sensitivity and specificity.

Stained Smears

Giemsa or Papanicolaou stain can be used. However, atypical cellular changes can be misinterpreted, particularly on the Papanicolaou smear. The organisms are routinely missed on Gram stains. The number of false-positive and false-negative results reported based on stained smears strongly suggests that confirmation should be accomplished by observation of motile organisms either from the direct wet mount or from appropriate culture media.

Antigen Detection

Several rapid diagnostic tests have been developed, including the OSOM *Trichomonas* rapid immunochromatographic capillary-flow dipstick assay (Genzyme Diagnostics, Cambridge, MA), which is more sensitive than the wet mount. Additionally, an immunofluorescent assay is available—T.VAG DFA (*T. vaginalis* DFA; Chemicon International, Temecula, CA)—that is capable of direct testing of the patient sample.

Nucleic Acid Detection

The use of PCR methods has led to improvements in *T. vaginalis* detection; nonviable organisms and cells and target sequences can be detected. In addition to various culture and transport options, several other products are available, including the Affirm VPIII probe from Becton Dickinson (Cockeysville, MD). The Affirm VPIII detects the three most common organisms associated with vaginal infections: *T. vaginalis, Gardnerella vaginalis,* and *Candida albicans.* An assay approved by the US Food and Drug Administration (FDA) that uses transcription-mediated amplification (Chapter 8) is available for the identification of *T. vaginalis* (Hologic, San Diego, CA). The assay can be automated for testing using either the Panther or Tigris instrumentation. Nucleic acid amplification tests (NAAT) from Cepheid Xpert TV or the GeneXpert system (Sunnyvale, CA) have also been cleared by the FDA for the detection of *T. vaginalis* in specimens from both women and men. A variety of highly sensitive and specific PCR assays are available for the detection of the organism in urine samples. Depending on the patient population, client base, number of requests, and cost, one or more of these options may be appropriate for a particular diagnostic laboratory.

Culture

A convenient plastic envelope method is available that allows immediate examination and culture in one self-contained system. This system is commercially available as the InPouchTV (BIOMED Diagnostics, San Jose, CA) and serves as the specimen transport container, the growth chamber during incubation, and the "slide" during microscopy. Once it is inoculated, it requires no opening for examination, and growth occurs within 5 days. The sensitivity of this system is reported to be superior to that of other available culture methods.

Therapy

Metronidazole remains the recommended option for the treatment of urogenital trichomoniasis and is currently the only drug approved for treatment in the United States. Resistance to both metronidazole and other 5-nitromidazoles has been reported. All sexual partners should be treated simultaneously to prevent reinfection. Tinidazole has also been used for therapy.

Trichomonas tenax

Trichomonas tenax, or oral trichomonas, is commonly found in the oral cavity of humans, dogs, and cats. This parasite colonizes patients with poor oral hygiene and advanced periodontal disease. Transmission is through saliva, droplet spray, and kissing or use of contaminated dishes or drinking water. Trophozoites survive in the body as mouth scavengers that feed on local microorganisms located between the teeth, in tonsillar crypts and pyorrheal pockets, and at the gingival margin around the gums. However, the trophozoites are unable to survive the digestive process.

General Characteristics

Of the three parasites in the genus *Trichomonas*, *T. tenax* is the smallest, measuring only 5 to 14 µm long and 6 to 9 µm wide. The organism can be identified by the long axostyle and tail, four anterior flagella, and an undulating membrane that spans two-thirds the length of the body. The undulating membrane may also resemble small legs. The flagellate has no cyst stage. *T. tenax* may be confused with *T. vaginalis* due to similar morphology. In such cases, the presence of an oral or vaginal parasite should be confirmed.

Pathogenesis and Spectrum of Disease

T. tenax is generally not found in the oral cavity of healthy individuals. It is known to play a pathogenic role in necrotizing ulcerative gingivitis and periodontitis. The organism is also implicated in chronic lung disease. Removal or clearance of the organism results in complete recovery. *T. tenax* is not known to cause specific pathology or disease symptoms. It may be involved in the degradation of periodontal tissue through the secretion of substances such as alkaline phosphatases and the fibronectin cathepsin. The organism appears to primarily worsen preexisting periodontal disease. In rare cases has been reported to cause bronchopulmonary infections in patients with cancer or other lung diseases.

Laboratory Diagnosis

The specimen of choice for the identification of *T. tenax* trophozoites is mouth scrapings. Microscopic examination with bright field or phase contrast microscopy of tartar, the gingival margin of the gums, tonsillar crypts, and pyorrheal pockets of patients suffering from *T. tenax* infections often yields trophozoites. *T. tenax* may be cultured on artificial media, as outlined previously for *T. vaginalis*.

Therapy

Proper oral hygiene in combination with regular dental visits to remove dental plaque prevents colonization.

Toxoplasma gondii

Toxoplasma gondii is a protozoan parasite that infects most species of warm-blooded animals, including humans. Members of the cat family, *Felidae,* are the only known definitive hosts for the sexual stages of *T. gondii* and serve as the main reservoirs of infection. Cats become infected with *T. gondii* through carnivorism or by ingestion of **oocysts.** Outdoor cats are much more likely to become infected than domestic cats that are confined indoors. After the cat has ingested tissue cysts or oocysts, organisms are released and invade epithelial cells of the cat's small intestine. In the small intestine, they undergo an asexual cycle followed by a sexual cycle with the formation of oocysts, which are excreted in the feces. The noninfective oocyst takes 1 to 5 days after excretion to become infective. Cats shed oocysts for 1 to 2 weeks, and large numbers may be shed, often more than 100,000 per gram of feces. Oocysts survive in the environment for several months to more than 1 year and are resistant to disinfectants, freezing, and drying. However, they are killed by heating to 70°C for 10 minutes. The life cycle in the cat takes approximately 19 to 48 days after infection with the oocysts but only 3 to 10 days after the ingestion of meat infected with cysts (e.g., a mouse) (Fig. 49.3).

General Characteristics

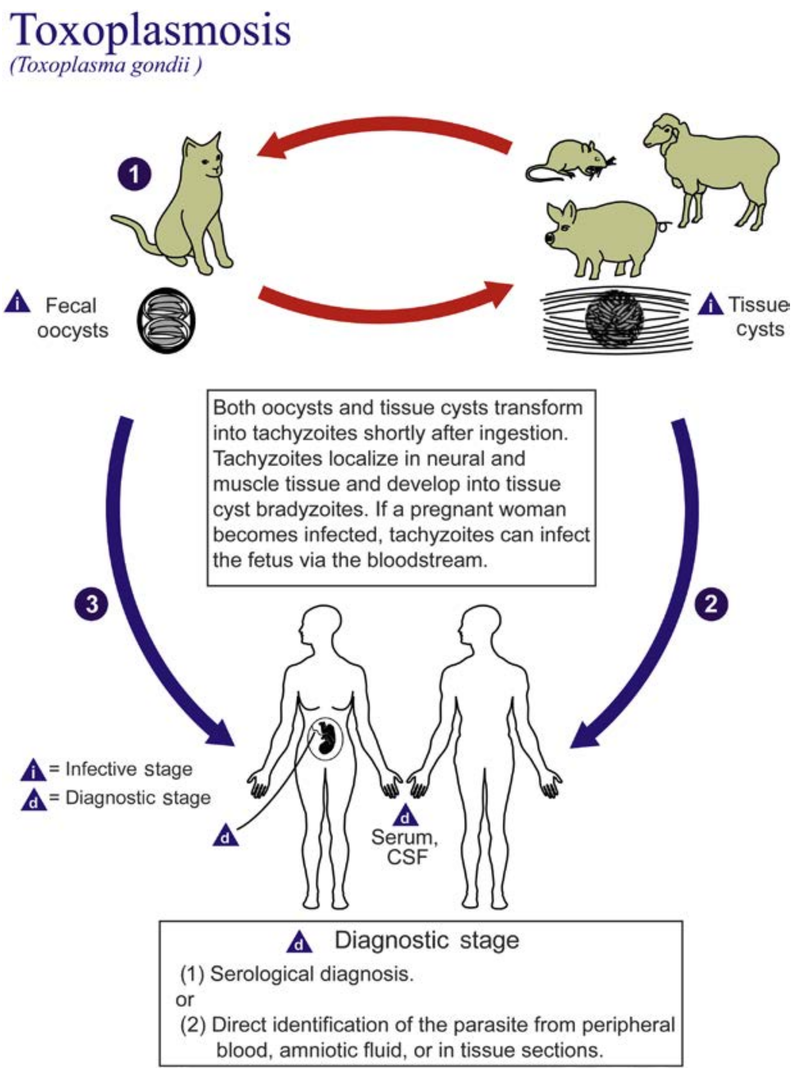
There are three infectious stages of *T. gondii:* the **tachyzoites** (in groups or clones), the **bradyzoites** (in tissue cysts), and the sporozoites (in oocysts from cat feces). Tachyzoites rapidly multiply in any cell of the intermediate host and in epithelial cells of the definitive host (cats). Bradyzoites are found within the tissue cysts and usually multiply very slowly. The cyst may contain few to hundreds of organisms, and intramuscular cysts may reach 100 µm in size. The tissue cysts can be found in visceral organs such as the lungs, liver, and kidneys. However, they are more prevalent in the brain, eyes, and skeletal and cardiac muscle. Intact tissue cysts can persist for the life of the host and do not cause an inflammatory response.

Tachyzoites are crescent-shaped and are 2 to 3 µm wide by 4 to 8 µm long (Table 49.3). One end tends to be more rounded than the other is. Giemsa is the stain of choice; the cytoplasm stains pale blue, and the nucleus stains red and is situated toward the broad end of the organism.

Cysts are formed in chronic infections, and the bradyzoites within the cyst wall are strongly PAS positive. During the acute phase, there may be groups of tachyzoites that appear to be cysts; however, they are not strongly PAS positive and have been termed **pseudocysts.**

Pathogenesis and Spectrum of Disease

As the tachyzoites actively grow, increase in number, and eventually rupture from the cell, they invade adjacent cells. This process creates additional lesions. Once the cysts have



Toxoplasmosis
(Toxoplasma gondii)
1
Fecal oocysts
Tissue cysts
Both oocysts and tissue cysts transform into tachyzoites shortly after ingestion. Tachyzoites localize in neural and muscle tissue and develop into tissue cyst bradyzoites. If a pregnant woman becomes infected, tachyzoites can infect the fetus via the bloodstream.

or
(2) Direct identification of the parasite from peripheral blood, amniotic fluid, or in tissue sections.

• **Fig. 49.3** An illustration depicting the life cycle of the protozoan *Toxoplasma gondii,* the causal agent for toxoplasmosis. (Photo Courtesy of the Division of Parasitic Diseases/Centers for Disease Control and Prevention.)

been formed, the process becomes quiescent, with little or no multiplication and spread. In immunocompromised or immunodeficient patients, a cyst rupture or primary exposure to the organisms often leads to lesions. The organisms can be disseminated via the lymphatic system and the bloodstream to other tissues.

Toxoplasmosis can be categorized into four groups: (1) acquired in the immunocompetent patient, (2) acquired or reactivated in the immunodeficient patient, (3) congenital, and (4) ocular.

Diagnoses and their interpretations may differ for each clinical category.

Immunocompetent Individuals

In almost all cases, no clinical symptoms are seen during the acute infection. However, 10% to 20% of patients with acute infection may develop painless cervical lymphadenopathy and a flulike illness. This presentation is self-limited, with symptoms resolving within weeks to months. Acute visceral manifestations are present in rare cases. Most infected patients remain asymptomatic or consider that they have experienced nothing more than a common cold.

Immunocompromised Individuals

Infections in immunocompromised patients can lead to severe complications. Underlying conditions that may affect the disease outcome include Hodgkin disease, non-Hodgkin lymphomas, leukemia, solid tumors, collagen vascular disease, organ transplantation, and AIDS. In the immunocompromised patient, the CNS is primarily involved, but these patients may also have myocarditis or pneumonitis. More than 50% of these patients will show an altered mental state, motor impairment, seizures, abnormal reflexes, and other neurologic sequelae. Toxoplasmosis in patients being treated with immunosuppressive drugs may result from either newly acquired or reactivated latent infection.

In transplant recipients, the disease presentation depends on prior exposure to *T. gondii* by the donor and recipient, the type of organ involved, and the patient's level of immunosuppression. Reactivation of a latent infection or an acute

TABLE 49.3 **Morphology of *Toxoplasma gondii* Stages Found in Humans**

Stage	Description
 Tachyzoites	Tachyzoites are crescent shaped and are 2–3 μm wide by 4–8 μm long. One end tends to be more rounded than the other is. Giemsa is the stain of choice; cytoplasm stains pale blue; nucleus stains red and is situated toward the broad end of the organism. Tachyzoites are usually seen in early, more acute phases of infection. Tachyzoites rapidly multiply in any cell of the intermediate host (many animals and humans) and in nonintestinal epithelial cells of the definitive host (cats).
Bradyzoites  Bone marrow, leukemia patient  Bradyzoites in tissue	Bradyzoites are found within tissue cysts and multiply very slowly; cyst may contain few to hundreds of organisms, and intramuscular cysts may reach 100 μm in size. Although tissue cysts are seen in visceral organs such as lungs, liver, and kidneys, they are more common in brain, eyes, and skeletal and cardiac muscle.

primary infection acquired directly from the transplanted organ can lead to severe disease. Stem cell transplant (SCT) recipients are particularly susceptible to severe toxoplasmosis, primarily attributable to reactivation of a previously acquired latent infection.

Before the use of highly active antiretroviral therapies (HAARTs), *Toxoplasma* encephalitis (TE) was a life-threatening opportunistic infection among patients with AIDS and was usually fatal if not treated. In AIDS patients with reactivated latent infections, psychiatric manifestations of *T. gondii* may be present, including altered mental status (60%) with delusions, auditory hallucinations, and thought disorders. *T. gondii* enhances HIV-1 replication within reservoir host cells and, at the same time, HIV-1 undermines acquired immunity to the parasite, promoting reactivation of chronic toxoplasmosis.

Congenital Infections

Congenital infection results when the mother acquires a primary infection during pregnancy. Most patients remain asymptomatic during the acute infection. However, congenital infections may be severe if the mother becomes infected during the first or second trimester. At birth or soon thereafter, symptoms in these infants may include retinochoroiditis, cerebral calcification, and occasionally hydrocephalus or microcephaly. Because treatment of the mother may reduce the severity of disease in the infant, prompt and accurate diagnosis is mandatory. Many infants who are asymptomatic at birth will subsequently develop symptoms of congenital toxoplasmosis; however, treatment may help to prevent subsequent sequelae. CNS involvement may not appear until several years later.

Ocular Infections

Ocular toxoplasmosis, an important cause of chorioretinitis, may be the result of congenital or acquired infection; acquired infection is more common than congenital infection. Patients with congenital infection may be asymptomatic until the second or third decade; at that point, cysts may rupture with lesions and develop in the eye. Chorioretinitis is characteristically bilateral in patients with congenital infection but is often unilateral in individuals with acute acquired *T. gondii* infection.

Laboratory Diagnosis

The most common method of diagnosis for toxoplasmosis is serologic testing for *T. gondii*–specific antibodies. Other procedures include PCR; examination of biopsy specimens, buffy coat preparations, or CSF; or isolation of the organism in tissue culture or in laboratory animals. It is important to remember that many individuals have been exposed to *T. gondii* and may have cysts within their tissues. Recovery of organisms from tissue culture or animal inoculation may be misleading because the organisms may be isolated but may not be the etiologic agent of disease. However, two situations in which organism detection may be very significant are (1) tachyzoites in smears and/or tissue cultures inoculated from CSF and (2) tachyzoites in patients with acute pulmonary disease and the demonstration of intracellular and extracellular tachyzoites in Giemsa-stained smears of BAL fluid.

When laboratory personnel decide to initiate *Toxoplasma*-specific antibody testing or switch to a different antibody detection kit, the user must carefully review the manufacturer's package insert and published literature for information on the sensitivity and specificity of the assay.

An in-laboratory comparison of kits should be performed using positive and negative samples confirmed by a toxoplasmosis reference laboratory.

The serologic diagnosis of toxoplasmosis is very complex. A variety of manual and automated assays are available that include enzyme immunoassays, enzyme-linked immunosorbent assays (ELISAs), direct agglutination, an immunosorbent agglutination assay, an indirect IFA, immunocapture, and immunoblot tests.

Nucleic Acid Detection

Nucleic acid–based testing has been successfully used to diagnose congenital toxoplasmosis in amniotic fluid and encephalitis in immunocompromised patients. Although the assay is not commercially available for routine use in clinical laboratories, the test is offered at the Toxoplasma Serology Laboratory in Palo Alto, California.

Therapy

Treatment is recommended for clinically active disease, congenital toxoplasmosis in newborns, pregnant women infected during gestation, chorioretinitis, and symptomatic disease in compromised patients. Therapy is recommended for preventive or suppressive treatment in HIV-infected persons. The currently recommended drugs work primarily against the actively dividing tachyzoite form of *T. gondii* and do not eradicate encysted organisms (bradyzoites).

The most common drug combination used to treat congenital toxoplasmosis consists of pyrimethamine and a sulfonamide (sulfadiazine is recommended in the United States) plus folinic acid in the form of leucovorin calcium to protect the bone marrow from the toxic effects of pyrimethamine. Spiramycin is recommended for pregnant women with acute toxoplasmosis when fetal infection has not been confirmed in an attempt to prevent transmission of *T. gondii* from the mother to the fetus.

In immunosuppressed persons with toxoplasmosis, the combination of pyrimethamine and sulfadiazine plus leucovorin is the preferred treatment. Clindamycin is a second alternative for use in combination with pyrimethamine and leucovorin in those who cannot tolerate sulfonamides. Because relapse often occurs after toxoplasmosis in HIV-infected patients, maintenance therapy with pyrimethamine plus sulfadiazine or pyrimethamine plus clindamycin is recommended. For prophylaxis to prevent an initial episode of toxoplasmosis in *Toxoplasma*-seropositive persons with CD4+ T-lymphocyte counts of less than 100/mL, trimethoprim-sulfamethoxazole is recommended as the first choice, with alternatives consisting of dapsone plus pyrimethamine or atovaquone with or without pyrimethamine. Leucovorin is administered with all regimens, including pyrimethamine. HIV-infected persons who are serologically negative for *Toxoplasma* IgG should be advised to protect themselves from primary infection by eating well-cooked meats and washing their hands after possible soil contact. Cats kept as pets should be fed commercial or well-cooked food, should be kept indoors, and should have their litter boxes changed daily.

Pyrimethamine and sulfadiazine are often used to treat patients with ocular disease. Clindamycin, in combination with other antiparasitic medications, may also be used to treat ocular disease. In addition to antiparasitic drugs, physicians may add corticosteroids to reduce ocular inflammation.

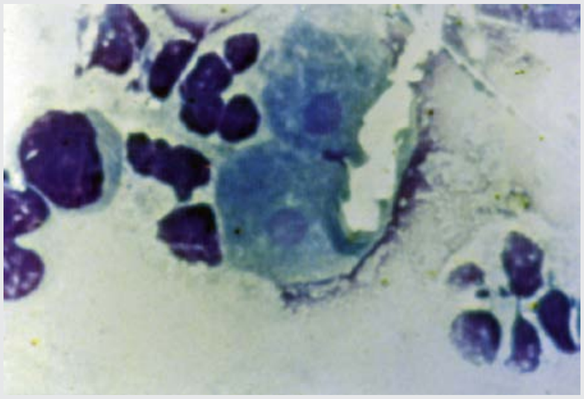
CASE STUDY 49.1

A 16-year-old male presented to the physician with a severe headache and nausea and vomiting. When he arrived at the emergency department he seemed somewhat confused and disoriented. He had chills but no fever. The physician noted that he was wearing swimming trunks under his clothes and, upon physical examination, had a few bruises on his arms. The young man said he had been staying at his friend's house for several days and, while swimming in his friend's pool, had slipped on the diving board.

Questions

1. What are the potential causes for the young man's symptoms?
2. What laboratory tests would be the most useful for quick diagnosis?
3. The physician ruled out bacterial infection because the young man's complete blood count was normal, as was his CT scan result. A spinal tap was completed. Examine the cytospin photograph presented in Fig. 49.4. What organism was identified and how should the young man be treated?



• **Fig. 49.4** Patient's specimen. (Photo courtesy Dr. Henry Travers, Sioux Falls, SD.)

Chapter Review

1. A 12-year-old female is brought to the emergency department with meningitis and a history of swimming in a warm-water spring. Motile amoebae that measure 10 µm in size are seen in the CSF and are most likely
  - **a.** *Iodamoeba bütschlii* trophozoites
  - **b.** *Endolimax nana* trophozoites
  - **c.** *Dientamoeba fragilis* trophozoites
  - **d.** *Naegleria fowleri* trophozoites
  - **e.** *Giardia duodenalis* trophozoites

2. *Toxoplasma gondii* (toxoplasmosis) is characterized by
  - **a.** Possible congenital infections
  - **b.** Infection from ingestion of raw/rare meats or oocysts from cat feces
  - **c.** Possible difficulties with interpretation of serologic tests for antibody
  - **d.** All of the above
  - **e.** None of the above

3. Eye infections with *Acanthamoeba* spp. have most commonly been traced to
  - **a.** Use of soft contact lenses
  - **b.** Use of hard contact lenses
  - **c.** Use of contaminated lens care solutions
  - **d.** Failure to remove lenses while swimming
  - **e.** Dust in the eyes

4. Which specimen is the least likely to provide recovery of *Trichomonas vaginalis*?
  - **a.** Vaginal discharge
  - **b.** Urethral discharge
  - **c.** Male urine
  - **d.** Female urine
  - **e.** Stool

5. True or False

_____ A nonnutrient agar plate is seeded with *Escherichia coli* and then is inoculated with a specimen taken from an eye lesion. Organisms were recovered from the plate and identified as *Acanthamoeba* species, the cause of keratitis.

_____ *Toxoplasma gondii* can cause severe CNS disease in patients with AIDS; the cause is often reactivation of latent toxoplasmosis.

_____ *Acanthamoeba* keratitis is often linked to swimming in contaminated freshwater lakes and ponds where free-living amoebae live in the water and soil.

_____ *Trichomonas vaginalis* causes disease and symptoms in both males and females; however, the majority of infected women remain asymptomatic during the infection.

_____ PAM is a chronic disease in which the patient may develop symptoms over a long period, often months.

6. Matching: *Match each term with the correct description.*

_____ *Trichomonas vaginalis*
_____ *Naegleria fowleri*
_____ *Toxoplasma gondii*
_____ trichomoniasis
_____ *Acanthamoeba* eye infection
_____ GAE
_____ PAM
_____ poor contact lens care
_____ *Balamuthia mandrillaris*
_____ toxoplasmosis

a. organism that is transmitted as congenital infection
b. chronic CNS disease, not associated with swimming
c. keratitis
d. also causes GAE
e. swimming in freshwater
f. acute, fatal disease
g. serologic testing
h. use of outdated solutions
i. males are often asymptomatic
j. no known cyst form

Intestinal Nematodes

OBJECTIVES

1. Describe the distinguishing morphologic characteristics and basic life cycle (vectors, hosts, and stages of infectivity) for each of the parasites listed.
2. Define and identify the following parasitic structures when appropriate: mammillated ovum, gravid, rhabditiform larvae, buccal capsule, esophagus, genital primordia, polar hyaline plugs, copulatory bursa, embryonated egg, cutting plates, and filariform larvae.
3. Describe the diseases and mechanism of pathogenicity, including route of transmission, for each of the species listed.
4. Differentiate *Ascaris lumbricoides* adult male and female worms.
5. Define and differentiate direct versus indirect life cycle as related to nematodes and the routes of transmission, including autoinfection and hyperinfections.
6. Identify and differentiate the characteristic morphologies and eggs for *A. lumbricoides, Enterobius vermicularis,* and *Trichuris trichiura.*
7. Compare clinical signs and symptoms, morphologic characteristics, and identification of the hookworm's rhabditiform larvae for *Ancylostoma duodenale* and *Necator americanus.*
8. Compare and contrast the morphologic characteristics and identification of the larval forms of *Strongyloides stercoralis.*
9. List the various methods used to diagnose intestinal nematode infections.
10. Identify the appropriate intestinal nematodes for which the following techniques are useful and explain the principle for each: the Baermann concentration method, agar culture, and Harada-Mori filter paper method for the recovery of intestinal nematodes.

PARASITES TO BE CONSIDERED

Helminths

Nematodes

Intestinal (roundworms)
    Ascaris lumbricoides
    Enterobius vermicularis (pinworm)
    Strongyloides fuelleborni
    Strongyloides stercoralis (threadworm)
    Trichostrongylus spp.
    Trichuris trichiura (whipworm)
Capillaria philippinensis (hookworm)
    Ancylostoma ceylanicum
    Ancylostoma duodenale (Old World)
    Necator americanus (New World)

There are more than 60 species of nematodes known to infect humans. *Ascaris lumbricoides,* hookworms (*Ancylostoma duodenale, Ancylostoma ceylanicum*, and *Necator americanus*), and *Trichuris trichiura* are estimated to infect more than 1 billion people. Nematodes are nonsegmented, elongate, cylindrical worms with a well-developed digestive tract and reproductive system. The adult worms have separate sexes, with the male generally smaller than the female. Most nematodes are diagnosed by finding the characteristic eggs in the stool. The infective stage of the nematodes varies with species; for example, transmission may occur through the ingestion of eggs, whereas others burrow through the skin and migrate to the intestine. The nematodes have very diverse life cycles that result in different routes of transmission and disease symptoms.

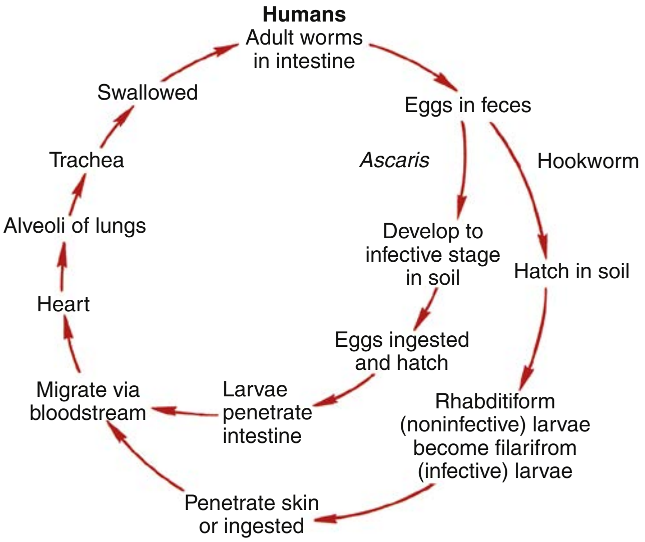
Ascaris lumbricoides

General Characteristics

A. lumbricoides is the most common and largest roundworm. The parasite has a worldwide distribution with higher prevalence in the tropical regions. Its eggs are ingested and hatch in the duodenum, penetrate the host's intestinal wall, and migrate to the hepatic portal circulation. The adult worms live and reproduce in the lumen of the small intestine. The ovum is a thick, oval, **mammillated** (outer protrusions) and embryonated egg. The eggs are passed in the feces and become infective 2 to 6 weeks after deposition, depending on the environment. The general life cycle is outlined in Fig. 50.1. The life cycle of *A. lumbricoides* is classified as an **indirect life cycle;** transmission is not via a direct route from one host to the next.

Epidemiology

Geographic distribution is associated with climate and poor sanitation. The eggs of *A. lumbricoides* require a warm, humid environment for the embryonated ovum to mature and become infective. Infection rates are elevated in poverty-stricken areas that have poor sanitation. Transmission is via the fecal-oral route, usually through the ingestion of eggs on contaminated material. *Ascaris* eggs are capable of survival within harsh environmental conditions, including dry or freezing temperatures.



Humans
Adult worms in intestine
Eggs in feces
Ascaris
Hookworm
Develop to infective stage in soil
Hatch in soil
Eggs ingested and hatch
Rhabditiform (noninfective) larvae become filarifrom (infective) larvae
Penetrate skin or ingested

Migrate via bloodstream
Heart
Alveoli of lungs
Trachea
Swallowed

• **Fig. 50.1** Life cycle of *Ascaris lumbricoides* and hookworm (indirect life cycle).

Pathogenesis and Spectrum of Disease

Many *A. lumbricoides* infections are asymptomatic. The presentation of symptoms correlates with the length of infection, the number of worms present, and the overall health of the host. Stool examination findings are typically normal in the absence of previous infection (during the first 40 days). Intestinal symptoms range from mild to severe intestinal obstruction. Some patients will develop pulmonary symptoms due to the migration of larvae through the lungs; such persons present with immune-mediated hypersensitivity pneumonia. The worms may cause an immune condition known as **Löffler syndrome,** characterized by peripheral eosinophilia. Ectopic ascariasis may occur when worms escape the gastrointestinal (GI) tract and enter the appendix or the hepatobiliary or pancreatic ducts and cause an obstruction. Table 50.1 provides a summary of associated diseases.

TABLE 50.1 **Pathogenesis and Spectrum of Associated Diseases**

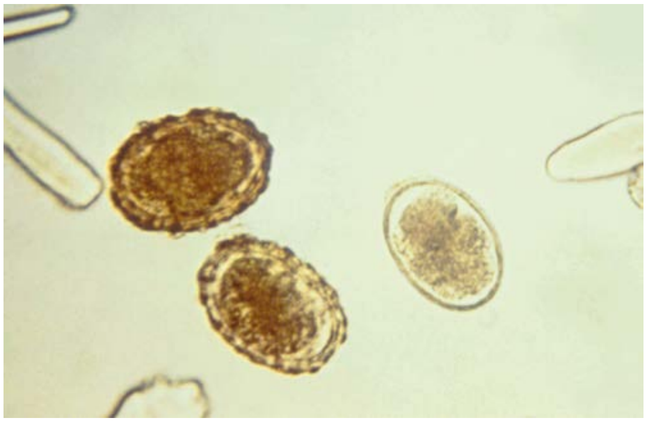
Organism	Pathogenesis	Mode of Transmission and Spectrum of Disease
Ascaris lumbricoides	Attributed to four main factors: 1. Host immune response 2. Effects from larval migration 3. Mechanical disruption and blockage by worms 4. Nutritional deficiency associated with worm burden	Fecal-oral transmission. Reinfection possible. Children and young adolescents have higher infection rates. Pregnant females: unknown effect on unborn fetus. Potential tissue damage from migration to lungs, liver, and immune cell infiltration (pneumonitis). Peripheral eosinophilia (Löffler syndrome). Nutritional impairment in young children. Hepatic ascariasis, including hepatic abscesses and obstructive cholangitis. Intestinal blockage, pancreatic or bile duct. Migration to other tissues may include kidneys, appendix, and pleural cavity.
Enterobius vermicularis	Worm burden may be a single organism to thousands. Rarely migration occurs to nearby tissues.	Fecal-oral or inhalation. Sexual transmission has been reported. Reinfection and autoinfection occur. More common in children and females. Mild nocturnal pruritus. Migration to vagina, uterus, and fallopian tubes where organisms become encapsulated granulomas. Hemorrhagic colitis and inflammation of ileum and colon in homosexual males. Uncommon sites include peritoneal cavity, lungs, liver, urinary tract, and natal cleft.
Strongyloides stercoralis and *Strongyloides fuelleborni*	Varies in severity depending on worm burden and area of body infected. Immune response affects symptoms.	Direct penetration. Chronic and hyperinfection may occur. May remain asymptomatic with peripheral eosinophilia. Cutaneous: • Pruritus and erythema • "Larva currens" tracks under skin from worm migration Pulmonary: • Asymptomatic to pneumonia • Löffler syndrome; shortness of breath and pulmonary infiltrates Intestinal: • Diarrhea, constipation, anorexia, and abdominal pain may occur • Damage to mucosa may occur in heavy infections

TABLE 50.1 **Pathogenesis and Spectrum of Associated Diseases—cont'd**

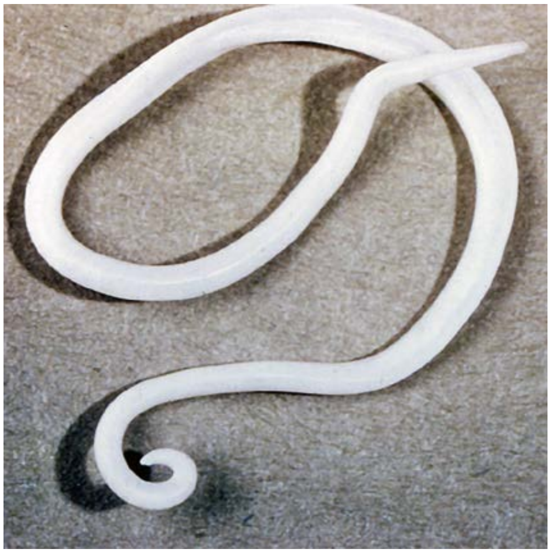
Organism	Pathogenesis	Mode of Transmission and Spectrum of Disease
Trichostrongylus spp.	Dependent on worm burden.	Diarrhea, anorexia, and general malaise. Damage to intestinal mucosa may occur, resulting in hemorrhage and tissue desquamation. Heavy worm burden may result in anemia and cholecystitis.
Trichuris trichiura	Dependent on worm burden. Mechanical damage to intestinal mucosa and allergic reaction. Migration of parasites.	Fecal-oral transmission. Ingestion of embryonated eggs. Asymptomatic to mild symptoms associated with low worm burden. Heavy infections may result in hemorrhage, weight loss, abdominal pain, blood-tinged stools, and diarrhea. Rectal prolapse and hypochromic anemia in repeated heavy infections in children. Inflammation of mucosa.
Capillaria philippinensis	Dependent on worm burden.	Fecal-oral transmission. Ingestion of larvae-infected seafood such as fish, crab, shrimp, and snails. Malabsorption, fluid loss, and associated loss of electrolytes. Extended infections can result in organ failure and death.
Hookworms: *Ancylostoma duodenale* *Necator americanus* *A. ceylonicum* *A. braziliense* and *A. caninum*	Vary according to life cycle phase and worm burden. Production of proteins that suppress host immune response. Hyaluronidase: facilitates digestion of connective tissue and penetration of epidermis and dermis. Migration of larvae to lungs. Mechanical: attachment, feeding, and anticoagulation production.	Direct penetration. Mild to severe pruritus and potential secondary infections. Ground itch: development of vesicles resulting from erythematous papular rash. Pneumonitis: decreased sensitization compared with *A. lumbricoides* and *S. stercoralis.* Gastrointestinal: • Tissue damage at site of attachment. • Blood loss, anemia. • Acute gastrointestinal phase demonstrates increased eosinophilia. • Increased worm burden may result in death, particularly in young children.
A. duodenale	Period of arrested development.	May be associated with vertical transmission and congenital infections. Eosinophilia peaks in approximately 1 month in gastrointestinal phase.
N. americanus	Proteolytic enzymes that degrade collagen, fibronectin, laminin, and elastin.	Skin-associated symptoms as described for hookworms. Eosinophilia peaks in approximately 2 months in gastrointestinal phase.
A. ceylonicum	Similar to *N. americanus.*	Chronic blood loss that leads to iron-deficiency anemia and protein malnutrition.
A. braziliense	No hydrolytic enzymes. Self-limiting.	Cutaneous larva migrans; organisms remain trapped in the superficial epidermis (up to 10 days), where they migrate to create the pathognomonic serpiginous tunnels.
A. caninum	Secrete various potential allergens; localized allergic reaction.	Eosinophilic enteritis Larvae remain dormant in skeletal muscles and create no symptoms. In some individuals, larvae migrate to the gut and mature into adult worms. Severe recurrent abdominal pain.

Laboratory Diagnosis

Female worms have an extremely high daily output of eggs, making diagnosis relatively easy through the identification of eggs in feces. The large, broadly oval mammillated ova are typically stained brown from bile (Fig. 50.2A). Some eggs are **decorticated,** or lacking the mammillated outer cover (Fig. 50.2B). Infertile eggs may be oval or irregularly shaped, with a thin shell and containing internal granules. Adult worms may also be identified in feces. The adult male worm is smaller (15–31 cm) than the female, with a curved posterior end (Fig. 50.3), and it contains three well-characterized



• **Fig. 50.2** *Ascaris lumbricoides* eggs. The ovum on the right is a decorticated example, exhibiting an absent outer layer. Once fertile eggs have embryonated, they become infective after 18 days to several weeks. If ingested, larvae can hatch, causing the intestinal infection known as ascariasis, which infects children more often than adults. (Photo courtesy the Division of Parasitic Diseases/Centers for Disease Control and Prevention.)



• **Fig. 50.3** *Ascaris lumbricoides* adult male worm. Note the curved posterior end. (Courtesy Dr. Henry Travers, Sioux Falls, SD.)

lips. Larvae may be found in sputum or gastric aspirates because of larval migration during development within the human host. *Ascaris*-specific antibodies may be found (not useful in acute infection and not protective) with serologic studies. Increases in IgE and later IgG may be found. Other diagnostic tests (e.g., polymerase chain reaction [PCR]) have been described for identifying infection with soil-transmitted helminths. However, these are typically used for population-based treatment programs in endemic areas.

Therapy

Anthelmintic treatment is recommended for all infections. Preferred therapy includes oral albendazole or mebendazole.

Prevention

Prevention is managed through proper sanitation and good hygiene.

Enterobius vermicularis

General Characteristics

Enterobius vermicularis (pinworm) has a worldwide distribution and is commonly identified in group settings of children 5 to 10 years of age. The life cycle is considered direct; transmission occurs from an infected host to another individual (Fig. 50.4). During the night, the mature female worm migrates out of the anus of the infected host and lays eggs in the perianal region. The embryonated eggs mature and a third-stage larva develops, resulting in infectivity within hours. Transmission occurs by ingestion or inhalation of eggs. **Retroinfection** may also occur when the eggs hatch and larvae return to the intestine, where they mature.

Epidemiology

Pinworm is more prevalent in school-age children up to about 14 years of age. Infections are associated with institutional crowding and are familial. In adults, pinworm infection is most common in parents aged 30 to 39 years, typically because of transmission from their children aged 5 to 9 years. Overall, males are affected twice as often as females except in people aged 5 to 14 years, when infection is predominantly in females. Transmission is also associated with an increased rate of reinfection within a group or **autoinfection** from hatched larvae.

Pathogenesis and Spectrum of Disease

Infections with *E. vermicularis* are typically asymptomatic. The most common complaint is perianal pruritus (itching) and resultant restless sleep. The movement of the female and the ova cause intense local itching. Ova may survive for up to 3 weeks before hatching. The hatched larvae can then migrate back into the anus and lower intestine, causing retroinfection. Embryonated eggs may be released into the air or onto fomites (e.g., bedding, clothing, toys, paper money) or onto hands and then placed directly into the mouth and swallowed (autoinfection), after which they settle in the small intestines. Occasionally, the parasite may migrate to other nearby tissues, causing pelvic, cervical, or peritoneal granulomas. Table 50.1 summarizes the detail of associated diseases.

Laboratory Diagnosis

Diagnosis is typically by microscopic identification of the characteristic flat-sided ovum (Fig. 50.5). The eggs are best obtained by dabbing the stretched, unwashed perianal folds in the early morning with clear cellophane tape or a

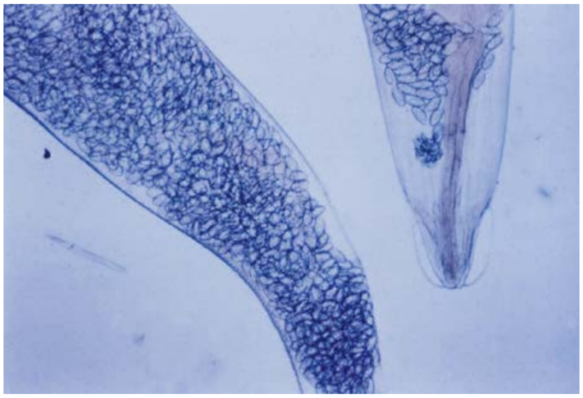
commercially available sticky paddle. Eggs are not typically identified in feces, although they may occasionally be found in a stool specimen. Although adult pinworms may be visible, they can easily be confused with small pieces of thread. The female worm is 8 to 13 mm long with a pointed "pin"-shaped tail. In gravid females, almost the entire body is filled with eggs (Fig. 50.6). The males measure only 2 to 5 mm in length, die after fertilization, and may be passed in feces.

Therapy

Anthelmintic therapy with albendazole or mebendazole is generally effective. Pyrantel and piperazine are effective and may be used during pregnancy. Reinfection with

E. vermicularis immediately after the completion of drug therapy is common. Additionally, young pinworms may be resistant to drugs. Successful eradication of pinworm infection requires two doses of medication; an initial dose followed by a subsequent dose 2 weeks later.



• **Fig. 50.6** *Enterobius vermicularis* gravid female. (Courtesy Dr. Henry Travers, Sioux Falls, SD.)

Prevention

Regular good personal hygiene is the major factor for prevention of continued reinfection and autoinfection.

Strongyloides stercoralis

General Characteristics

Infection with *Strongyloides stercoralis* is less common than that with other intestinal nematodes. The organism is endemic in the tropics and subtropical regions of Asia, Latin America, and Africa. It is estimated that 30 to 100 million people are infected with *Strongyloides* worldwide. A limited geographic distribution exists in the United States and Europe.

S. stercoralis, commonly referred to as the threadworm, may inhabit the intestine or exist as a free-living organism in the soil. The life cycle can be classified as direct, indirect (free-living phase), or autoinfective (Fig. 50.7). The **filariform** (infective) **larvae** penetrate the skin and migrate via the circulatory system to the heart and lungs. The organism

• **Fig. 50.8** *Strongyloides stercoralis* rhabditiform larva, iodine stain.

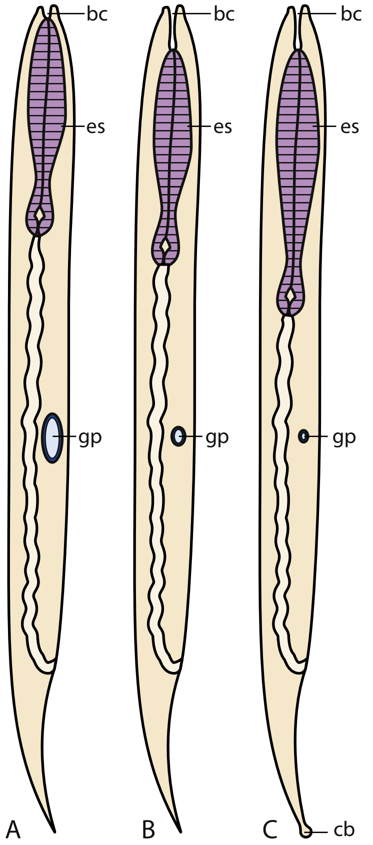
enters the bronchial tree and then is swallowed; it then lives in the digestive tract and matures into an adult worm. In the intestine, the filariform larvae may also penetrate the mucosa, resulting in autoinfection. The female worm produces eggs by **parthenogenesis** (a form of asexual reproduction in which growth and development occur without fertilization), because parasitic adult male worms are nonexistent. Within the indirect life cycle, the **rhabditiform** (noninfective) **larvae** develop into mature males and egg-producing females (Fig. 50.8). The free-living life cycle may revert to the production of infective larvae at any time.

Epidemiology

S. stercoralis and S. *fuelleborni* are transmitted via direct penetration in endemic areas. Person-to-person transmission of *S. stercoralis* occurs within institutionalized groups, in day care centers, and among homosexual males. *S. fuelleborni* larvae have been identified in breast milk, indicating that a transmammary infection may occur.

Pathogenesis and Spectrum of Disease

Infections may be asymptomatic or consist of a variety of disseminated **strongyloidiasis** syndromes. Reinfection is more commonly associated with immunocompromised patients. Acute infections may develop into a localized, pruritic, erythematous papular rash. Some patients develop a **macropapular** or **urticarial** (red and raised) or **serpiginous** rash on the buttocks, perineum, and thighs. The migration of larvae may cause epigastric pain, nausea, diarrhea, and blood loss. **Hyperinfection,** an increased worm burden within the lungs and intestines, may occur from penetration of the intestine by filariform larvae. Damage to the bowel may also increase the risk of bacterial infection with enteric microorganisms, leading to septicemia or meningitis. Disseminated infections may also result in larvae within the central nervous system, kidneys, and liver.



• **Fig. 50.9** Rhabditiform larvae. (A) *Strongyloides*. (B) Hookworm. (C) *Trichostrongylus*. *bc,* Buccal capsule; *cb,* beadlike swelling of caudal tip; *es,* esophagus; *gp,* genital primordia.

S. fuelleborni, a primate parasite, has been isolated from humans in Africa and Papua New Guinea; infection causes a severe, often fatal systemic illness involving protein-losing enteropathy, which sometimes presents with peritoneal ascites ("swollen belly syndrome"). *S. fuelleborni* follows the same life cycle as *S. stercoralis*, with the important distinction that the eggs (rather than larvae) are passed in the stool. The eggs hatch shortly after passage into the environment, releasing the rhabditiform larvae. Since eggs do not hatch within the host, as with *S. stercoralis*, autoinfection is believed to be impossible. Transmission of *S. fuelleborni* to infants as a result of breastfeeding has been reported. Table 50.1 summarizes the detail of associated diseases.

Laboratory Diagnosis

The rhabditiform larva is the primary diagnostic stage for strongyloidiasis in humans through microscopic examination of stool. The larvae are 250 to 300 μm long; they have a short **buccal capsule,** a large **bulb** on the esophagus, and a prominent **genital primordium** (Fig. 50.9). The filariform larvae are larger (up to 500 μm) and have a notched tail with an esophageal-to-intestinal ratio of 1:1. The eggs, which are rarely identified, are segmented, with a thin shell.

S. stercoralis larvae are most commonly found in human stool specimens. Depending on the fecal transit time through the intestine and the patient's condition, both rhabditiform and rare filariform larvae may be present. If stool examination is delayed, embryonated ova may be found.

Culture of feces for larvae is useful to (1) reveal the presence of parasites when they are too scant to be detected by concentration methods; (2) distinguish whether the infection is due to *S. stercoralis* or hookworm, based on rhabditiform larval morphology, by allowing hookworm egg hatching to occur, thus releasing first-stage larvae; and (3) allow development of larvae into the filariform stage for further differentiation. In the agar culture method, a stool sample is placed on a nutrient agar dish and incubated for 48 hours. The larvae crawl over the top of the agar, leaving tracks in the bacterial growth.

Serologic Testing

Serologic testing is indicated when infection is suspected and the organism cannot be isolated by repeated stool examinations, string test, or duodenal aspirates. A variety of serologic tests are available commercially, including an enzyme immunoassay (EIA), *Strongyloides* IgG EIA (DRG International Inc., Springfield, NJ). The Centers for Disease Control and Prevention also offers a highly sensitive (>95%) cross-reacting enzyme-linked immunosorbent assay (ELISA) with other parasites, including microfilaria, hookworm, *Paragonimus,* and *Echinococcus.* Immunocompromised persons with disseminated strongyloidiasis usually have detectable IgG antibodies despite their immunosuppression, although false-negative results can occur. Cross-reactions in patients with filariasis, schistosomiasis, and ascariasis may also occur, depending on the antigen used. Cross reactivity to sera from *S. fuelleborni*–infected patients probably occurs, but performance has not been evaluated. A positive serologic test result warrants continuing efforts to establish a parasitological diagnosis followed by anthelminthic treatment, as positive serology does not differentiate between past and current infection. Serologic reversion to antibody-negative status is unusual in most strongyloidiasis patients, although antibody levels decrease markedly within 6 months after successful chemotherapy. Thus, serologic monitoring may be useful in the follow-up of treated patients.

Nucleic Acid Detection

Although not available in routine laboratories, real-time PCR methods have been developed that amplify the small subunit of the 18S rRNA, the 18S rRNA, or the cytochrome c oxidase subunit 1 gene. These assays are used to detect DNA in fecal samples and have a demonstrated sensitivity and specificity of 100%. A high-throughput multiplex assay is also available that includes primer and probe pairs for *S. stercoralis* as well as other intestinal nematodes and protozoa.

Additional specimens such as sputum, body fluids, and tissues may be used for the diagnosis of hyperinfection.

Therapy

Ivermectin is the recommended treatment for uncomplicated infections. Albendazole and mebendazole are alternatives but have not proven to be as effective. Thiabendazole has been used to treat children with *S. fuelleborni* swollen belly syndrome. Hyperinfection and disseminated conditions require anthelmintic therapy in combination with broad-spectrum antibiotics to prevent secondary bacterial enteric infections. In addition, patients taking immunosuppressive medications should discontinue their use during infection and treatment. Follow-up examinations are indicated, and treatment should be reinstituted if larvae are identified within 2 weeks after cessation of therapy.

Prevention

Immunocompromised individuals and patients taking immunosuppressive medications should avoid beaches and other areas known to be contaminated.

Trichostrongylus spp.

General Characteristics

Although commonly found in mammals and birds worldwide, approximately 10 different species of *Trichostrongylus* have been found in human infections, including *T. orientalis, T. colubriformis*, and *T. axei*. The worms are small and live in the mucosa of the small intestine. The adult worm has no visible buccal capsule.

Epidemiology

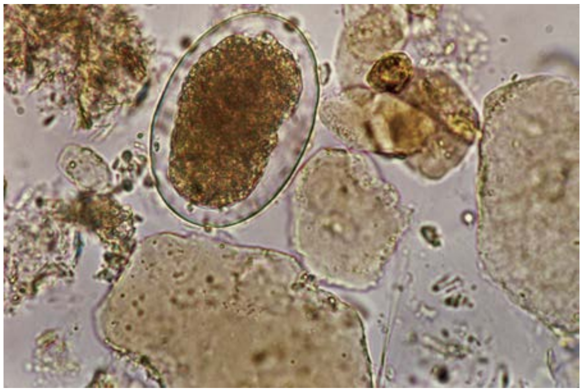
Human infections have been identified in areas within Asia and Africa. Additionally, approximately 70% of the human population in southwestern Iran and a village in Egypt is infected. Infection in humans is acquired by ingestion of plant material contaminated with larvae.

Pathogenesis and Spectrum of Disease

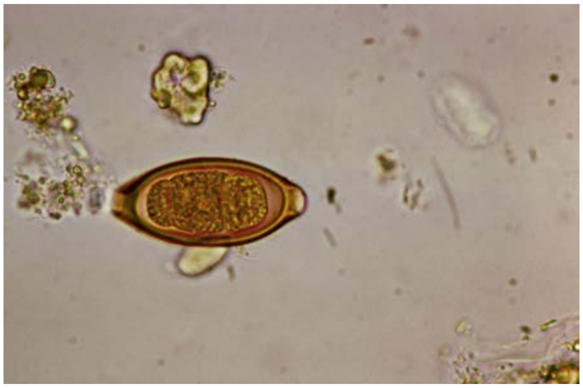
After they are ingested, the larvae mature and migrate through the lungs. Most infections are asymptomatic. Symptoms, when present, are related to the worm burden and the amount of damage within the intestine. Heavy infections can cause GI problems (abdominal pain, diarrhea, anorexia), headache, fatigue, anemia, and eosinophilia. Table 50.1 summarizes the detail of associated diseases.

Laboratory Diagnosis

Laboratory diagnosis includes identification of eggs or hatched larvae in the stool. Eggs are oval, thin-shelled, and



• **Fig. 50.10** *Trichostrongylus* sp. egg. (Courtesy Dr. Henry Travers, Sioux Falls, SD.)



• **Fig. 50.11** *Trichuris trichiura* egg. Note the evident polar hyaline plugs. (Courtesy Dr. Henry Travers, Sioux Falls, SD.)

colorless; they measure 75 to 95 µm in length by 40 to 50 µm in width. Eggs taper at one end and the inner membrane may be wrinkled. The eggs resemble hookworm eggs except that they are slightly longer and more pointed (Fig. 50.10). Patients may have coinfections with hookworm and *S. stercoralis* larvae, so care must be taken to differentiate the two (Fig. 50.9).

Therapy

Anthelmintic agents are recommended, including mebendazole and pyrantel pamoate. Albendazole is the treatment of choice.

Prevention

Thorough washing of plant material, including cultivated vegetables, before handling or ingestion is recommended.

Trichuris trichiura

General Characteristics

T. trichiura, or whipworm, has a worldwide distribution and is usually asymptomatic; however, heavily infected individuals may have symptoms. Unlike other intestinal nematodes discussed in this chapter, there is no tissue migration phase within the life cycle of *T. trichiura.*

Epidemiology

T. trichiura is typically found in moist, warm climates around the world. Infections are relatively common in Asia, Africa, and South America, with some cases identified in the southeastern United States. Often the nematode is identified in coinfections along with *A. lumbricoides* or hookworm in children.

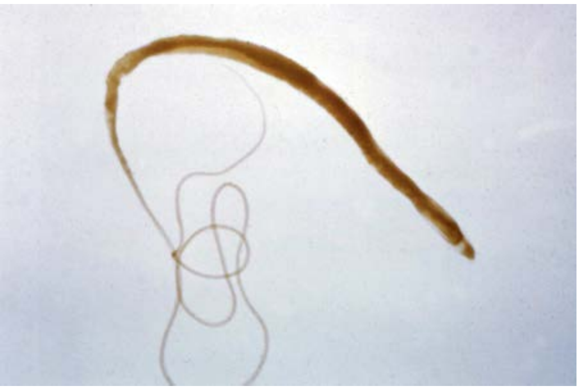
Poor hygiene is associated with increased transmission, especially in children. Humans are infected by ingestion of the embryonated eggs. Larvae are released in the intestine, where they mature into adult worms. Eggs containing the unsegmented **ovum** (diagnostic stage) are then passed in the feces and deposited in the soil. The eggs require a warm, moist environment for embryonation and to become infective to another host.

Pathogenesis and Spectrum of Disease

The pathogenesis and severity of the disease are closely related to the worm burden. The lack of symptoms is related to the life cycle, which does not include a tissue or pulmonary migration stage, resulting in no pulmonary or extra-GI symptoms, as are seen in other nematode infections. Infections range from mild, with a very low worm burden, to severe infections with bleeding and weight loss in heavy worm infestations. Heavy infections, especially in small children, can cause GI problems (abdominal pain, diarrhea, rectal prolapse) and possibly growth suppression. The characteristic whiplike worm buries its threadlike anterior into the intestinal mucosa and feeds on tissue secretions, causing an inflammatory reaction and peripheral eosinophilia. Table 50.1 summarizes the detail of associated diseases.

Laboratory Diagnosis

Diagnosis is typically from the identification of eggs and rarely the adult worm within the feces. An adult female may produce up to 20,000 eggs per day. However, during the lengthy development of mature worms within the intestine, there may be no shedding of eggs for up to 3 months. Eggs appear as brown barrel-shaped structures. They are unembryonated and contain a thick wall with **hyaline polar plugs** at each end (Fig. 50.11). The adult female worm ranges in size from 35 to 50 mm and demonstrates a gradually increasing width from anterior to posterior, with a straight end (Fig. 50.12). The adult male ranges in size from 30 to 45 mm and demonstrates the same broadening morphology with a coiled posterior end. PCR using new sequencing techniques is now available in specialized laboratories.



• Fig. 50.12 Adult female *Trichuris trichiura*. (Courtesy Dr. Henry Travers, Sioux Falls, SD.)

Therapy

Therapy may or may not be indicated, depending on the nutritional status of the host, the length of infection, and the level of worm burden. Anthelmintics such as albendazole are recommended when necessary.

Prevention

Prevention includes practicing proper hygiene and sanitation as well as careful disposal of dirt or soil contaminated with feces.

Capillaria philippinensis

General Characteristics

Capillariasis is a parasitic disease in humans caused by two different species of capillarids: *Capillaria philippinensis* and *Capillaria hepatica* (Chapter 51), a tissue nematode.

C. philippinensis is transferred through the ingestion of infected small freshwater fish and causes intestinal capillariasis. *C. philippinensis* was first recognized as a human parasite in the late 1960s and now has a well-known wide distribution. This parasite is prevalent in the northern Philippines, hence the name *C. philippinensis,* and has also been found in Thailand, Japan, Taiwan, Iran, and Egypt. The parasite reproduces in the gut, resulting in autoinfection and hyperinfection very similar to that observed in *S. stercoralis.*

Epidemiology

C. philippinensis is currently considered a parasite of fish-eating birds, which seem to be the natural definitive host. Human infection is believed to occur from the ingestion of uncooked fish harboring infective larvae. Typically, unembryonated eggs are passed in the stool by birds or humans and become embryonated in the external environment. After the ingestion of raw or undercooked freshwater fish, larvae hatch, penetrate the intestine, and migrate to the tissues. The adult worms reside in the small intestine, where they burrow into the mucosa. The females deposit unembryonated eggs. Some of these become embryonated in the intestine and release larvae that can cause autoinfection and may cause hyperinfection. In the Philippines, where the organism is prevalent, the people ingest a large spectrum of raw seafood, including fish, shrimp, crabs, and snails. In addition, defecation in the fields or water sources where snails, shrimp, and crabs are collected is common.

Pathogenesis and Spectrum of Disease

C. philippinensis cannot be transmitted human to human and requires an intermediate freshwater fish host. However, adult *C. philippinensis* worms in humans can release eggs that hatch into larvae in the intestine and cause hyperinfection. Initial signs and symptoms of infection include general abdominal pain and diarrhea. Symptoms will vary with the level of worm burden. The larvae are ingested and reside in the small intestine, where they burrow into the mucosa. Because of the parasite's mechanical insertion into the intestinal wall, patients lose weight rapidly, experiencing nausea, vomiting, malabsorption, and fluid loss. Long-term infections lasting weeks to months may result in death attributable to a severe loss of electrolytes, particularly potassium (hypokalemia), and associated organ failure. Table 50.1 summarizes the detail of associated diseases.

Laboratory Diagnosis

Tissue biopsy of the small intestine can be used for the diagnosis of infection with *C. philippinensis*. However, the diagnosis is typically made from the identification of eggs, adult worms, or larvae in stool specimens. The eggs resemble those produced by *T. trichiura.* They are somewhat smaller, with a thick, striated shell and less prominent polar plugs. Female worms produce the characteristic thick-shelled eggs as well as thin-shelled and free larvae.

Therapy

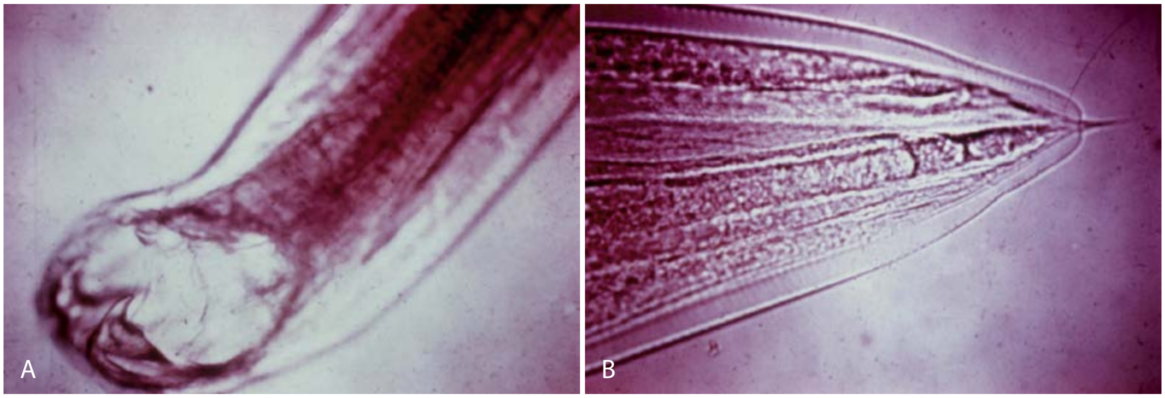
Anthelmintic agents including albendazole and mebendazole are recommended.

Prevention

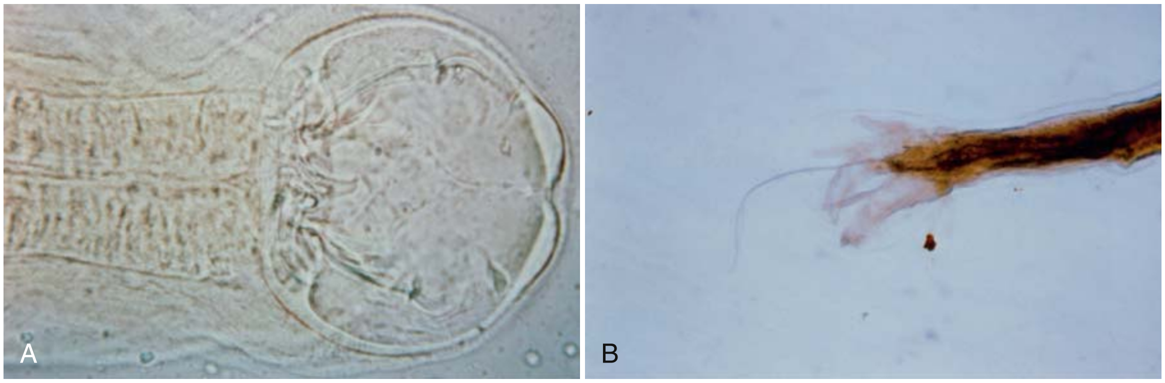
Adequate preparation and cooking of seafood—including fish, snails, crabs, and shrimp—in endemic areas is encouraged.

Hookworms

Hookworms are known to have a worldwide distribution. The two most common species known to infect humans include *A. duodenale* (Fig. 50.13) and *N. americanus* (Fig. 50.14). Additional hookworm organisms that play a lesser role in human infections include *A. ceylonicum, A.*



• Fig. 50.13 (A) *Ancylostoma duodenale* head. (B) Tail; note that it is pointed. (Courtesy Dr. Henry Travers, Sioux Falls, SD.)



• Fig. 50.14 (A) *Necator americanus* head; note the evident rounded cutting plates protruding from the head. (B) Copulatory bursa. (Courtesy Dr. Henry Travers, Sioux Falls, SD.)

braziliense, and *A. caninum*. Hookworms are the second most common helminthic infection reported in humans. The eggs and rhabditiform larvae of the species are indistinguishable. Differentiation of the species is based on the morphology of the buccal capsule and the adult male **copulatory bursa** (Fig. 50.14B).

The parasites, infective filariform larvae, penetrate the skin and enter the circulation, where they are capable of breaking through the capillaries and entering the lungs of the host. The larvae migrate up the bronchial tree and over the epiglottis and are swallowed. Upon entering the digestive system, the hookworms attach to the mucosa of the small intestine. Here they secrete anticoagulants and ingest blood as their source of nourishment. The worms mature and eggs are passed in the feces and deposited in soil, where they mature into rhabditiform larvae. The noninfective rhabditiform larvae will then mature into filariform larvae.

Epidemiology

Hookworms are found in areas with moist, warm soil capable of supporting their life cycle. Transmission is generally through direct skin penetration by filariform larvae.

Ancylostoma duodenale

General Characteristics

A. duodenale, or Old World hookworm, is prevalent in southern Europe, northern Africa, Southeast Asia, and South America. The adult male tends to be larger than the adult female of *N. americanus.* They attach to the intestinal mucosa by well-developed mouthparts (Fig. 50.13).

Pathogenesis and Spectrum of Disease

A. duodenale is capable of maturation within the intestine without migrating through the lungs of the host. Table 50.1 summarizes the detail of associated diseases.

Necator americanus

General Characteristics

N. americanus, or New World hookworm, is prevalent in Africa, Southeast Asia, and South and Central America as well as the southeastern United States. It attaches to the intestinal mucosa by well-developed **cutting plates** (Fig. 50.14A).

Pathogenesis and Spectrum of Disease

The major clinical presentation associated with hookworm infections is iron deficiency anemia. Table 50.1 summarizes the detail of associated diseases.

Ancylostoma ceylonicum, Ancylostoma braziliense, and *Ancylostoma caninum*

General Characteristics

A. ceylonicum primarily infects canines and felines but can cause mild hookworm disease in humans. *A. braziliense* is a canine and feline hookworm that, in humans, causes cutaneous larva migrans, or creeping eruption. The condition is generally self-limiting and characterized by the formation of serpiginous burrows as the larvae migrate through the epidermis. *A. caninum* is a canine hookworm that causes eosinophilic enteritis in humans and can causes cutaneous larva migrans.

Pathogenesis and Spectrum of Disease

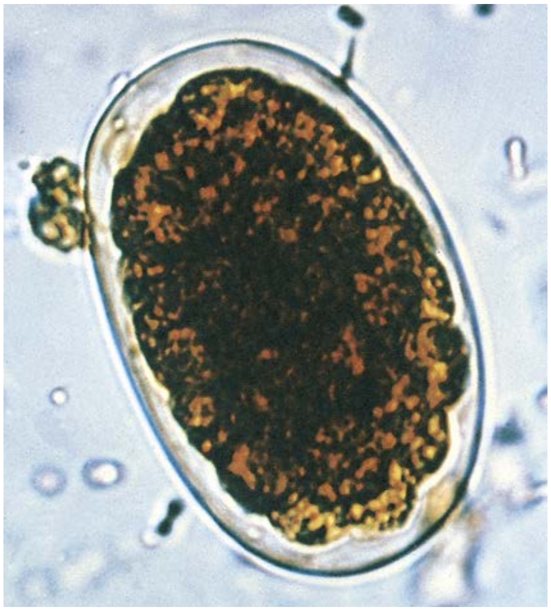
Hookworm infection gives rise to the following three clinical presentations in humans: (1) classic hookworm disease, a GI infection characterized by chronic blood loss that leads to iron-deficiency anemia and protein malnutrition primarily associated with *N. americanus* and *A. duodenale* and less commonly by the zoonotic species *A. ceylonicum*; (2) cutaneous larva migrans, an infection limited to serpiginous tracks in the skin and most commonly caused by *A. braziliense*; and (3) eosinophilic enteritis, a GI infection characterized by abdominal pain but no blood loss caused by the dog hookworm *A. caninum*.

In cutaneous larva migrans, the infective larvae do not elaborate sufficient concentrations of hydrolytic enzymes to penetrate the junction of the dermis and epidermis. The larvae remain trapped in the epidermis, where they migrate laterally at a rate of 1 to 2 cm/day and create the pathognomonic serpiginous tunnels associated with this condition. Larvae can survive in the epidermis for about 10 days before dying.

In eosinophilic enteritis, *A. caninum* larvae typically enter a human host by penetrating the skin, though infection by oral ingestion is also possible. These larvae probably remain dormant in skeletal muscles and create no symptoms. In some individuals, larvae may reach the gut and mature into adult worms. Why some individuals sustain *A. caninum* development and then respond with a severe localized allergic reaction is unknown. Adult worms secrete various biomolecules that may act as allergens in the intestinal mucosa. Some patients have been reported to experience increasingly severe recurrent abdominal pain.

Laboratory Diagnosis

Hookworms are typically diagnosed by the presence of eggs or rhabditiform larvae in stool specimens. The eggs and larvae of *N. americanus, A. duodenale*, and *A. ceylonicum* are indistinguishable. They are oval and thin-shelled, containing clearly visible four- to eight-cell-stage embryos. There is a characteristic clear space between the shell and the developing embryo (Fig. 50.15). Recovery and identification of eggs on direct smear or from concentration methods is recommended. Eggs may appear distorted on permanently stained smears. The rhabditiform larvae are typically 250 to 300 µm in length with a long buccal capsule and an inconspicuous genital primordium (Fig. 50.16). The larger filariform larvae are approximately 500 µm, with a pointed tail and an esophageal-to-intestinal ratio of 1:4. Both the rhabditiform and filariform larvae must be differentiated from *S. stercoralis*.



• **Fig. 50.15** Hookworm egg, iodine stain.

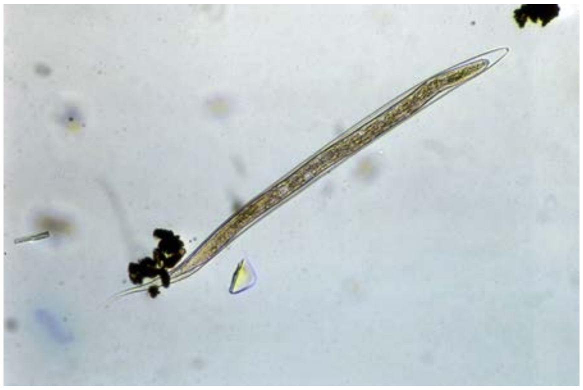
Fresh stool stored at room temperature may result in the continued maturation and hatching of larvae. Larvae may be cultured according to the Harada-Mori method previously described in this chapter.

In cases of cutaneous larva migrans, stool examination is not indicated because the larvae remain confined to the skin in almost all cases. In cases of eosinophilic enteritis, no eggs are found, as the adult *A. caninum* worms do not produce eggs in human hosts.

Progress is being made in the development of PCR-based methods for the specific diagnosis of hookworm infection but not available clinically.

Therapy

Anthelmintic agents including albendazole and mebendazole are indicated. However, because of variation in species and geographic distribution, some agents may not be effective in a specific population of parasites, and regional recommendations should be followed because of potential drug tolerance or resistance. Iron supplementation may also be required in severely anemic patients.



• **Fig. 50.16** Hookworm rhabditiform larvae. (Courtesy Dr. Henry Travers, Sioux Falls, SD.)

Prevention

Contaminated soil and beaches should be avoided. Appropriate footwear such as enclosed shoes should be worn in potentially contaminated areas.

Because of the immunosuppressive activity associated with the production of hookworm proteins, vaccination may be only partially effective. Currently no preventive vaccine exists. However, a protein, ASP-2, secreted by infective larvae of *N. americanus* is being investigated as a potential recombinant vaccine (www.clinicaltrials.gov).

Results and Reporting

Any identification of larvae or eggs in a patient's feces should be reported to the clinician. Treatment is typically recommended in asymptomatic and symptomatic infections. Quantitation of organisms is not required. Because parasite shedding may be intermittent or dependent on specimen quality, a single negative result does not ensure that the patient is not infected, and repeat testing may be necessary.

Visit the Evolve site for a complete list of procedures, review questions, and case studies.

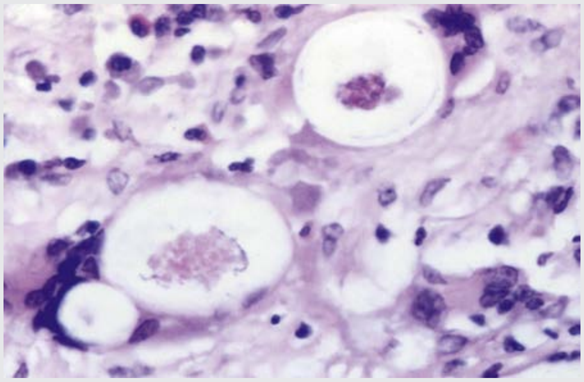
CASE STUDY 50.1

A 56-year-old male presented to the emergency department with fever, chest discomfort, and a nonproductive cough. A complete blood count indicated a mild elevation in the level of eosinophils with no additional abnormalities. The patient's chest x-ray demonstrated patchy lobular infiltration. He was then hospitalized for further evaluation. Three stool samples were collected over a period of 3 days with no evidence of parasitic infection. The patient died the following day.

Questions

1. What, if any, additional laboratory tests might have been helpful to improve the diagnosis and evaluation of the patient's condition?
2. The autopsy revealed liver damage associated with deposition of the inclusions identified in Fig. 50.17. Based on their morphologic appearance and the patient's initial symptoms, what is the likely parasite implicated in the patient's death?



• **Fig. 50.17** Nematode eggs embedded in liver tissue. (Courtesy Dr. Henry Travers, Sioux Falls, SD.)

Chapter Review

1. The filariform larva is the infective stage for
a. *Ascaris lumbricoides, Trichostrongylus* spp.
b. *A. lumbricoides, Strongyloides stercoralis*
c. *Ancylostoma duodenale, S. stercoralis*
d. *Trichuris trichiura, Necator americanus*

2. *Enterobius vermicularis* infection is diagnosed by
a. Identification of eggs in a concentrated stool specimen
b. Wet prep and iodine stain of a fresh stool specimen
c. The Baermann funnel method
d. Cellophane tape and microscopic slide preparation

3. A stool specimen from a patient was collected at 8 p.m. After collection, the specimen was not submitted to the laboratory until 11 p.m. The laboratory technologist found larvae in the fecal sample; each had long buccal capsule and a small, reduced genital primordium. The larvae are most likely
a. *A. duodenale*
b. *S. stercoralis*
c. *T. trichiura*
d. Unable to determine

4. Which of the following intestinal nematodes is transmitted through the ingestion of infective eggs?
a. *Trichostrongylus* spp.
b. *A. lumbricoides*
c. *Capillaria philippinensis*
d. *Strongyloides fuelleborni*

5. Which of the following roundworms is capable of autoinfection, hyperinfection, and a heavy worm burden with characteristic larval migration required in the life cycle?
a. *A. duodenale*
b. *E. vermicularis*
c. *S. stercoralis*
d. *A. lumbricoides*

6. A 4-year-old child presents to the physician. The mother claims the child has been persistently irritable and has not slept well in approximately 2 weeks. The child attends day care regularly, and the mother states that the day care provider has claimed there have been no other children complaining of illness. A urine sample was collected. Upon microscopic analysis, an oval, flat-sided ovum was identified. The most probable diagnosis is
a. *Taenia solium*
b. *E. vermicularis*
c. *Schistosoma japonicum*
d. *A. lumbricoides*

7. The intestinal nematode considered capable of vertical transmission and the potential cause of congenital infections is:
a. *A. lumbricoides*
b. *E. vermicularis*
c. *T. trichiura*
d. *A. duodenale*

8. True or False
_____ The severity of clinical signs and symptoms associated with intestinal nematode infections is often related to the level of worm burden.
_____ Löffler syndrome is associated only with *A. lumbricoides* infections.
_____ *S. stercoralis* can be differentiated from hookworm by its short buccal capsule and prominent genital primordium.
_____ *T. trichiura,* whipworm, is often easily identified because the adult worm is passed in feces.

9. Matching: *Match each term with the correct description.*

_____ autoinfection
_____ whipworm
_____ mammillated ovum
_____ *C. philippinensis*
_____ sexual transmission
_____ attachment by teeth
_____ indirect life cycle
_____ Harada-Mori
_____ *A. duodenale*
_____ parthenogenesis
_____ cutting plates
_____ Baermann funnel
_____ gravid
_____ copulatory bursa
_____ *T. trichiura*

a. asexual reproduction
b. no person-to-person transmission
c. *A. lumbricoides*
d. egg-producing female
e. reinfection from endogenous source
f. *S. stercoralis*
g. culture technique
h. concentration method
i. *T. trichiura*
j. hookworm
k. prominent polar plugs
l. *N. americanus*
m. migration not required during maturation
n. *A. duodenale*
o. seafood

51

Tissue Nematodes

OBJECTIVES

1. Describe the distinguishing morphologic characteristics and basic life cycle (vectors, hosts, and stages of infectivity) for each of the parasites listed.
2. Describe the diseases and mechanism of pathogenicity, including route of transmission, for each of the species listed.
3. Describe the life cycle of *Trichinella spiralis* in humans and swine, including the infectious form and location of adult worms.
4. Describe trichinosis and disease progression in humans, including body sites affected, peripheral blood presentation, severity of disease, and prognosis.
5. List the various methods used to diagnose tissue nematode infections.
6. Explain the diagnosis and recommended treatment for dracunculosis.
7. Define and differentiate visceral larva migrans, ocular toxocariasis larva migrans, and cutaneous larva migrans.
8. Correlate patient signs, symptoms, and route of transmission with the correct organisms described in this chapter.

PARASITES TO BE CONSIDERED

Helminths

Nematodes (Roundworms)

Tissue
Trichinella britovi
Trichinella murrelli
Trichinella native
Trichinella nelsoni
Trichinella papuae
Trichinella patagoniensis
Trichinella pseudospiralis
Trichinella spiralis
Trichinella zimbabwensis
Neural larva migrans (*Baylisascaris procyonis*)
Visceral larva migrans *(Toxocara canis* or *Toxocara cati)*
Ocular larva migrans toxocariasis *(T. canis* or *T. cati)*
Cutaneous larva migrans *(Ancylostoma braziliense* or
  Ancylostoma caninum)
Capillaria hepatica
Dirofilaria immitis
Dirofilaria hongkongensis
Dracunculus medinensis
Parastrongylus (Angiostrongylus) cantonensis
Parastrongylus (Angiostrongylus) costaricensis
Gnathostoma spinigerum

Tissue nematodes have life cycles similar to those of intestinal nematodes, consisting of five distinct stages including adult male and female worms and four larval stages. These organisms have a worldwide distribution and are predominantly found in the tropics and subtropics. The organisms are transmitted by three routes: biting and subsequent blood-feeding arthropods (filarial worms), as discussed in Chapter 52; ingestion of small freshwater crustaceans; and ingestion of contaminated meat. In most cases, adult worms do not multiply and develop within the human host. Clinical symptoms are dependent on the number of infecting parasites, the tissue invaded, and the host's general health and immune response. Diagnosis is typically by microscopic visualization of the organisms in tissue when appropriate.

Trichinella spp.

General Characteristics

The family *Trichinellidae* contains nine recognized species and three genotypes including *Trichinella spiralis, Trichinella nativa* (T2 and T6), *Trichinella nelsoni, Trichinella murrelli* (T5 and T9), *Trichinella papuae, Trichinella zimbabwensis, Trichinella patagoniensis, Trichinella pseudospiralis,* and *Trichinella britovi* (T3 and T8), all capable of causing trichinosis. The three species with a second genotype are indicated in parentheses. However, *T. spiralis* is the most common human pathogen. The organism is unique compared with other helminths in that all stages of development, including the adult and larval stages, occur within a single host.

Epidemiology

Trichinella occurs worldwide with the cycle maintained in several different mammalian, avian, and reptile species. The primary host serves as the definitive host for the adult worm and the intermediate host for the encysted larvae. Humans acquire the infection by eating undercooked meat that contains the infective encysted larvae. Although this is typically transmitted in pork, human cases have been associated with the ingestion of bear, walrus, and horsemeat as well as the meat of other mammals. The encysted larvae are ingested. When the undercooked meat is digested in the stomach, the larvae are resistant to the gastric pH and pass to the intestine, where they invade the mucosa. In about 1.5 days, the larvae mature and mate, and the female worm begins to release motile larvae. These larvae then migrate to the peripheral bloodstream, lymphatic system, or mesenteric venules and become distributed throughout the body. The larvae then deposit in the striated muscle tissue, where they can continue development and begin to coil, forming nurse cells that nourish the parasite and protect it from the human host's immune response. The nurse cell completes the formation of the cyst within about 2 to 3 weeks, becoming infective. The larvae encyst in the active striated muscle, including the diaphragm, larynx, tongue, jaws, neck, ribs, biceps, and gastrocnemius muscle. The generalized life cycle is depicted in Fig. 51.1. The larvae may remain viable within the cyst for several years. They eventually die, and the encysted capsules become calcified.

Pathogenesis and Spectrum of Disease

Trichinosis is a disease of the muscle caused by infection with the encysted larval form of *Trichinella* spp. (Fig. 51.2). The adult stages reside in the human intestine. The disease ranges from mild to severe depending on the number of parasites present. The intestinal stage lasts approximately 1 week and typically includes mild symptoms of nausea, abdominal discomfort, diarrhea, or constipation. Diarrhea may last as long as 14 weeks with no apparent muscle involvement. The migration of the larvae results in an intense inflammatory response causing periorbital edema, fever, muscle pain or tenderness, headache, and myalgia. A marked peripheral eosinophilia is often present. If the parasitic infection is low, eosinophilia may be the only diagnostic sign evident. Occasionally, splinter hemorrhages may be present below the nails. In addition to the typical infection of the active striated muscle as previously indicated, occasionally larvae migrate into the brain, meninges, and myocardium. However, the larvae do not encyst in these tissues. Brain and meningeal infections result in neurologic symptoms, and infection of the myocardium may result in myocarditis and dysrhythmias, leading to sudden death.

Laboratory Diagnosis

Diagnosis may be difficult because the symptoms may resemble a variety of flulike illnesses. Clinical symptoms that are indicators of trichinosis include fever, muscle pain, gastrointestinal symptoms, facial edema, and eosinophilia as well as subconjunctival, subungual, and retinal hemorrhages. A thorough patient history that includes consumption of laboratory-confirmed parasitized meat or link to a laboratory-confirmed case by exposure to the same common source may help the physician to diagnose the condition in a timely fashion. Identification of encysted larvae through muscle biopsy provides a definitive diagnosis. However, based on location, some tissues may be difficult to access; therefore, the condition may not be diagnosed until a postmortem examination. Histologic examination of formalin-fixed or paraffin-imbedded tissue may be used to visualize encysted larvae. Occasionally, depending on the length of infection, calcified larvae may be seen in x-rays.

Serologic Testing

Trichinella infections are most often diagnosed in the laboratory based on the detection of antibodies to excretory/secretory *Trichinella* antigen by enzyme-linked immunosorbent assay (ELISA) or indirect immunofluorescence assay (IFA). Serologic diagnosis is sufficient in most cases. Testing is rarely positive in early disease. Patients will present with a specific immunoglobulin G (IgG) antibody response in 3 to 5 weeks after acute illness. A negative serologic test followed by a positive seroconversion is considered a definitive diagnosis.

Nucleic Acid Detection

Molecular species–specific nucleic acid–based amplification assays have been developed. This technique, however, is generally used as confirmatory rather than a screening test due to the high expenditure of labor and time and intensive costs. The direct detection of muscle-stage larvae based upon appropriate examination of muscle biopsies etiologically proves the diagnosis. Furthermore, isolated larvae enable the molecular identification of the *Trichinella* species or genotype—a procedure that is not possible by serology. The disadvantages of this method is that it requires a significant surgical intervention in the affected person, and the sensitivity of the diagnosis depends on the amount of muscle sample tested. Currently these methods are predominantly used in animal epidemiologic studies and have not been implemented within the diagnostic laboratory.

Therapy

Thiabendazole is used during the intestinal phase to reduce the number of potentially infective larvae, and although the encysted larvae cannot be removed, albendazole is used to limit the continued pathologic development of the organism. Supportive measures including analgesics, antihistamines, and steroids, which may be administered to decrease the effects of the generalized inflammatory response.

Prevention

The most effective prevention relies on eating thoroughly cooked meat as well as maintaining good animal husbandry for domestic swine. This is not typically a concern in the United States because of the US Department of Agriculture (USDA) meat inspection requirements and regulations.

Toxocara canis (Visceral Larva Migrans) and *Toxocara cati* (Ocular Larva Migrans)

General Characteristics

Toxocara canis (intestinal ascarid of dogs) and *Toxocara cati* (intestinal ascarid of cats) are the cause of a human syndrome resulting from larval migration within the host.

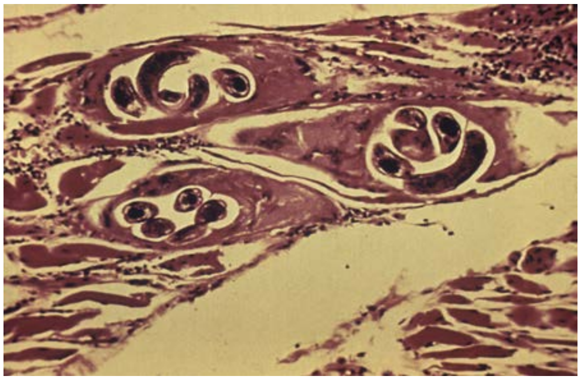
(PORK, etc.)

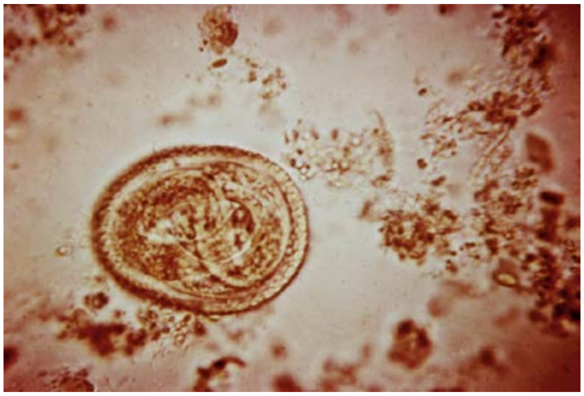
• **Fig. 51.1** The various life-cycle stages through which the intestinal nematode *Trichinella spiralis* passes as it matures from an egg to its adult form. Trichinellosis is acquired by ingesting meat containing cysts, or encysted larvae, of *Trichinella* spp. organisms. After exposure to gastric acid and pepsin, the larvae are released from the cysts, invading the small bowel mucosa, where they develop into adult worms. (Image Courtesy the Division of Parasitic Diseases/Centers for Disease Control and Prevention.)

Epidemiology

Toxocariasis is a zoonotic disease with worldwide distribution. Humans become infected after the accidental ingestion of the parasite's eggs (Fig. 51.3). The definitive hosts, dogs *(T. canis)* and cats *(T. cati),* pass the larvae transplacentally or lactogenically to their offspring and pass unembryonated eggs in the feces. The eggs mature in 10 to 20 days and then become infective. Once the eggs have been ingested, the larvae are released in the small intestine, penetrate the mucosa, and migrate to the liver, lungs, or other body sites. The adult worms are unable to mature in a human host and



• **Fig. 51.2** Trichinosis; developing *Trichinella* spp. encysted larvae contained within a section of human muscle tissue. (Image Courtesy the Division of Parasitic Diseases/Centers for Disease Control and Prevention.)



• **Fig. 51.3** *Toxocara canis* egg. Note the rough appearance on the outer surface of the egg. The egg also contains an infectious L2 larva. (Courtesy Dr. Henry Travers, Sioux Falls, SD.)

therefore wander throughout the body, causing the migratory syndromes.

Pathogenesis and Spectrum of Disease

Typically, these infections are mild, but they can sometimes be severe. Severe life-threatening infections occur when there is involvement in the heart, brain, or other vital organs. Disease is more common in young children and may persist for long periods with minimal pathologic manifestations. Larvae that remain in the liver or lungs may become encapsulated in fibrous tissue. **Visceral** (tissue) **larva migrans (VLM)** may result in a high degree of eosinophilia; however, this may be absent in **ocular larva migrans (OLM).** Symptoms may include fever, hepatomegaly, hyperglobulinemia, pulmonary infiltration, cough, neurologic symptoms, and endophthalmitis. OLM may result in the development of a granulomatous reaction in the retina of the eye. In the **covert or common toxocariasis (CT)** form of toxocariasis, patients exhibit nonspecific symptoms that can be accompanied by eosinophilia and positive *Toxocara* serology. **Neurotoxocariasis (NT)** is caused by invasion of *Toxocara* larvae to the brain and spinal cord, leading to cerebral lesions and neurologic damage, predominantly in the cerebral and cerebellar white matter with occlusion of cerebral blood vessels. Table 51.1 summarizes the four types of toxocariasis.

Laboratory Diagnosis

Toxocariasis must be differentiated from other migratory helmintic diseases including *Ascaris lumbricoides, Strongyloides stercoralis,* and *Trichinella* spp. A history of exposure to dogs and cats is of importance when an infection with *Toxocara* spp. is being considered. Because humans are an insufficient host for completion of the organism's life cycle, eggs are not passed in the stool. Diagnosis typically requires biopsy of tissue to detect the migrating larvae.

Direct Microscopy

Demonstrating the presence of *Toxocara* larvae in tissue biopsy, cerebrospinal fluid (CSF), or ocular fluids using direct microscopy remains the "gold standard" for the diagnosis of toxocariasis. However, this method is invasive, insensitive, and time consuming. In addition, it can be difficult to distinguish between the larvae of *Toxocara* and those of other ascarids, especially when the larvae are degenerated or when only parts of the larvae are recovered from tissues.

Serologic Testing

Serologic diagnosis has proven effective, particularly in OLM. Aqueous humor–elevated antibody titer specific for *Toxocara* spp., compared with serum levels, is considered diagnostic. Although serologic testing has been useful, it is important to note that antibody titers may vary depending on the location of the infection. A serum titer of 1:8 is considered significant for OLM; 1:32 is significant for VLM.

Nucleic Acid Detection

Molecular techniques have high analytical specificity and shorter turnaround times than other diagnostics. Polymerase chain reaction (PCR)–based assays using a variety of genetic markers have been developed and have enabled the identification and phylogenetic analysis of *T. canis, T. cati*, and other ascarids. PCR-based testing has been utilized to identify *T. canis* larvae collected from human biopsies in OLM and from CSF in neuronal toxocariasis (NT). PCR-based assays, including quantitative real-time PCR (qPCR) and PCR-RFLP have been used for accurate identification and diagnosis of *Toxocara* eggs isolated from feces or soil. The development of loop-mediated isothermal amplification (LAMP) of nucleic acid has provided a rapid and cheap approach for assessing the contamination of soil with *Toxocara* eggs. Molecular methods with improved performance characteristics have the potential to advance the diagnosis of toxocariasis.

Therapy

Effective therapy depends on the location of infection, but several anthelmintic medications have been used, including thiabendazole, ivermectin, albendazole, and

TABLE 51.1 Characteristics of the Different Clinical Forms of Toxocariasis

Clinical Syndrome	Primary Population Affected	Primary Affected Sites	Associated Symptoms
VLM	Children age 2–7 years	Liver, heart, lungs, kidneys, and muscle	Fever, respiratory symptoms (such as cough, wheezing, dyspnea, bronchospasm, asthma), hepatomegaly, abdominal pain, vomiting, diarrhea, anorexia, weight loss, fatigue, neurologic manifestations, and pallor
OLM	Children age 5–10 years	Eye	*Toxocara* larval invasion of the peripheral retina and vitreous can cause three major clinical types of OT/OLM syndrome over days to weeks: diffuse nematode endophthalmitis, peripheral inflammatory mass type. In addition, posterior pole granuloma type. In addition, diffuse unilateral subacute neuroretinitis (DUSN), bilateral distal symmetric sensory neuropathy (DSN), and choroidal neovascular membrane formation have been attributed to prolonged *Toxocara* infection. There may be predominant unilateral or uncommon bilateral ocular involvement, characterized by visual impairment, strabismus, leukocoria, solid retinal mass predominantly at the posterior pole, vitreous mass or haze, retinal detachment, cataract, endophthalmitis, papillitis, uveitis, as well as visual loss, vitritis, papillitis, and evanescent outer retinal lesions leading to optic atrophy, retinal-artery narrowing, and diffuse-pigment epithelial degeneration.
CT	Children and adults	No specific site	In adults: breathing difficulties, rash, pruritus, weakness, and abdominal pain, elevated titers of anti-*Toxocara* antibodies, eosinophilia, and elevated total IgE levels
NT (NLM)	Children and adults	Central nervous system	Headache, fever, photophobia, weakness, dorsalgia, confusion, tiredness, visual impairment, epileptic seizures, neuropsychological disturbances, dementia, and depression. Motor impairment can also be observed in clinical NT/NLM cases, such as ataxia, rigor, para- or tetraparesis dysesthesia, urinary retention, and fecal incontinence. Rarely, recognizable neurologic signs of eosinophilic meningitis, encephalitis, myelitis, cerebral vasculitis, epilepsy, neuropsychologic deficits or combined pathological presentations, which may be associated with repeated low-dose infections, or cerebral vasculitis under anthelmintic therapy, optic neuritis, other cranial nerve involvement, and meningoradiculitis. Unlike NT, NLM generally results in rapid progression followed by severe damage, coma, and death.

CT, Covert or common toxocariasis; *DSN*, distal symmetric sensory neuropathy; *OLM*, ocular larva migrans; *NT*, neurotoxocariasis; *NLM*, neuronal larva migrans; *VLM*, visceral larva migrans.

diethylcarbamazine. Antiinflammatory medications including corticosteroids may be used to reduce the pathology associated with inflammation. Photocoagulation has been used to treat OLM. The prognosis is good, even in cases of OLM, with prompt diagnosis and proper treatment.

Prevention

Small children should be kept out of sandboxes and playgrounds frequented by dogs and cats. Sandboxes should be covered when not in use. Encouraging regular hand washing and teaching children to keep dirt out of their mouths will decrease the potential for infection. In addition, regular deworming of dogs and cats will reduce the spread of infective eggs.

Baylisascaris procyonis (Neural Larva Migrans)

General Characteristics

B. procyonis is found predominantly in raccoons but has now been recognized as causing neural larva migrans (roundworm encephalitis) in more than 100 different species of mammals and birds. Human infections generally result in severe neurologic disease or death.

Epidemiology

The organism can be found in raccoons in North America. The raccoons become infected after ingesting infective eggs or intermediate hosts, rabbits, rodents, or birds infected with encysted larvae. The larvae penetrate the mucosa of the small intestine and mature in the lumen. Humans are accidental intermediate hosts by ingesting eggs that have been released in the raccoon feces into the environment. Reports indicate that the organism has also been identified in domestic dogs and puppies, thus increasing the likelihood of human exposure.

Pathogenesis and Spectrum of Disease

Pathogenesis results from larval migration causing tissue damage and severe inflammatory reactions. Symptoms may include a macular rash on the face and truck, pneumonitis, and hepatomegaly. The larvae invade the eyes (OLM), spinal cord, and brain (NLM). Patients may present with eosinophilic meningoencephalitis or unilateral neuroretinitis. Granulomas have also been identified in the heart, pleura, lungs, large bowel, mesenteric lymph nodes, and other soft tissues. Patients suffering from NLM may experience mild neuropsychological problems progressing to loss of coordination, seizures, coma, and death.

Laboratory Diagnosis

Diagnosis is often made by eliminating other causes related to the presentation of symptoms. Hematologic and CSF examinations are nonspecific. Identification of the migrating larvae, lesions, or larval tracks in the eyes support the diagnosis.

Serologic Testing

Acute and convalescent serum or CSF can be used to detect *B. procyonis* antibodies. Antibodies have been found in asymptomatic family members and other individuals with routine contact with raccoons. Serologic testing is available from the Centers for Disease Control.

Therapy

Systemic corticosteroids and antihelminthic agents have been used to treat infections. Upon diagnosis and at the beginning of treatment the patient has generally already suffered severe neurologic damage.

Ancylostoma braziliense and *Ancylostoma caninum* (Cutaneous Larva Migrans)

General Characteristics

Ancylostoma braziliense and *Ancylostoma caninum* are common hookworms of dogs and cats. The parasites penetrate the skin and cause **cutaneous larva migrans (CLM),** also referred to as creeping eruption.

Epidemiology

Ancylostoma braziliense and *Ancylostoma caninum* are found in warm climates in the southeastern United States. Dogs and cats are the natural definitive host. The infective larvae penetrate the skin of the host and migrate in the circulation. The adult worms reside in the intestine. The eggs are shed in the feces of dogs and cats and undergo maturation in moist, sandy soil of areas protected from desiccation, such as under shady trees and beneath houses. Children are often infected while playing in sandboxes that have been contaminated with dog and cat feces.

Pathogenesis and Spectrum of Disease

The infective larvae penetrate the skin of the human host and migrate through the subcutaneous tissue. The host develops pruritic papules at the site of penetration, followed by serpiginous, vesicular, elevated linear tracks. The larvae will migrate several millimeters each day, forming these continued tracks. The area surrounding the tracks becomes inflamed with marked edema. The patient may present with a peripheral eosinophilia. Infection is typically self-limiting. As the larvae migrate, the host may scratch and scar the tissue, subjecting the host to potential secondary bacterial infections. The signs and symptoms resemble those of infection with similar insect larvae, *S. stercoralis,* and other animal hookworms. Systemic involvement is rare; however, cases of pneumonitis resulting from larval migration into the lungs have been identified. In addition, gastrointestinal discomfort including abdominal pain, diarrhea, and weight loss has been associated with these infections. This condition is referred to as **eosinophilic enteritis.** Table 51.2 summarizes the associated diseases.

Laboratory Diagnosis

Laboratory diagnosis is limited. Evidence of visible tracks and a patient history of possible exposure are usually sufficient. A biopsy (if performed) must be taken 1 to 2 cm ahead of the leading edge of a tract or else the larva may be missed. The patient may present with a peripheral eosinophilia. In systemic cases, larvae may be recovered from sputum, and Charcot-Leyden crystals may be evident.

Therapy and Prevention

Even though CLM is self-limiting, the intense pruritus and risk for infection mandate treatment. Prevention is key and involves avoidance of direct skin contact with fecally contaminated soil. Anthelmintic therapy may include ivermectin or thiabendazole.

Dracunculus medinensis

General Characteristics

Dracunculus medinensis, commonly referred to as the guinea worm, is the cause of a subcutaneous infection known as

TABLE 51.2 **Pathogenesis and Spectrum of Associated Diseases**

Organism	Pathogenesis	Mode of Transmission and Spectrum of Disease
Tissue nematodes	Attributed to three main factors: 1. Host immune response 2. Parasitic burden 3. General overall health of host	
Trichinella spp.	Worm burden may be small to several hundred. Migration and deposition of larvae in tissue depends on tissue involved in infection.	Ingestion of poorly cooked meat, particularly domestic swine, but may be found in several mammalian species.
Toxocara canis and *Toxocara cati*	Migration in host tissue and immune response.	Accidental ingestion of eggs. Mild to severe disease dependent on tissue.
Ancylostoma braziliense or *Ancylostoma caninum*	Migration, inflammation, and edema. Secondary bacterial infections.	Penetrate skin and migrate in circulation. Pneumonitis may occur. Systemic involvement is rare.
Capillaria hepatica	Dependent on worm burden. Migration of larvae to liver via portal vein and other organs such as lungs and kidneys.	Fecal-oral transmission. Ingestion of embryonated eggs in fecal-contaminated food, water, or soil. Hepatitis, anemia, fever, hypereosinophilia. Extended infection can result in organ failure and death.
Dirofilaria immitis	Pulmonary obstruction, subcutaneous nodules and inflammation. Granulomatous reaction.	Infection upon ingestion by a mosquito during a blood meal. Localized, limited inflammatory reaction.
Dirofilaria hongkongensis	Ocular obstruction and inflammation. Granulomatous reaction.	Infection upon ingestion by a mosquito during a blood meal. Localized; limited inflammatory reaction.
Dracunculus medinensis	Larvae migration, inflammation, and secondary bacterial infections.	Ingestion of infected copepods. Blisters develop where female exits the skin.
Parastrongylus cantonensis	Migration to central nervous system.	Ingestion of infected shrimp, fish, crabs, and frogs. Often self-limiting but may cause meningoencephalitis or meningitis.
Parastrongylus costaricensis	Migration resulting in inflammation and lesions in bowel.	Ingestion of salad contaminated with infected slugs or snails.
Gnathostoma spinigerum	Migration resulting in inflammation.	Ingestion of contaminated fish. Tissue damage based on worm burden and migration pattern.

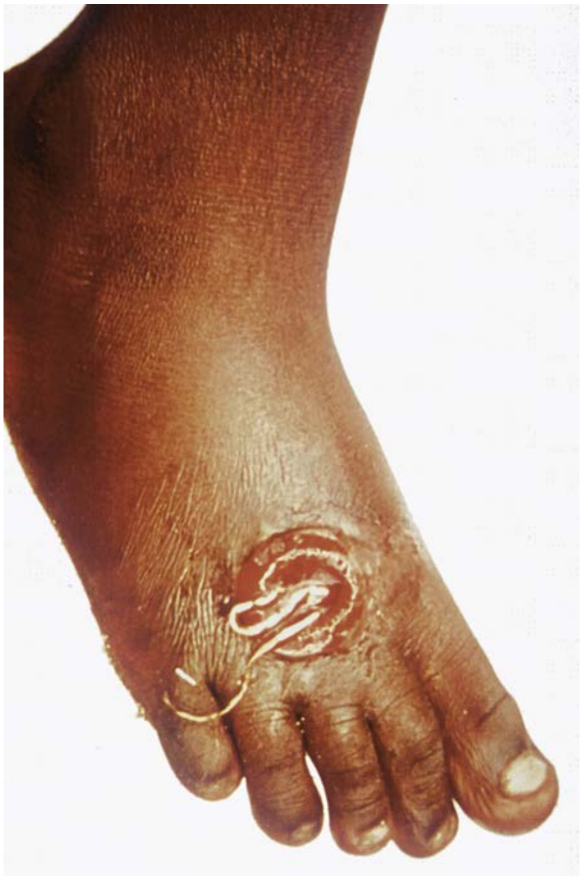
dracunculiasis. The worm has a characteristic thick cuticle and a large uterus that fills the body cavity and contains **rhabditoid** larvae.

Epidemiology

The parasite was once known to have a worldwide distribution affecting millions of people. In 2008, the World Health Organization in collaboration with governmental groups and other organizations attempted to eradicate the organism. Efforts have reduced the incidence of infection, confining the remaining endemic area to Africa. Humans are infected by the ingestion of freshwater from stagnant ponds containing larvae-infected copepods. The copepods are digested in the stomach, releasing the larvae. The larvae then penetrate the small intestine and migrate through the thoracic musculature. Both male and female worms mature in approximately 2 to 3 months. The gravid female develops in approximately 10 to 14 months, migrating to the lower extremities. The gravid female produces a blister on the skin; when the host submerges the affected area in water, the blister erupts and releases larvae into the water (Fig. 51.4).

Pathogenesis and Spectrum of Disease

The blisters formed by the gravid female worm cause burning and itching. Systemic symptoms may include



• **Fig. 51.4** *Dracunculus medinensis* emerging from a blister on an infected individual's foot.

fever, nausea, vomiting, diarrhea, headache, urticaria, and eosinophilia. Secondary bacterial infections may occur. In addition, dead worms within the host may be absorbed or may calcify, causing secondary inflammatory symptoms.

Laboratory Diagnosis

Diagnosis is by the identification of larvae or adult worms in clinical specimens. Serology may be used to identify infected patients before there is evidence of blistering and emersion of the worm. No nucleic acid–based tests have yet been developed for the diagnosis of *D. medinensis* infection.

Therapy

Treatment requires removal of the adult worms. The female worms are attached to a stick and slowly retracted from the host by gradual turning of the stick and removal of the worms. Although anthelmintic medications, such as metronidazole or thiabendazole, are not lethal, they are administered to assist with the retraction of the worms. Analgesics and antimicrobials are administered for discomfort and to prevent secondary infections.

Parastrongylus cantonensis (Cerebral Angiostrongyliasis)

General Characteristics

Parastrongylus cantonensis, previously known as *Angiostrongylus* sp., is a filarial worm commonly referred to as the rat lungworm.

Epidemiology

Parastrongylus spp. has a worldwide distribution; however, it remains an endemic health threat mainly in Southeast Asia and the Asian Pacific Islands. Varieties of rodents serve as the definitive host. The adult worms reside in the pulmonary artery and right side of the heart. The eggs shed by the female lodge in the pulmonary capillaries, where the larvae hatch and migrate up the trachea. The larvae are swallowed and passed in the rodent feces. Once released, the larvae infect the intermediate hosts, which are mollusks. The mollusks are consumed by a variety of **paratenic** (not required for the development or life cycle of the parasite) hosts such as shrimp, fish, crabs, and frogs. The rodents then consume the paratenic hosts and the larvae penetrate the intestine, enter the circulation, and migrate to the central nervous system (CNS). After two successive molts, the larvae then reenter the circulation and migrate to the pulmonary artery. Humans are infected by ingestion of either the intermediate or the paratenic host.

Pathogenesis and Spectrum of Disease

The pathogenesis correlates with the worm burden and the site of infection. The larvae may migrate to the CNS, causing meningitis or meningoencephalitis. Symptoms include headache, fever, eosinophilia, eosinophilic meningitis (with cells numbering >10/μL of CSF), increased CSF protein, and neurologic manifestations. Occasionally the larvae may migrate to the eye, causing blindness. Most often, the disease caused by *Parastrongylus* spp. is self-limiting.

Laboratory Diagnosis

Definitive diagnosis relies on histologic identification of the adult female worm, which has a distinctive morphologic appearance with a spiral, winding uterus resembling a barber pole. Highly specific serologic assays are available for patients with elevated eosinophils. Some cross reactivity has been reported between *A. cantonensis* and trichinosis, making diagnosis less specific.

Therapy

Anthelmintic therapy, such as mebendazole, may be helpful. It is important to monitor therapy closely because the therapy may actually exacerbate the inflammatory response of the host and cause more systemic damage. If larvae are located within the eye, surgical removal is recommended.

Parastrongylus costaricensis (Abdominal *Angiostrongyliasis*)

General Characteristics

Parastrongylus costaricensis is found primarily in the cotton rat and black rat.

Epidemiology

The parasite is endemic in areas of Central and South America, including Mexico and Costa Rica.

Pathogenesis and Spectrum of Disease

The life cycle is very similar to that of *P. cantonensis.* Human infection is typically by ingestion of salad contaminated with excretions from infected slugs or snails. The larvae create inflammatory lesions in the wall of the bowel, resulting in tissue inflammation, necrosis, vomiting, and diarrhea. The patient may experience lower-right-quadrant abdominal pain similar to that manifested in appendicitis. The eggs of *P. costaricensis* may also remain embedded in the tissue of the human host and are not passed in the patient's feces.

Laboratory Diagnosis

Histologic identification of the adult worm, larvae, or eggs in tissue sections results in definitive diagnosis. Patients often present with leukocytosis and eosinophilia. Radiologic imaging may be useful. Currently no molecular tests specific for this infection are available. However, for research purposes, *A. costaricensis* can be identified in tissue by conventional PCR followed by DNA sequencing analysis.

Therapy

Traditional anthelmintic therapy is recommended.

Gnathostoma spinigerum

General Characteristics

Gnathostoma spp., a gastric Spirurida, is found in a variety of mammals worldwide. Dogs and cats serve as the definitive host for *Gnathostoma spinigerum.* Although *G. spinigerum* is the most common species identified in humans, *G. hispidum, G. nipponicum, G. binucleatum, G. procyonis, G. binucleatum* and *G. doloresi* have also been associated with infection.

Epidemiology

The adult worms reside in the stomach of the definitive host, where they mate and produce eggs that are passed in the feces. When the feces are deposited in water, the larvae hatch and infect copepods. The larvae mature in the copepods and are then ingested by a variety of intermediate hosts including fish, snakes, and frogs. Inside the intermediate host, the larvae then migrate to the musculature and encyst until the tissue is ingested by the definitive host. The intermediate hosts may serve as a food staple for a paratenic host, such as a bird. Once ingested by the bird, the larvae can remain viable and be passed to the definitive host or to humans. Once in the definitive host, the larvae excyst and penetrate the gastric wall, migrating and maturing in the stomach. Humans act as accidental hosts when they ingest larvae in contaminated fish.

Pathogenesis and Spectrum of Disease

The worms are incapable of maturation within the human host and migrate aimlessly, causing tissue damage and inflammation, thus causing a disease that resembles visceral larva migrans. The infection is not typically fatal; however, it depends on the migration pattern and organs infected. Any organ system can be involved, but the most common manifestation of infection is localized, intermittent, migratory swelling in the skin and subcutaneous tissues. Such swellings may be painful, pruritic, and/or erythematous. In addition, *Gnathostoma* spp. commonly cause a parasitic eosinophilic meningitis due to larval migration into the CNS. Systemic infection is typically associated with peripheral eosinophilia, in which the percentage of eosinophils may exceed 50% of the circulating white blood cells (WBCs).

Laboratory Diagnosis

Identification of the larvae in tissue is definitive for diagnosis. The larval head contains four rows of **cephalic hooklets**, and the body is covered with transverse rows of spines that diminish anteriorly to posteriorly.

Serologic Testing

Both ELISA to detect IgG antibodies and immunoblot testing for neurologic disease has been described; however, these tests are not widely available in the United States and many other countries.

Therapy

Supportive corticosteroid treatment is recommended. Although anthelmintics are not lethal to this organism, they are often recommended. Surgical excision of the larvae is optimal.

Capillaria hepatica

General Characteristics

Capillariasis is a parasitic disease in humans caused by two different species of capillarids: *Capillaria hepatica* and *Capillaria philippinensis* (Chapter 50).

C. hepatica is transferred through the fecal matter of infected animals and can lead to hepatic capillariasis. Infection is rare but has been reported worldwide. Infective eggs hatch in the intestine of the human host, releasing larvae. The larvae migrate via the portal vein to the liver, where humans are considered a terminal host for the parasite.

Epidemiology

C. hepatica is often found in the liver of such animals as small rodents, monkeys, and prairie dogs and can cause cirrhosis in the animal hosts. When these animals are eaten by larger carnivores, capillarid eggs are ingested and passed in the feces. When this fecal matter is deposited in the soil, the eggs become infective in about 30 days. Accidental ingestion of the eggs from contaminated soil occurs in both animals and humans. The eggs hatch and the larvae migrate to the liver and mature into adult worms. The adult worms lay eggs in the liver. Humans are usually infected after ingesting embryonated eggs in fecal-contaminated food, water, or soil.

Pathogenesis and Spectrum of Disease

C. hepatica can be transmitted human to human when eggs are deposited through human fecal matter into the soil. The eggs then become infective in the soil, and humans ingest infective soil directly by eating soil (pica) or consuming it accidentally or indirectly through contaminated food or water. When a human is infected with only one *C. hepatica* worm, there are often no signs or symptoms. The adult worms lay eggs in the liver, resulting in clinical manifestations including hepatitis, anemia, fever, hypereosinophilia, and even death. Larvae may also migrate to the lungs, kidneys, or other organs. Table 51.2 summarizes the associated diseases.

Laboratory Diagnosis

No eggs are excreted in the feces in true human infections. *C. hepatica* can be diagnosed by performing a liver biopsy, needle biopsy, or after death at autopsy to identify the adult worm or eggs.

Therapy

Anthelmintic agents including albendazole and mebendazole are recommended. Steroids have been used with *C. hepatica* infections to help control the inflammation of the liver.

Prevention

Adequate preparation and cooking of seafood—including fish, snails, crabs, and shrimp—in endemic areas is encouraged.

Dirofilaria immitis and Other Species

General Characteristics

The filarial dog heartworm *Dirofilaria immitis* causes human **pulmonary dirofilariasis** worldwide. Although *D. immitis* is the most common species isolated from humans in the United States, additional species infect other mammals. *D. repens* infects wolves, coyotes, and foxes. Other species include *D. ursi* in bears; *D. striata,* wildcats; *D. tenuis,* raccoons; *D. striata,* bobcats and pumas; and *D. subdermata,* porcupines. These organisms are occasionally associated with human infections. *D. repens* is found in cats and dogs in Europe, Africa, and Asia. *Dirofilaria hongkongensis* is a newly identified species from Hong Kong and Asia. The parasite is transmitted by dogs and cats, causes **ocular dirofilariasis**, and is closely related to *D. repens*.

Epidemiology

The adult worms reside in the right ventricle of the heart of the infected mammal. The adult worm releases microfilariae into the bloodstream, which are then ingested by a mosquito. The microfilariae mature into infective larvae in the insect and are then transferred to another host when the mosquito feeds. The larvae migrate through the host, eventually reaching the heart, where they mature into adult worms. Humans are accidental hosts, and the worms are unable to reach maturity. The organisms die and are swept into the pulmonary circulation, where they become lodged in arteries or arterioles. This obstruction of the pulmonary circulation results in thrombosis, infarction, and inflammation. Eventually a wall of fibrous tissue is deposited around the worm, creating a granulomatous reaction. Species of *Dirofilaria* that manifest subcutaneously produce nodules that are often tender and may be fixed or migratory. *D. repens*–associated lesions can occur in a variety of locations, the most typical being exposed sites (e.g., scalp, arms, legs, eyelids, chest), but occasionally lesions have been found in deeper tissue such as the breast, epididymis, spermatic cord, and subconjunctiva. Many reports of *D. tenuis* involve the facial region (e.g., ocular and periocular sites, oral mucosa, cheek) and breast. There are very rare reports of subcutaneous infections with *D. striata, D. ursi*, and possibly *D. subdermata* in humans. *D. hongkongensis* larvae migrate to the ocular region and cause recurrent eyelid swelling in both eyes and conjunctival inflammation with watery discharge.

Pathogenesis and Spectrum of Disease

Approximately 50% of patients with dirofilariasis are asymptomatic and present with subcutaneous nodules or lung disease. Symptomatic patients present with generalized symptoms such as cough, chest pain, fever, malaise, chills, and **hemoptysis.** Some patients may present with a peripheral eosinophilia. The respiratory granulomas may be identified radiographically and are typically removed to rule out malignancies. Excision of the nodule or granuloma is typically sufficient treatment, resulting in no long-term pathology.

Laboratory Diagnosis

Definitive diagnosis of the parasite from a nodule may be extremely difficult because of the worm's degeneration in the granuloma. However, the presence of a worm within a pulmonary artery is usually supportive of the diagnosis. Serologic tests are available; however, cross-reactivity may occur with other nematodes; therefore, a negative reaction does not exclude infection. Currently no molecular methods are available in the United States for diagnosis of human dirofilariasis.

Therapy

As previously noted, excision of the granuloma or adult worm is typically sufficient, and additional treatment is not needed.

Blood and Tissue Filarial Nematodes

OBJECTIVES

1. Describe the distinguishing morphologic characteristics and basic life cycle (vectors, hosts, and stages of infectivity) for each of the parasites listed.
2. Define *microfilariae*, *hydrocele*, *chyluria*, and *sheath*.
3. Describe the diseases and mechanism of pathogenicity, including route of transmission, for each of the species listed.
4. Explain periodicity, including nocturnal and diurnal, as it relates to infection with microfilariae and correlate it with the life cycle of the associated arthropod vector.
5. Differentiate the microfilariae based on the presence or absence of a sheath and the arrangement and number of tail nuclei.
6. Describe the two methods of concentrating blood specimens for the identification of organisms within the peripheral blood.
7. Determine the cause of infection based on patient history, signs and symptoms, and laboratory results.

PARASITES TO BE CONSIDERED NEMATODES

Blood and Tissues (Filarial Worms)

Brugia beaveri
Brugia leporis
Brugia malayi
Brugia pahangi
Brugia timori
Dirofilaria spp.
Loa loa
Mansonella ozzardi
Mansonella perstans
Mansonella streptocerca
Onchocerca volvulus
Wuchereria bancrofti

Blood and tissue filarial nematodes are roundworms that infect humans. These organisms are transmitted via a blood-sucking arthropod vector such as a mosquito, midge, or fly. The filarial nematodes infect the subcutaneous tissues, deep connective tissues, body cavities, and lymphatic system. The life cycles of the filarial nematodes are complex (Fig. 52.1). The infective larval stage resides in the insect vector, and the adult worm stage, which is the pathogenic form, resides in humans. When the arthropod vector feeds on a human blood meal, the infective larvae are injected into the bloodstream. The larvae are motile and migrate to the lymphatic vessels. The infective larvae grow and develop into the adult gravid worm in the human host over a period of months. The male and female adult worms mate in the definitive human host. The female worm produces large numbers of larvae called **microfilariae.** Depending on the species, the microfilariae may maintain the egg membrane as a **sheath** or may rupture the egg membrane, resulting in an unsheathed form. These parasites can reside in the host for many years and cause chronic, debilitating conditions and severe inflammatory responses. Identification of the various species is based on the morphology of the microfilaria, the defined circadian rhythm, and the location within the human host. The morphologic characteristics of the microfilariae are important in the identification process and include the presence or absence of the sheath and the presence and arrangement of the nuclei in the worm's tail (Fig. 52.2). A comparison of the morphologic characteristics of the pathogenic filarial worms is depicted in Fig. 52.3. Diagnosis of infection is based on the identification of the microfilariae in the host's blood or tissues.

Wuchereria bancrofti

General Characteristics

Wuchereria bancrofti is transmitted via a mosquito, the *Culex fatigans, Anopheles,* or *Aedes* spp. The adult worm, or microfilaria, has a sheath that stains faintly or not at all. It may grow to approximately 298 µm long and 7.5 to 10 µm wide. The tail is pointed and no nuclei are present (Fig. 52.4).

Epidemiology

W. bancrofti is the most commonly identified species of filarial worms that infect humans. It is widely distributed in the tropics and subtropics, including Africa, South America, Asia, the Pacific Islands, and the Caribbean. The mosquito vectors have complex life cycles that include laying eggs and developing larvae on the surface of a water source. When

the larvae mature into adult mosquitos, the males and females will swarm in the evening and mate. The female requires a blood meal to reproduce. The mosquito becomes the intermediate host for the microfilarial parasite. Humans are the definitive host and the reservoir for *W. bancrofti.* The parasite has two forms that demonstrate different periodicities. The nocturnal periodic form is found in the peripheral blood during the night between 10 p.m. and 4 a.m. The second form is found only in the Pacific Islands and is present in the blood at all times, but more frequently during the day in the afternoon hours.

Pathogenesis and Spectrum of Disease

Microfilarial clinical disease varies geographically based on the species of nematode causing the infection. The disease

• **Fig. 52.4** Microfilaria of *Wuchereria bancrofti* in thick blood film.

may present as acute or asymptomatic for many years. *W. bancrofti* causes **bancroftian filariasis** and **elephantiasis.** The adult worm resides in the lymphatic vessels distal to the lymph nodes. The presence of organisms within the host results in an immunologic response including inflammation, lymphedema, and hyperplasia. Lymphedema most often occurs in the lower extremities. Elephantiasis is a crippling condition that results from extended periods of filarial infection. Obstruction of the lymphatic vessels causes fibrosis and a proliferation of dermal and connective tissue, resulting in the wrinkled, dry appearance of an "elephant" extremity. Lymphedema may also occur in the arms, female breasts, and scrotum of infected individuals.

Acute lymphatic filariasis results from worms residing within the lymph nodes. The lymph nodes swell, and lymphangitis may appear peripherally from the infected node. A **hydrocele—**a fluid-filled sac within the scrotum—may form when adult worms block the retroperitoneal or subdiaphragmatic lymphatic vessels. Obstruction of the lymphatic vessels may result in a condition referred to as **chyluria,** which is a result of lymphatic rupture and fluid entering the urine. The urine will appear milky white. Resulting infection and changes in the skin may lead to increased bacterial infections.

Patients residing in tropical regions where filarial parasites are endemic may present with a syndrome referred to as **tropical pulmonary eosinophilia (TPE).** The microfilariae migrate through the pulmonary blood vessels to the lungs, causing an allergic hypersensitivity in the host. The patients develop a strong immune response to the presence of the parasites with an elevated serum immunoglobulin E (IgE) level. Symptoms of TPE include weight loss, low-grade fever, cough and wheezing at night, and lymphadenopathy. Without treatment, patients may develop chronic and progressive respiratory complications leading to death.

Endosymbiont

W. bancrofti, Brugia spp., and *Onchocerca volvulus* harbor *Wolbachia* sp., an endosymbiotic alpha-proteobacterium. *Wolbachia* is an obligate intracellular organism.

The parasites require the endosymbiont for larval development, viability, and fertility. The bacteria have been implicated in the pathogenesis of the infection with filarial parasites. The bacterial antigens enhance the host's inflammatory response, leading to increased scarring and damage within the host's lymphatic system. The bacterium is sensitive to tetracycline, doxycycline, azithromycin, and rifampin. Combination antibiotic treatment in conjunction with treatment for the parasite infection improves clearance of the filarial parasite.

Laboratory Diagnosis

Direct Detection

Definitive laboratory diagnosis is based on identification of the parasites in blood, fluids, or tissue. Blood samples should be drawn in accordance with the periodicity of the infection to optimize the likelihood of isolating the infecting organism. Direct examination of blood, urine, hydrocele fluid, or chyle may serve to identify the parasite. The fluid is placed on a slide and air-dried to prevent distortion of the parasite. The specimen should be stained with Giemsa, Wright, or hematoxylin stain and examined microscopically. Ultrasound may be used to visualize the organisms within the tissues.

Nucleopore filtration or the **Knott concentration** may be used to increase the likelihood of isolating a filarial parasite from blood. The blood is passed through a polycarbonate filter that contains a 2-µm pore. Distilled water is passed through the filter, lysing the red blood cells and improving visualization of the parasites. The filter is air-dried, stained with Wright or Giemsa, and examined for the presence of microfilaria. The Knott concentration uses centrifugation to concentrate the organisms onto a slide. One milliliter of anticoagulated blood is placed in 9 mL of 2% formalin and centrifuged at 1500 rpm for 1 minute; the sediment is applied to a microscope slide. The slide is stained and examined microscopically. With high-frequency ultrasound, adult worms can sometimes be visualized moving within the lymphatics.

Serologic Testing

Serologic assays that measure antibody response have limited utility in the diagnosis of infections with microfilariae. The antibodies tend to demonstrate a high cross reactivity with other antibodies made in response to a wide variety of parasitic worm infections. The absence of an antibody reaction indicates the lack of infection by a microfilarial species. Laboratory detection of *W. bancrofti*–circulating antigens has demonstrated high specificity (>97%) and sensitivity (from 70% to 80%) in detecting parasitic infections. The commercial testing formats available are not approved by the US Food and Drug Administration (FDA).

Antigen Detection

A variety of rapid antigen tests are capable of detecting circulating antigens of *W. bancrofti* from whole blood, serum, or plasma. These tests can be used on blood drawn at any time, thus avoiding the need for specimen collection that depends on the periodicity of the microfilariae. Two rapid-format immunochromatographic tests have been shown to be useful and sensitive for the detection of *W. bancrofti* and are being used widely by lymphatic filariasis elimination programs.

Nucleic Acid Detection

Nucleic acid–based methods have been shown to be the most sensitive diagnostic tests for definitive diagnosis of infection with microfilariae. A variety of formats have been developed, including DNA hybridization, polymerase chain reaction (PCR), multiplex PCR, restriction length polymorphism (RFLP), quantitative PCR, and a PCR enzyme-linked immunosorbent assay. These methods can discriminate past and current infection and can be used to monitor therapy. PCR amplification is available in reference laboratories for the rapid diagnosis of an infection with blood microfilariae including *W. bancrofti* and *Brugia* spp. Multiplex PCR-RFLP can differentiate *W. bancrofti, Dirofilaria imminitis, Dirofilaria repens, Brugia pahangi,* and *Brugia malayi* in blood. *B. pahangi* is a common parasite of dogs and cats in Malaysia and has been implicated in human infections. A loop-mediated isothermal application assay has also been developed that may be useful in the field or as a point-of-care diagnostic test. These tests are not currently commercially available.

Brugia malayi and *Brugia timori*

General Characteristics

The *Brugia* spp. are lymphatic filarial parasites resembling *W. bancrofti.* The adult parasites, microfilariae, vary in size (*Brugia timori,* 310 µm long and 5 to 6 µm wide; *Brugia malayi,* 177 to 230 µm long and 5 to 6 µm wide), have a different geographic distribution, and do not typically cause lymphadenitis in the genital regions.

Epidemiology

The *Brugia* spp. are distributed throughout the Far East including China, Indonesia, Korea, Malaysia, Japan, India, and the Philippines. The distribution of *B. timori* is limited to the two islands of Timor, an island of Indonesia. The organism is transmitted via mosquitos included in the genus *Anopheles* and *Mansonia.*

Pathogenesis and Spectrum of Disease

As in infections with *W. bancrofti,* two periodic forms exist. The nocturnal form is the most common and is located near areas of coastal rice fields, whereas the nonperiodic form is associated with infections in areas near swampy forests. The pathogenesis and spectrum of disease is essentially the same as for *W. bancrofti,* with the exception that involvement of the genital lymphatic vessels is predominantly associated with *W. bancrofti.* Urogenital involvement with chyluria does not occur in infections with *Brugia* spp. Clinical disease progresses faster after infection with *B. malayi* than with *W. bancrofti.* Microfilariae may appear in the blood in as little as 3 to 4 months.

Brugia spp. have been implicated in zoonotic infections of dogs, cats, rabbits, and raccoons worldwide. Mosquitos transmit the infection by feeding on an infected animal and then a human host in approximately 2 weeks. Cases of human infection have occurred in the United States in the northeastern region with *B. beaveri. B. beaveri* infect raccoons, bobcats, or mink and *B. leporis* infects rabbit. Clinical disease is typically asymptomatic but may present with a tender region in the cervical, axillary, or inguinal region. The lymphatic mass may contain either a live or a dead worm. If the worm is no longer viable, the mass may be surrounded by a granulomatous reaction.

Laboratory Diagnosis

Definitive diagnosis is generally by identification of microfilariae in the blood of infected individuals. The microfilariae can be distinguished from *W. bancrofti* morphologically. The *B. malayi* microfilariae are sheathed and contain four to five subterminal and two terminal nuclei in the tail. *B. timori* also contains five to eight subterminal and terminal nuclei in the tail, but they are much larger than *B. malayi.* The *B. malayi* sheath will stain bright pink with Giemsa, whereas the *B. timori* sheath does not stain. The microfilariae of *B. timori* tend to be somewhat longer. High-frequency ultrasound has been useful in identifying adult worms in various locations within the patient, such as lymphatic vessels of the legs, inguinal area (groin or lower abdomen), lymph nodes, and female breasts. Nucleic acid–based methods have been developed as previously indicated in the diagnosis of *W. bancrofti* and can differentiate microfilariae.

Therapy

Diethylcarbamazine (DEC) is the treatment of choice for lymphatic filarial parasites including *W. bancrofti* and *Brugia* spp. Additionally, ivermectin and albendazole may be used. Death of the microfilarial worms may result in an increased hypersensitivity reaction requiring the need for treatment with antihistamines to limit the inflammatory symptoms.

Prevention

The use of insect repellent is recommended for travelers in areas where the parasites are endemic. DEC has also been used for prophylactic treatment before travel. Vector control studies in combination with mass drug administration of DEC and ivermectin have successfully decreased the population of the arthropod (insect) vectors and decreased filarial infection in the human hosts.

Loa loa

General Characteristics

Loa loa, commonly referred to as the eye worm, is a microfilaria that circulates in the bloodstream with a diurnal periodicity that peaks in the afternoon between 12:00 p.m. and 2:00 p.m. and resides in the subcutaneous tissue in the human host. The microfilariae may grow up to 300 µm.

Epidemiology

The parasite is found within the rain forests of West and Central Africa. The organism is transmitted through a bite of the tabanid fly or deer fly of the genus *Chrysops.* The female lays her eggs on the leaves of small plants near the water. The larvae feed on small insects and develop in wet soil. The male fly feeds on pollen, and the female feeds on blood.

Pathogenesis and Spectrum of Disease

The organism is often associated with asymptomatic infection. The larvae develop into adult worms in approximately 6 to 12 months but can persist in the human host for up to 17 years. The infection is typically identified when the adult worm is seen migrating within the subconjunctiva of the host. Symptoms associated with infection include episodic **calabar swellings,** which are localized areas of transient angioedema in response to the production of parasitic metabolic products. Predominant swelling on the extremities with inflammation of nearby joints and peripheral nerves may occur. Immune-mediated encephalopathy, nephropathy, and cardiomyopathy may occur.

Laboratory Diagnosis

Infections with *Loa loa* may be asymptomatic for many years before the appearance of microfilariae in the peripheral blood. Therefore patient diagnosis is often made based on the patient's clinical symptoms, including calabar swelling, eosinophilia, and travel or residency in an endemic area.

Direct Detection

Definitive diagnosis is made by identification of adult worms in the eye or in tissue or by identification of microfilariae in the peripheral blood. Microfilariae have a sheath that does not stain with Giemsa. The adult females are larger than the adult males, and the nuclei extend to the tail in an irregularly arranged fashion.

Serologic Testing

As with other filarial infections, serologic assays have limited use for diagnosis. A *Loa*-specific recombinant protein (LLSXP-1) has been used in the development of an enzyme-linked immunosorbent assay (ELISA) and has demonstrated improved specificity but limited sensitivity. A rapid detection test for LLSXP-1 IgG has been developed that demonstrates a sensitivity greater than 90% and a specificity of approximately 95%. Detection of IgG may be useful in confirming the diagnosis in travelers to areas of endemicity in the presence of unexplained eosinophilia and appropriate clinical symptoms.

Nucleic Acid Detection

PCR-based techniques have been developed for the detection of *Loa loa*, with specificities and sensitivities as high as 100% and 95%, respectively. However, these techniques yield negative results during prepatency, the period between initial infection and detectability in the host. These tests also demonstrate false-positive results in individuals with previous *L. loa* infections, as they also detect DNA from dead microfilariae in blood. Real-time qPCR assays have also been developed with high species specificity and sensitivity (96%) for *L. loa*. These have been adapted to loop-mediated isothermal amplification (LAMP), allowing the potential for point-of-care and in-field use. A single PCR assay test for loiasis has been approved for diagnostic use in the United States.

Therapy

DEC is the treatment of choice. In heavy infections, inflammation and allergic reactions may occur, requiring the administration of antiinflammatory medications. Allergic responses can result in central nervous system damage, encephalitis, coma, and death.

Prevention

Prophylactic treatment with DEC has been used to prevent infection.

Onchocerca volvulus

General Characteristics

Onchocerca volvulus predominantly resides in tissue nodules within the host. Microfilariae measure approximately 300 µm long by 5 to 9 µm wide.

Epidemiology

O. volvulus is found throughout Africa, Central America, and South America. The parasite is transmitted by the black fly, *Simulium* spp. The black fly lays its eggs in running water where the larvae attach to rocks. The larvae feed on algae and bacteria. The adults emerge as a flying insect. The females require a blood meal, whereas the males are nectar feeders. The flies feed predominantly during the day.

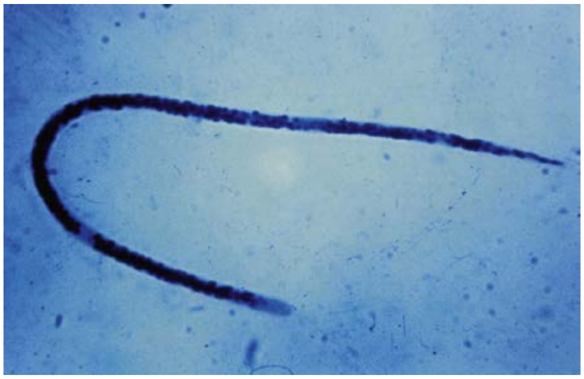
Pathogenesis and Spectrum of Disease

Onchocerciasis, commonly referred to as river blindness, is a result of subcutaneous infection with the parasite. The infections are typically localized to the skin, lymph nodes, and eyes. Skin infections result in pruritus, edema, and erythema. Hypopigmentation or hyperpigmentation can occur after a lengthy infection. Nodules containing the adult worms vary in size and are firm and tender. Lymphadenopathy may be found in the inguinal or femoral regions. Enlargement of the lymph node may result in a condition referred to as "hanging groin," which may develop into a hernia. Onchocercal eye disease may be seen in moderate to heavy infections. Infections of the eye may lead to serious damage and blindness. Mortality increases among adults who experience blindness and systemic infection.

Laboratory Diagnosis

Direct Detection

Definitive diagnosis is made from the identification of the microfilariae from tissue such as in a nodule or skin snip.



• **Fig. 52.6** Microfilaria of *Onchocerca volvulus.* (Courtesy Dr. Henry Travers, Sioux Falls, SD.)

Skin samples are placed in physiologic buffered saline for up to 24 hours. After incubation, the microfilariae will emerge from the tissue and can be visualized microscopically. Occasionally the microfilariae may be found in blood or urine after treatment. Microfilariae may also be visible in the cornea and the anterior chamber of the eye.

The microfilariae lack a sheath. The tail is tapered, appears bent or flexed, and does not include extension of nuclei to the tip (Fig. 52.6).

Serologic Testing

Although serologic tests generally lack specificity, recombinant ELISAs using multiple antigens have demonstrated increased sensitivity and specificity for the diagnosis of onchocerciasis. A rapid test, the SD Bioline Onchocerciasis, for the detection of an *O. volvulus* antigen known as OV-16, is commercially available. The test is used predominantly for surveillance and elimination of infection but may also be used for the diagnostic confirmation of infection.

Nucleic Acid Detection

PCR amplification assays using material from skin snips or skin scratches provides high sensitivity and specificity; these have been developed, but the limited availability of technical expertise as well as the high cost of the test restrict its use in resource-limited settings and to research laboratories.

Therapy

Ivermectin is the recommended treatment and is effective against both adult worms and microfilariae. However, in Africa, where *O. volvulus* and *L. loa* are coendemic, ivermectin treatment is often associated with encephalopathy in patients with heavy microfilaria infections. Surgical excision of nodules containing adult worms is recommended when they are located on the head. There is evidence that a 6-week course of doxycycline is useful in targeting the endosymbiotic proteobacteria *Wolbachia* spp. This causes sterility in the female adult worms for extended periods, reducing the infection in the host.

Prevention

Black fly larval control using insecticides in endemic areas has been used to assist in the control of transmission of *O. volvulus.* Community-based administration of ivermectin every 6 to 12 months is also being used to interrupt the transmission of the parasite in endemic areas and has been successful for the elimination of the parasite in Latin America.

Mansonella spp. (*M. ozzardi, M. streptocerca, M. perstans*)

General Characteristics

Mansonella spp. are generally not associated with serious infections. The microfilariae of all species are very similar in size, ranging from approximately 200 to 225 µm long and 4 to 6 µm wide.

Epidemiology

Mansonella spp. are distributed throughout varied geographic regions in Africa and South America. *Mansonella ozzardi* is limited to Central and South America and the Caribbean islands. The parasites are transmitted by biting midges of the genus *Culicoides.* The female requires a blood meal for the maturation of eggs and typically bites in the early evening or morning hours. Transmission of *M. ozzardi* has also been associated with bites from the blackfly *(Simulium amazonicum).*

Pathogenesis and Spectrum of Disease

Mansonella streptocerca is found in the skin; however, most infected individuals appear to be asymptomatic. Patients may present with a pruritic or papular rash and pigmentation changes. In addition, lymphadenitis may occur. *Mansonella perstans* resides in the pericardial, pleural, and peritoneal cavities. The location of the *M. ozzardi* adult worms is unknown. Symptomatic patients present with swelling of the arms, face, or other body parts similar to the calabar swelling identified in infections with *L. loa, M. ozzardi,* or *M. perstans* found in the blood.

M. perstans and *M. ozzardi* do not demonstrate periodicity when circulating within the bloodstream. *M. ozzardi* infections are often asymptomatic and therefore are not well characterized. Some infections with *M. ozzardi* demonstrate headache, joint pain, fever, pulmonary symptoms, adenopathy, hepatomegaly, and pruritus.

Laboratory Diagnosis

Laboratory diagnosis for *M. perstans* and *M. ozzardi* is generally made by identifying the microfilariae in blood or other body fluids. *M. perstans* and *M. streptocerca* can be diagnosed by identifying the microfilariae in skin snips.

Mansonella spp. microfilariae do not possess sheaths. *M. streptocerca* and *M. perstans* tails contain nuclei that extend to the end of the tip. The tail of *M. streptocerca* is often referred to as a shepherd's crook. *M. ozzardi* organisms have tails with nuclei that do not extend to the tip.

Nucleic Acid Detection

A few studies have evaluated the use of PCR for the detection of *Mansonella* spp. from venous and capillary blood samples. The tests appear to be more sensitive and specific than microscopy. Currently there are no commercially available nucleic acid tests for *Mansonella* spp**.**

Therapy

Ivermectin is effective in the treatment of *M. ozzardi* infections. DEC is effective in treating both the adult and microfilarial forms of *M. streptocerca.* Treatment of *M. perstans* infections has not been effective in most cases. However, because of infection with the endosymbiotic bacteria, *Wolbachia* spp., treatment with doxycycline has demonstrated some limited success.

Prevention

Prevention relies on the use of insect repellents and adequate clothing.

Dirofilaria spp. (*D. immitis, D. repens, D. tenuis*)

General Characteristics

Filarial nematodes of the genus *Dirofilaria* cause dirofilariasis. There are many species of *Dirofilaria*, but human infection is most commonly associated with three species, *D. immitis*, *D. repens*, and *D. tenuis*. Female adult worms grow up to 10 to 12 in in length, whereas males are 4 to 6 in long and have spirally coiled tails. Microfilariae are white, long, and threadlike.

Epidemiology

The definitive natural hosts for these three species are dogs and wild canids, such as foxes and wolves (*D. immitis* and *D. repens*) and raccoons (*D. tenuis*). *D. immitis* is also known as heartworm and is the cause of human dirofilariasis in the eastern and southeastern United States. *D. repens* is the leading cause of human dirofilariasis in Europe and is found in Africa and Asia. *D. tenuis* is found in raccoons in the United States. The adult worms produce microfilariae within the definitive animal host; these circulate in the blood and are ingested by mosquitoes during a blood meal. In mosquitoes, the microfilariae develop into larvae that migrate to the proboscis (the long tubular part of the mosquito's mouth). During a blood meal, the larvae are released into the skin of the human host. The worms are unable to reach maturity in the human host, therefore no microfilariae are detectable. Occasionally larvae will migrate to the pulmonary vessels. Several types of mosquitoes are capable of transmitting *Dirofilaria* infection, including *Aedes*, *Anopheles*, and *Mansonia*.

Pathogenesis and Spectrum of Disease

Humans and a wide range of other mammals are accidental hosts that play no role in the transmission of *Dirofilaria*. In these hosts, *Dirofilaria* larvae can develop into adult worms but the worms remain sexually immature and no microfilariae are produced.

The number of human dirofilariasis cases reported has increased dramatically in recent years. The worms produce an inconspicuous granulomatous reaction in the subcutaneous tissue, resulting in the formation of a nodule, or they may migrate to the lung, causing human dirofilariasis. Pulmonary infections are usually asymptomatic but may cause chest pain, cough, fever, and pleural effusion. If the worm lodges in the pulmonary artery, an infarct may occur. Eye infections with *Dirofilaria* have been identified in North America, Europe, Australia, Africa, Asia, and the Middle East. These infections present with moderate to severe inflammation, blurred vision, and swelling of the eyes. All *Dirofilaria* examined have contained the *Wolbachia* endosymbiont.

Rarely, *D. immitis* worms have been identified in the brains and testicles of humans.

Laboratory Diagnosis

Dirofilariasis is diagnosed most frequently by the examination of inflammatory lung tissue or skin nodules. The worm's cuticle contains chitin, which can be visualized in tissue sections by staining with calcofluor white.

Therapy

The only method of treatment of human dirofilariasis is surgical removal of the lesion or extraction of the worm. Extraction is not essential, however, as the worms die and are often cleared or sequestered in granulomata without treatment.

Prevention

Routine methods for avoiding mosquito vectors will help to prevent infection.

Visit the Evolve site for a complete list of procedures, review questions, and case studies.

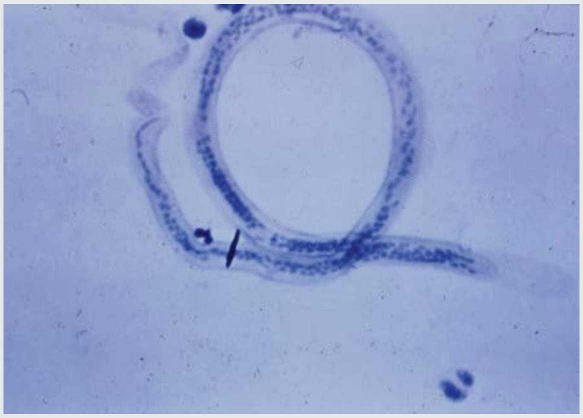
CASE STUDY 52.1

A 45-year-old male returned to the United States after a 3-week safari in Central Africa. He presented to his physician complaining of a tender area near his groin and discomfort during urination. In addition, he was having difficulty sleeping at night because of intermittent periods of fever. A complete blood count was drawn, and the patient exhibited a mild eosinophilia. All other results appeared normal. Urinalysis revealed no abnormal laboratory results. A computed tomography scan of the patient's lower abdomen and groin showed an unusual mass in his inguinal region. The physician admitted the patient for further observation and tests. Subsequent testing included additional peripheral blood collection during the periodic fevers. Thick and thin smears disclosed no unusual organisms. After concentration of a blood sample and staining with Giemsa, the organism depicted in Fig. 52.6 was identified.

Questions

1. Identify the parasite depicted in Fig. 52.7.



• **Fig. 52.7** Identified organism from a patient. (Courtesy Dr. Henry Travers, Sioux Falls, SD.)

2. What is the recommended treatment for this patient?
3. What additional parasite could be associated with this patient's symptoms?

Chapter Review

1. Periodicities associated with filarial infection are
- **a.** Periods of increased microfilariae in the peripheral circulation
- **b.** Always regular during the nighttime hours between 10 p.m. and 4 a.m.
- **c.** Present in all filarial infections
- **d.** Correlated directly with the patient's symptoms

2. Lymphatic vessel involvement within the retroperitoneal region is associated with infection with
- **a.** *M. perstans*
- **b.** *B. malayi*
- **c.** *W. bancrofti*
- **d.** *L. loa*

3. The endosymbiont *Wolbachia* sp. is required for parasite reproduction in all of the following *except:*
- **a.** *O. volvulus*
- **b.** *B. timori*
- **c.** *L. loa*
- **d.** *W. bancrofti*

4. A 25-year-old female patient residing in the Amazon Basin presented to the mobile clinic complaining of intermittent fever, swollen lymph nodes, and a nonproductive cough. Her symptoms persisted for several months. Laboratory results indicated a normal white blood cell count. Serum protein electrophoresis demonstrated an elevated gamma fraction. What additional laboratory tests would assist the physician's diagnosis?
- **a.** Serologic assay
- **b.** Serologic assay coupled with PCR for microfilariae identification
- **c.** Fractionation of the gamma fraction to identify her antibody abnormality
- **d.** Nasal aspirate and sputum specimen for viral and bacterial culture

5. Treatment for microfilariae can be complicated because of:
- **a.** Diethylcarbamazine resistance
- **b.** Ivermectin resistance
- **c.** Allergic reactions to dying parasites
- **d.** Drug toxicity

6. True or False

_____ *L. loa* requires surgical removal from the infected host.

_____ Heavy microfilaria infections are associated with the development of onchocerciasis.

_____ All species of *Mansonella* contain a sheath and terminal nuclei.

_____ The definitive host for dirofilariae causes severe infection in the lungs and eyes.

7. Matching: *Match each term with the correct description.*

_____ Knott concentration
_____ chyluria
_____ *B. timori*
_____ *L. loa*
_____ *B. malayi*
_____ *O. volvulus*
_____ *M. streptocerca*
_____ *D. immitis*

a. unsheathed, five to eight subterminal nuclei
b. shepherd's crook
c. sheathed, four to five subterminal nuclei
d. centrifugation
e. dog heart worm
f. lymph fluid
g. calabar swelling
h. river blindness

53

Intestinal Cestodes

OBJECTIVES

1. Describe the distinguishing morphologic characteristics, clinical disease, basic life cycle (vectors, hosts, and stages of infectivity), and laboratory diagnosis for the intestinal cestodes included in this chapter.
2. Define and identify (where appropriate) the following parasitic structures: scolex, proglottids, rostellum, hermaphroditic, oncosphere, hexacanth embryo, strobila, bothria, and coracidium.
3. Compare and contrast autoinfection and hyperinfection.
4. List several methods of control and prevention of tapeworm infection.
5. Correlate the life cycles with the specific diagnostic stage(s) for each organism.

PARASITES TO BE CONSIDERED

Intestinal Cestodes (Tapeworms)

Diphyllobothrium latum
Diphyllobothrium nihonkaiense
Diphyllobothrium spp.
Dipylidium caninum
Hymenolepis nana
Hymenolepis diminuta
Taenia asiatica
Taenia crassiceps
Taenia saginata
Taenia solium
Taenia spp.

The intestinal cestodes are commonly referred to as **tapeworms.** Tapeworms have a long, segmented, ribbonlike body with a specialized structure for attachment, or **scolex,** at the anterior end. The adult tapeworm consists of a chain of segments: **proglottids,** which develop posteriorly from the neck region of the scolex forming the body or **strobila.** Proglottids may be classified as immature, mature, or gravid containing the uterus and eggs. The crown of the scolex, the **rostellum,** may be smooth or armed with hooks. The body of the worm (proglottids) varies in the geometric characteristics or number of segments according to the genus and species of the cestode. The mature cestode is **hermaphroditic.** In other words, the organism contains both male and female reproductive organs. Food is absorbed from the host through the worm's **integument,** the outer covering or skin of the organism. Adult worms typically inhabit the small intestine; however, humans may be host to either the adult or the larval forms, depending on the infecting species. Humans infected with a cestode pass the eggs in the feces. The embryo may be visible within the tapeworm egg as an **oncosphere** (larva tapeworm within an embryonic envelope, infective stage) or **hexacanth embryo.** The intermediate host ingests feces containing the adult tapeworm eggs, which further develop into the larva of the cestode. Cestodes generally require one or more intermediate hosts for the completion of their life cycle. Intestinal tapeworm infections are generally asymptomatic. However, if the larval stage develops in human organs outside the intestine, they may cause additional life-threatening complications.

Fresh or preserved stools are the specimens of choice for ova and parasites (O&P) examination and cestode identification. Preserved stool containing adult worms or a string of segments (**strobila**) or the scolex may also be used for diagnosis. Development of serologic testing and molecular assays are more sensitive than stool examination. Although this type of testing may be useful for primary screening, it is most commonly used for confirmation testing for parasitic disease. Chapter 46 describes the methods and specimen requirements in more detail as they relate to parasitology.

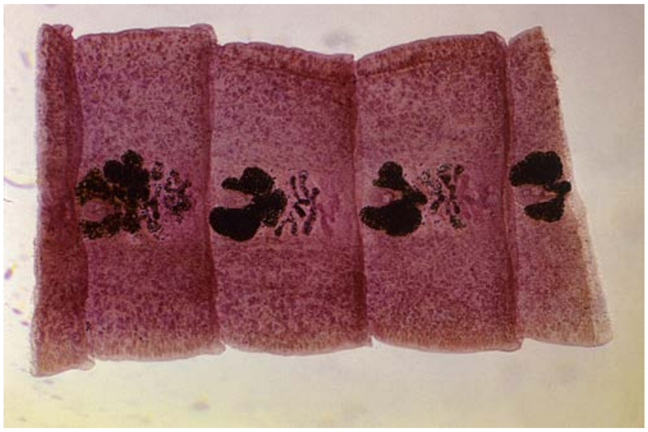
Diphyllobothrium latum

General Characteristics

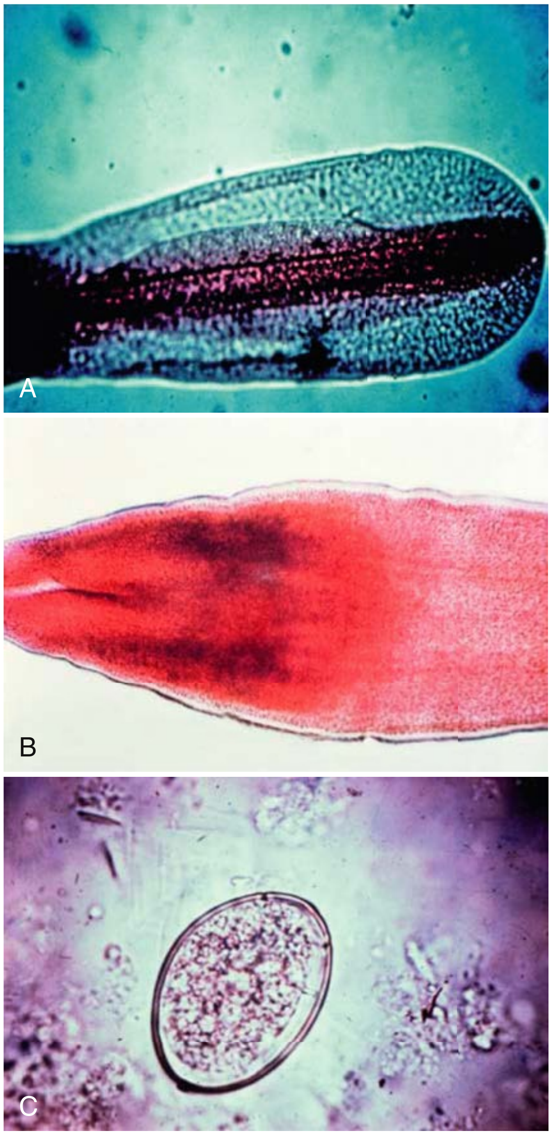
Diphyllobothrium latum, the freshwater broad fish tapeworm, is the largest human tapeworm and the most common species identified within this genus. Adult worms have been known to reach up to 15 m in length, with more than 3000 to 4000 proglottids, and reside within a host for 30 years or more. The proglottids are characteristically wider than long, with a central rosette-shaped uterine structure (Fig. 53.1). The scolex is spatulate and contains two shallow sucking grooves referred to as **bothria** (Fig. 53.2A and B). *Diphyllobothrium* spp. have unembryonated eggs. The eggs are **operculated** (appears as a lid) with a terminal knob, similar to trematode eggs (Fig. 53.2C). The intermediate hosts include crustaceans and freshwater fish.

Epidemiology

Diphyllobothrium is not found in the tropics; it is commonly found worldwide where cool lakes are contaminated



• **Fig. 53.1** Proglottid demonstrating rosette-shaped uterus in *Diphyllobothrium latum.* (Courtesy Division of Parasitic Diseases/ Centers for Disease Control and Prevention.)



• **Fig. 53.2** (A) *Diphyllobothrium latum* scolex. (B) *D. latum* scolex, bothria visible. (C) *D. latum* ovum. (Courtesy Dr. Henry Travers, Sioux Falls, SD.)

by sewage. *Diphyllobothrium species* can be found wherever freshwater or marine fish are eaten raw, pickled, or marinated. This includes such freshwater fish as burbot, pike, perch, ruff, and salmon. The parasite is found in North America, including the upper Midwest around the Great Lakes, Alaska, and Canada. *D. nihonkaiense*, originally endemic in Japan, is an emerging parasite in other areas of Europe. There are 14 species of *Diphyllobothrium*, all capable of infecting humans. Other species of *Diphyllobothrium* that have been identified in human infection include *D. pacificum* (Southern Pacific coast of South America), *D. cordatum, D. ursi, D. dendriticum* (New Guinea and Australia), *D. lanceolatum, D. dallieae,* and *D. yonagoensis.*

Pathogenesis and Spectrum of Disease

Diphyllobothrium spp. is the only cestode to have an aquatic life cycle (Fig. 53.3). Fish serve as the reservoir host, with humans serving as the definitive host for *D. latum, D. nihonkaiense, D. dendriticum*, and *D. pacificum. D. latum* eggs are found in the feces of infected humans and other fish-eating mammals. Once passed into a water source, such as a lake, the life cycle requires two intermediate hosts. After incubation in freshwater for approximately 2 weeks, the mature eggs release the first larval stage (**coracidium**). The coracidium larva is ciliated and bears six terminal hooks. The coracidium larvae are ingested by copepods. The coracidium larva sheds its epithelium and further develops into a **procercoid** larva (infective form). The fish feed upon the small crustaceans ingesting the procercoid larvae. Within the freshwater fish, the larvae develop into the **plerocercoid** ribbonlike organism with an undivided scolex. The procercoid may pass through multiple paratenic hosts until consumed by a mammal or human. *Diphyllobothrium* infection occurs through the ingestion of infected fish containing the plerocercoid larval form. *Diphyllobothrium latum* and other species mature to an adult tapeworm within the human small intestine. Infection is usually asymptomatic, but mild gastrointestinal symptoms may occur, such as diarrhea, abdominal pain, fatigue, vomiting, or dizziness. Symptoms vary depending on the worm burden and the host's immune response to the organism. The tapeworm nutritional requirements may decrease the host's vitamin B_{12} level, resulting in **pernicious anemia**.

Laboratory Diagnosis

Both eggs and proglottids may be found in the patient's feces. Visualization of the eggs is enhanced using a wet preparation of the patient's stool sample. Diagnosis is made by identification of the ovoid, operculated, yellow-brown eggs (58 to 75 µm × 40 to 50 µm) passed in abundance in the stool. They are sometimes confused with the eggs of *Paragonimus.* The mature gravid proglottids are wider than long (3 mm × 11 mm), often in chains, and contain a rosette-shaped central uterus (Fig. 53.1). *Diphyllobothrium* identification is through assessment of the morphologic characteristics of

the proglottids as previously described. Speciation within the genus *Diphyllobothrium* is difficult to impossible using morphological characteristics. Nucleic acid amplification and sequencing is the only reliable tool for speciation. Because all of the species cause similar infections and the therapy is similar, speciation is not necessary for treatment but remains important for epidemiological reasons. Molecular approaches to differential identification of *D. latum* and *D. nihonkaiense* have been successful using restriction fragment length polymorphisms (RFLP) utilizing the ribosomal DNA sequence of the mitochondrial cytochrome c oxidase I (cox1) gene. No serologic tests are available.

Therapy

Humans infected with *Diphyllobothrium* develop little to no protective immunity. Reinfection is common. Treatment with praziquantel or niclosamide is effective and nontoxic. Subsequent stool specimens should be reexamined 6 weeks after treatment. The patient may require a vitamin B_{12} supplement if anemia develops.

Prevention

Prevention simply includes avoiding the consumption of raw fish. The larval stage is destroyed when food is thoroughly cooked at 55°C for 5 minutes or frozen at −20°C for 7 days or flash freezing to −35°C for 15 hours, if the flesh is less than 15 cm thick. Treatment of patients infected with adult tapeworms is indicated to prevent accidental autoinfection. Good hygiene and proper sanitation measures will also prevent reinfection. Treatment of sewage before it enters lakes may help reduce the prevalence of infection.

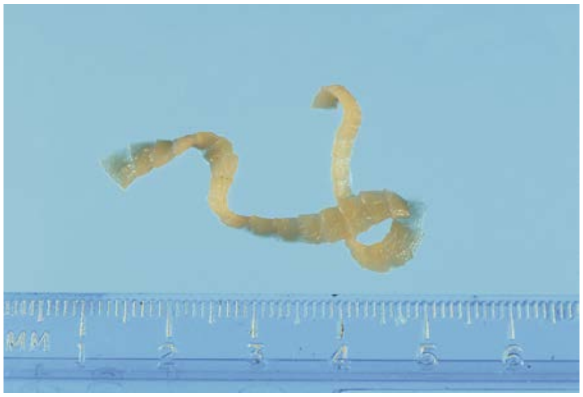
Dipylidium caninum

General Characteristics

D. caninum, the cat or dog tapeworm (Fig. 53.4), is a double-pored (genital pores) tapeworm consisting of many small proglottids. As the tapeworm matures, the proglottids separate and pass in the stool. They may be recognized based on their characteristic “cucumber seed” appearance when they are wet, as well as their resemblance to a dried grain of rice. Adult tapeworms measure 10 to 70 cm in length. The scolex contains four suckers and an **armed rostellum. Egg packets** may also be found in the feces of the host.

Epidemiology

Infection is common worldwide. In the case of *D. caninum,* human infection is acquired through the accidental ingestion of fleas. Infection is most often seen in young children because of close contact with infected pets. The tapeworms are found in both wild and domestic dogs and cats.



• Fig. 53.4 *Dipylidium caninum* tapeworm. (Courtesy Dr. Henry Travers, Sioux Falls, SD.)

Pathogenesis and Spectrum of Disease

Ingestion of an infected flea may result in *D. caninum* infection (Fig. 53.5). The flea is the intermediate host in which infective **cysticercoids** (larval form) develop; humans, dogs and cats are the reservoir hosts. The cysticercoid larval stage is ingested by a dog or cat and develops into cysticercoid **metacestode larvae.** The adult worm develops and matures within the reservoir host. An infected human host will usually pass proglottids in a bowel movement, or they may stick to the skin around the anal area. This may result in misdiagnosis of the infection as *Enterobius vermicularis.* Humans usually have very mild symptoms, such as indigestion, appetite loss, weight loss, perianal itching, persistent diarrhea, and vague abdominal pain. The severity of the disease is dependent on the worm burden. Human infection is usually self-limited.

Laboratory Diagnosis

Symptoms of *Dipylidium* infection are similar to those of pinworm infection; however, the treatments are very

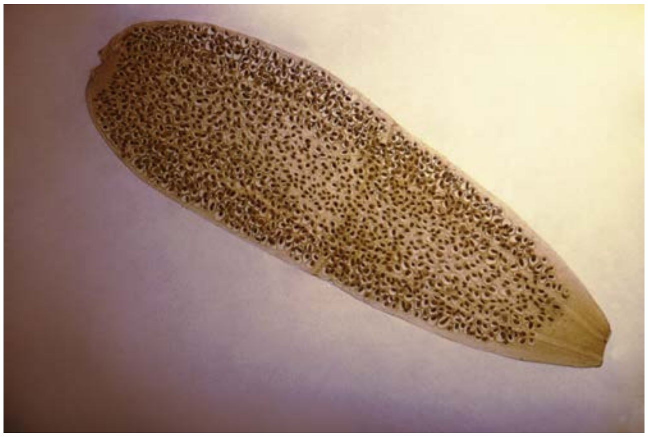
different. The laboratory should confirm suspected infections. Proglottids (8 to 23 μm) may be seen in the stool. *D. caninum* is also referred to as the "cucumber seed" tapeworm, as previously described (Fig. 53.6). The first sign of infection may be the appearance of seedlike particles in the stool or undergarments of the patient. These particles are the egg-bearing segments of the tapeworm. Groups of egg packets may be found in the stool (Figs. 53.7E). The adult worms have a scolex with four suckers and a conical/retractile rostellum armed with four to seven rows of small hooklets (Fig. 53.8). Patients may also develop a moderately elevated eosinophilia. Serologic tests are typically performed because of the asymptomatic and self-limiting nature of the infection. Nucleic acid–based testing, testing using RFLP analysis, and hydrolysis probe-based genotyping assays have been developed and validated for genotyping *D. caninum*; currently, however, they are not utilized for clinical diagnostics.

Therapy

Praziquantel and niclosamide are typically effective for treating *D. caninum* infection. The medication causes the tapeworm to dissolve within the intestine. The drugs are generally well tolerated by the patient. Household pets should be treated simultaneously to prevent reinfection.

Prevention

To reduce the risk of infection, flea control of pets in the household will reduce exposure to humans via the intermediate host. Keeping cats indoors will help prevent infection by limiting their exposure to fleas by household cats.



• **Fig. 53.6** This photomicrograph reveals ultrastructural details exhibited by a single *Dipylidium caninum* reproductive proglottid. These *D. caninum* proglottids, which when mature average 12 mm × 3 mm, are pumpkin seed-shaped, are passed with the animal's feces, and often resemble rice grains when dried. Each proglottid contains egg packets that contain 8 to 15 ova, which are held together by an outer embryonic membrane. (Courtesy Division of Parasitic Diseases/Centers for Disease Control and Prevention.)

Hymenolepis nana

General Characteristics

Hymenolepis nana, also known as the dwarf tapeworm, is very small compared with other tapeworms. The organism has a worldwide distribution and may reach up to 4 cm in length. The proglottid contains a scolex with a short-armed rostellum. It is the most common tapeworm. An intermediate host is not required, thus making person-to-person spread possible. An adult dwarf tapeworm can live within the host for approximately 4 to 6 weeks.

Epidemiology

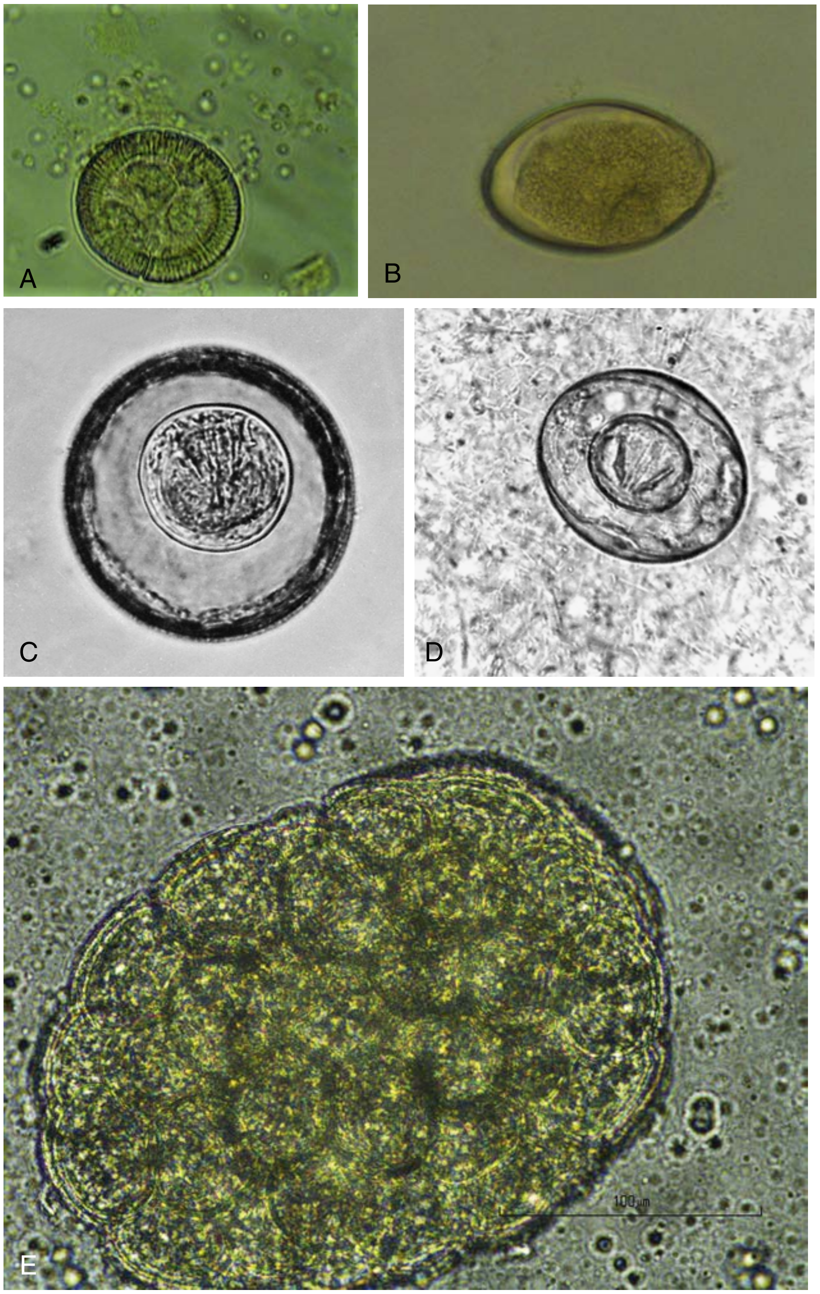
H. nana is generally found in children. Although it is most prevalent in the southern United States, it has a wide distribution—particularly in crowded areas. It is more common in populations living in conditions of poverty or poor hygiene, in daycare centers, and in persons living in institutional settings or prisons.

Pathogenesis and Spectrum of Disease

H. nana has an unusual life cycle; ingestion of the egg can lead to the development of the adult worm in humans, thus bypassing the need for an intermediate host. Humans can serve as both intermediate and definitive hosts. Infection occurs by accidentally ingesting dwarf tapeworm eggs. This happens most commonly through direct fecal-oral transmission or accidental ingestion of an infected arthropod. The worm resides within the upper ileum of the intestinal tract. Once infection occurs, the dwarf tapeworm may reproduce inside the body, thus causing autoinfection. Autoinfection is essentially a reinfection or constant reproduction of the parasite within the host. Massive infection with several thousand worms may follow autoinfection, resulting in hyperinfection. Hyperinfection refers to a large parasitic burden within the host. Autoinfection appears to initiate a cellular and humoral immune response. The immune response will provide the host with some protective immunity. Most patients are asymptomatic. Symptomatic patients may experience weight loss, nausea, and weakness, loss of appetite, diarrhea, and abdominal discomfort. Young children, especially those with a heavy infection, may develop headaches, an itchy perianal area, or have difficulty sleeping.

Laboratory Diagnosis

Adult worms and proglottids are rarely seen in stool specimens. Diagnosis is typically through the identification of eggs in stool specimens. Eggs are characterized by the presence of a thin shell enclosing an embryo (oncosphere) with six hooklets contained within two layers of membrane that is separated from the outer shell. The eggs are spheroidal, pale, and thin-shelled (30 to 47 μm in diameter). The eggs of *H. nana* and *Hymenolepis diminuta* are very similar. However,



• **Fig. 53.7** (A) *Taenia* spp. egg iodine preparation (400× total magnification). (B) *Diphyllobothrium latum* egg iodine preparation (400× total magnification). (C) *Hymenolepis diminuta* egg. (D) *Hymenolepis nana* egg. (E) *Dipylidium caninum* egg packet iodine preparation (500× total magnification).

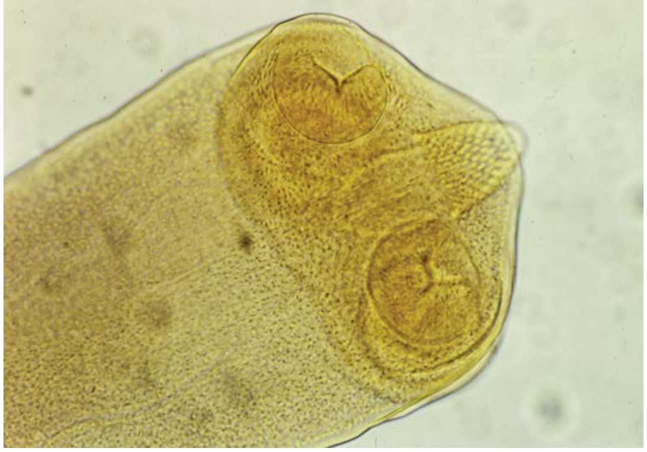
H. nana eggs are smaller and have 4 to 8 **polar filaments** present in the space between the oncosphere and the eggshell (Fig. 53.7). The egg morphology is easily distinguishable in fresh or formalin-fixed fecal samples. It is important to note that eggs are infectious, and therefore unpreserved specimens should be handled carefully. Concentration techniques and repeated examinations will increase the likelihood of detecting light infections. Some patients may demonstrate a low-grade eosinophilia. Nucleic acid–based methods and serological techniques are being developed; however, further evaluation is needed to determine the efficacy and use of these assays in clinical applications.

Therapy

Praziquantel remains the therapy of choice. Niclosamide is also effective and can be repeated with reinfection. Human adults living in endemic areas are provided some immunity as a result of their cellular and humoral immunologic responses.

Prevention

Good hygiene is the best method for control and prevention. Preventing fecal contamination of food and water is the first line of defense. General sanitation measures, along



• **Fig. 53.8** *Dipylidium caninum* scolex demonstrating the armed rostellum. (Courtesy Dr. Henry Travers, Sioux Falls, SD.)

with rodent control, are helpful in controlling the flea population.

Hymenolepis diminuta

General Characteristics

H. diminuta, the rat tapeworm, is larger than *H. nana* and can measure 20 to 60 cm in length. Outbreaks of human infection are rare.

Epidemiology

H. diminuta is an uncommon tapeworm in humans and is typically found in rodents, including rats and mice. Rats are typically the natural reservoir. *H. diminuta* can infect humans after contamination of grains and flours with rodent feces.

Pathogenesis and Spectrum of Disease

The life cycle of *H. diminuta* involves insects, similar to the life cycle of *H. nana. H. diminuta* rarely infects humans but may do so if a human accidentally ingests an arthropod infected with cysticercoids. Multiple adult worms may mature in the human intestine. Infections are usually well tolerated by the host because of the small size of the organism. Symptoms may include diarrhea, anorexia, nausea, headache, and dizziness. The infection is more common in children, causing mild diarrhea, remittent fever, and abdominal pain.

Laboratory Diagnosis

Proglottids are rarely seen in the stool; diagnosis is made by the identification of eggs. The eggs (70 to 85 μm × 60 to 80 μm) are large, ovoid, yellowish, and moderately thick-shelled. The eggs contain a six-hooked oncosphere with the absence of polar filaments in the space between the oncosphere and the eggshell (Fig. 53.7). The eggs are clearly differentiated from *H. nana* because of the absence of polar filaments. Nucleic acid–based methods and serological techniques are being developed; however, further evaluation is needed to determine the efficacy and use of these assays in clinical applications.

Therapy

H. diminuta is readily treated with praziquantel, although the disease is self-limiting and treatment is often not necessary.

Prevention

Prevention is dependent on controlling the populations of infected mice and rats, along with good hygiene and sanitation.

Taenia solium

General Characteristics

T. solium, the pork tapeworm, is the intestinal cestode capable of causing serious pathologic damage to the human host. Humans serve as the definitive host, whereas pigs serve as the intermediate host. Humans can also serve as the intermediate host. *T. solium* may result in an intestinal infection in which the larvae mature and reside in the small intestine for up to 25 years. The organisms can grow to be 2 to 7 m long and produce more than 1000 proglottids, each containing about 50,000 eggs. **Cysticercosis** (larval forms throughout the body) is the extraintestinal form of the disease and can be much more severe. The disease is life threatening if the organism invades the central nervous system causing neurocysticercosis.

Epidemiology

T. solium has a worldwide distribution. Higher rates of illness have been seen in Latin America, Asia, sub-Saharan Africa, and parts of Oceania. The parasite is found in the United States, typically among immigrants from zones of endemicity. The tapeworm is more prevalent in underdeveloped communities with poor sanitation, and when pork is ingested as undercooked or raw.

Pathogenesis and Spectrum of Disease

T. solium infection can result in the presence of both adult and larval stages in the human host (Fig. 53.9). Infection begins when the intermediate host ingests embryonated eggs in feces. Once the egg is ingested, the hexacanth embryo, armed with three pairs of hooks, is released into the intestine where the embryo penetrates the mucosa. The embryo then matures into a **cysticercus larvae** (containing a fluid-filled bladder) in the tissue. Humans may become infected

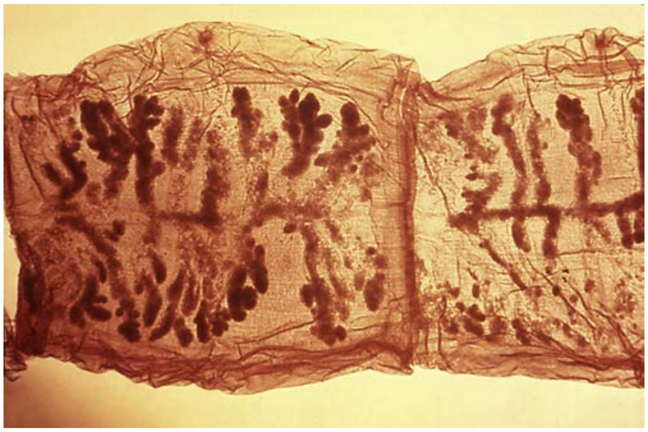
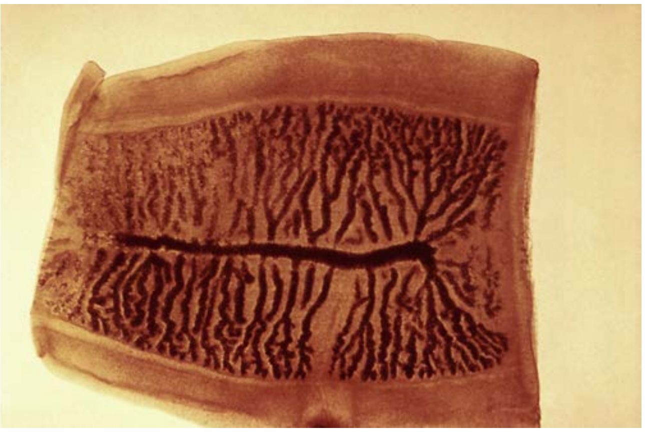
when they eat raw or undercooked pork containing embedded larvae with cysts. Pork tapeworm infection is usually caused by ingestion of multiple worms. During ingestion and subsequent digestion of the infected meat, the cysticercus is released and attaches to the mucosa within the small intestine of the human host. The cysticercus matures into an adult worm within approximately 5 to 12 weeks. The eggs are then released in the host's feces. Accidental ingestion of the eggs by the human host may also result in migration of the embryo through the intestine to other areas of the body, including the eyes, brain, muscle, or bone. In addition, the proglottids are motile and may migrate out of the anus. Infection of the adult tapeworm causes few clinical symptoms, although abdominal pain, diarrhea, indigestion, and loss of appetite may be present because of irritation to the mucosa of the intestinal wall. The major complication with *T. solium* is cysticercosis, in which the human host becomes the intermediate host and harbors the larvae in tissues as previously described. This infection is further discussed in Chapter 74.

Laboratory Diagnosis

Diagnosis of *Taenia* tapeworm infection is through the examination of stool samples. Individuals suspected of infection with *T. solium* should be asked if they have passed any notable tapeworm segments in their stool. Stool specimens should be collected on 3 different days and microscopically examined for the presence of *Taenia* eggs (Fig. 53.7A). Tapeworm eggs can be detected in the stool 2 to 3 months after the tapeworm infection is established. Eggs are round or slightly oval (31 to 43 µm in diameter) and yellow-brown with a thick, striated shell containing a six-hooked oncosphere. Diagnosis is based on the recovery of eggs or proglottids in stool or from the perianal area. *T. solium*, *T. saginata*, and *T. asiatica* cannot be differentiated based on

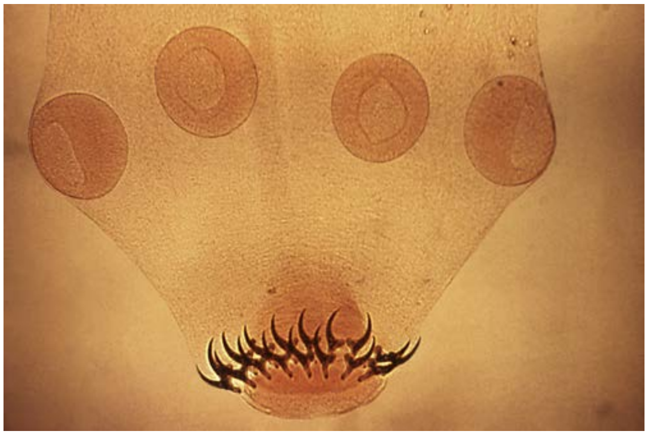


• **Fig. 53.10** This photomicrograph reveals some of the ultrastructural morphology exhibited by a gravid proglottid from a *Taenia solium* tapeworm. The number of primary lateral uterine branches, represented by the dark, India ink-stained irregularities, allows differentiation between the two species. *T. solium* shows 7 to 13 branches on each side. (Courtesy Division of Parasitic Diseases/Centers for Disease Control and Prevention.)



• **Fig. 53.11** This photomicrograph reveals some of the ultrastructural morphology exhibited by a gravid proglottid from a *Taenia saginata* tapeworm. (Courtesy Division of Parasitic Diseases/Centers for Disease Control and Prevention.)

egg morphology. Speciation requires the examination of gravid proglottids or the scolices. *T. solium* gravid proglottids are longer than wide (19 mm × 17 mm) and may be distinguished from *T. saginata and T. asiatica* according to the number of uterine branches. *T. solium* contains 7 to 13 lateral uterine branches along the proglottid (Fig. 53.10), whereas *T. saginata* and *T. asiatica* contain more than 13 branches. Uterine branches may be visualized by staining the proglottids with India ink (Fig. 53.11). The scolex contains a neck region that is typically short and half the width of the scolex, and differs from that of *T. saginata* by the presence of four suckers with hooks in a double row (Fig. 53.12). The adult worm is usually 3 to 5 m long. Extreme care should be taken when handling infectious stool, because *T. solium* proglottids and eggs are extremely infectious. Additional laboratory findings may include a low-grade eosinophilia, increased serum IgE level, and the presence of atypical lymphocytes in the cerebrospinal fluid.



• **Fig. 53.12** This photomicrograph reveals some of the ultrastructural morphology exhibited by the cephalic end of a *Taenia solium*, highlighting the worm's scolex, and its four suckers and two rows of hooks. (Courtesy Division of Parasitic Diseases/Centers for Disease Control and Prevention.)

Serologic assays specific to the adult *T. solium* tapeworm have been developed for the diagnosis of neurocysticercosis. Complement fixation, hemagglutination, enzyme-linked immunosorbent assay (ELISA), and immunoblot can be used for the detection of anticysticercal antibodies in serum, cerebrospinal fluid, and saliva. The enzyme-linked immunoelectrotransfer blot assay is the most effective method for the detection of antibodies, with sensitivity and specificity as high as 100% and 98%, respectively. However, the sensitivity decreases to about 70% in patients with a single cyst or in those with only calcified lesions. ELISA is more reliable when performed in cerebrospinal fluid than in serum, but the accuracy depends on the viability and location of the cysticerci. These advanced serologic tests are not yet commercially available and are generally only available in specialized laboratories. Stool antigen testing detects at least 2 to 3 times more cases of *Taenia* infection than stool microscopy.

Therapy

Adult worms can be eradicated with praziquantel or niclosamide followed by use of a laxative. Expulsion of the scolex must be verified to assume satisfactory treatment.

Prevention

Good hygiene and immediate treatment are essential for the prevention of autoinfection. Pork should be cooked or frozen thoroughly. Cysticerci do not survive temperatures below −10°C or above 50°C. Educational programs concerning the hazards associated with living near human sewage and contaminated drinking water are important in populations at risk. When traveling in countries where food is likely to be contaminated, all raw vegetables and fruits should be washed, peeled, or cooked with clean water before eaten.

Taenia saginata

General Characteristics

T. saginata, or beef tapeworm, has a worldwide distribution and is more common than *T. solium.* The worm can grow 4 to 12 m and contain 1000 to 2000 segments. *T. saginata* may produce 100,000 eggs and live up to 25 years in the human intestine.

Epidemiology

T. saginata has a similar life cycle to that of *T. solium.* Cattle are the intermediate hosts, and humans are infected through the ingestion of cysticerci (larval form with an unarmed scolex) in raw or undercooked beef (Fig. 53.9).

Pathogenesis and Spectrum of Disease

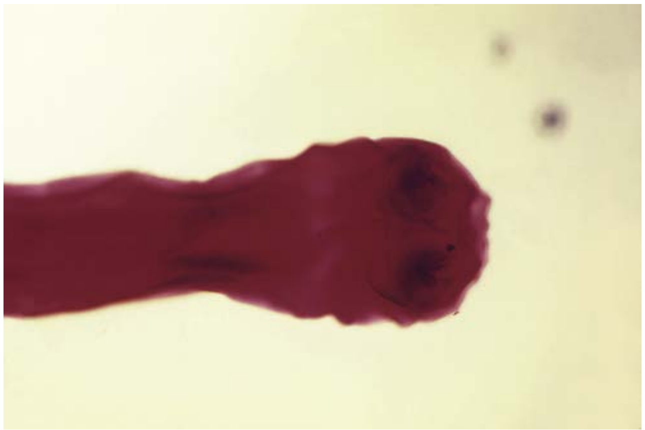
The life cycle of *T. saginata* begins with human ingestion of undercooked or raw meat infected with larvae. The larvae are ingested in the meat and, after digestion, released into the small intestine, where the worm attaches to the mucosa and matures. In about 3 months, the worm may grow up to 4 to 5 m in length, and gravid segments will begin to break off and pass in stool. After deposition of gravid segments in the soil, an intermediate bovine host may ingest the segments. The segments are digested and the eggs hatch, releasing an oncosphere that penetrates the muscle tissue. After penetration of the mucosa, the organisms are carried via the lymphatic vessels and bloodstream throughout the intermediate host. Humans then ingest the infected meat of the intermediate host, as previously indicated. Humans typically are asymptomatic or experience very mild indigestion, loss of appetite, vomiting, and abdominal discomfort. A rare case of severe infection may result in intestinal obstruction and appendicitis. Patients are often unaware of their infection until gravid motile segments are passed in the feces and cause psychological distress.

Laboratory Diagnosis

The stool should be examined for proglottids and eggs; eggs may also be present on anal swabs. The eggs of *T. saginata* are indistinguishable from other *Taenia* spp. The adult worms can reach up to 25 m in length. The uterus of *T. saginata* is longer than wide and typically contains 15 to 18 lateral branches on each side (Fig. 53.11). The scolex has four suckers and is unarmed or does not contain any hooklets (Fig. 53.13). Stool specimens should be handled with care, because the eggs cannot be distinguished from *other Taenia* spp. Slight eosinophilia may develop.

Therapy

Recommended treatment includes praziquantel or niclosamide. Treatment of *T. saginata* can be considered successful when no proglottids are passed for 4 consecutive months.



• **Fig. 53.13** Under a low magnification, this photomicrograph highlights the scolex, or head region of the cestode, *Taenia saginata*. (Courtesy Division of Parasitic Diseases/Centers for Disease Control and Prevention.)

Prevention

Beef should be inspected for cysticerci and thoroughly cooked before it is ingested.

Taenia asiatica

General Characteristics

T. asiatica, or Asian tapeworm, is found primarily in remote areas of the East and Southeast Asian countries to include Taiwan, Indonesia, Korea, Vietnam, the Philippines, Thailand, China, and Japan. The morphology of *T. asiatica*'s gravid proglottids and adult worm is difficult to distinguish from that of *T. saginata*.

Epidemiology

T. asiatica has a similar life cycle to that of *T. solium.* It has been suggested that *T. asiatica* is possibly misdiagnosed as *T. solium* since both species share some of the same hosts, and co-infections are thought to occur more frequently than reported. Pigs, cattle, and goats are the intermediate hosts, and humans are infected through the ingestion of cysticerci (larval form with an unarmed scolex) in raw or undercooked liver from cattle or pork.

Pathogenesis and Spectrum of Disease

The pathogenesis of *T. asiatica* is identical to that of *T. saginata*; which begins with human ingestion of undercooked or raw liver infected with larvae (Fig. 53.9). After penetration of the mucosa, the organisms are carried via the lymphatic vessels and bloodstream throughout the intermediate host. Humans then ingest the infected liver of the intermediate host, as previously indicated. Humans typically are asymptomatic or may experience abdominal pain, nausea, weakness, weight loss, headache, and changes in appetite. Patients are often unaware of their infection until gravid motile segments are passed in the feces. Eosinophilia is seen in some patients.

Laboratory Diagnosis

The stool should be examined for proglottids and eggs; eggs may also be present on anal swabs. The eggs of *T. asiatica* are indistinguishable from those of *T. solium* or *T. saginata.* The uterus of *T. asiatica* is longer than wide and typically contains 12 to 26 lateral branches on each side. The scolex has two rows of rudimentary hooklets that are lost in the mature worm. The adult worm is smaller than *T. saginata*, measuring 4 to 8 m long, and contains fewer proglottids. Stool specimens should be handled with care, because the eggs cannot be distinguished from those of *T. solium* or *T. saginata.*

Therapy

Recommended treatment includes praziquantel or niclosamide, followed by a laxative. Treatment of *T. asiatica* is not usually required; however, if prescribed, it can be considered successful when no proglottids are passed for 4 consecutive months.

Prevention

Pork and beef liver should be inspected for cysticerci and thoroughly cooked before ingested.

Taenia crassiceps

General Characteristics

Taenia crassiceps is a parasitic organism whose adult form infects the intestines of carnivores and has been isolated in human cases of cysticercosis.

Epidemiology

It is commonly found in the Northern Hemisphere, especially throughout Canada and the northern United States. The larval stages of *T. crassiceps* develop subcutaneously or in their body cavities as cysticerci. *T. crassiceps* inhabits the intestines of carnivores. Inside the carnivore, the tapeworm reproduces. The eggs are passed in the feces, with the natural intermediate hosts of this organism usually being small rodents and moles. When the intermediate host is eaten by another carnivore, the parasite's life cycle repeats. Humans serve as intermediate hosts when food or water contaminated with feces from infected hosts is consumed. Close contact with infected domestic dogs has been associated with several human infections.

Pathogenesis and Spectrum of Disease

T. crassiceps rarely infects humans, as a healthy adult human's immune system typically removes the parasite before permanent damage occurs. However, individuals who were infected tended to be immunosuppressed patients. Patients are generally asymptomatic but may present with symptoms, such as headache, nausea, and vomiting. Parasites may accumulate in skeletal muscle and subcutaneous tissue, and some patients present with intraocular infections referred to as ocular larva migrans that can cause serious damage to the eyes, even blindness.

Laboratory Diagnosis

Diagnosis is made by the observation of cysticerci in biopsy or autopsy specimens. Positive ELISA for anticysticercal antibodies helps confirm the diagnosis; however, negative test results do not exclude cysticercosis. The patient may present with eosinophilia.

Therapy

Surgical removal is mandatory for individuals with intraocular cysts. Ocular cysticercosis can be effectively treated with anthelmintics, such as albendazole or praziquantel, and oral corticosteroids for inflammation.

Prevention

Avoid food and water sources that could be contaminated with feces. Animal products consumed should be inspected for cysticerci and thoroughly cooked before ingested.

Nucleic Acid Detection (All Species)

All three species of *Taenia*, and two genotypes of *T. solium*, can be differentiated using nucleic acid base excision sequence scanning thymine-base reader analysis for mitochondrial genes. Polymerase chain (PCR) amplification of the cytochrome oxidase subunit 1 (*cox1*) has been successfully used to identify several *Taenia solium* infections from fixed tissue associated with cases of human cysticercosis. Additional nucleotide sequences used to differentiate the organisms from clinical material include the mitochondrial 12S rRNA, ND1 (NADH dehydrogenase 1), and ITS2 (ribosomal internal transcribed spacer 2). Two additional species were also identified using PCR: *T. serialis* and *T. crassiceps. T. serialis* (Chapter 54) was identified in a cystic parasitic larva sample from a subcutaneous sample of a patient's jaw. *T. crassiceps* was identified in sternocleidomastoid muscle of the patient's neck. There have been 12 reported cases of human infection with this species. Four cases of *T. martis* cysticercosis have been identified in human infections.

CASE STUDY 53.1

A 50-year-old male presented to the physician complaining of headaches and difficulty maintaining his balance. On physical examination, the physician noticed a lump in the man's left calf. Initial laboratory results, including a complete blood count and differential, were normal. The erythrocyte sedimentation rate (ESR) was slightly elevated, indicating generalized inflammation. The physician asked the man if he had traveled to any areas outside of the United States in the past 12 months. The man had recently returned from volunteering in Haiti. The physician prescribed niclosamide and had the patient collect three stool samples over the next 12 days. After treatment, the parasite seen in Figs. 53.10 and 53.12 was recovered from the man's stool.

Questions

1. Identify the parasite to the species level.
2. Explain the morphologic characteristics that would definitively identify the parasite.
3. What, if any, additional treatments are available for this patient?

Chapter Review

1. Which tapeworm infects cattle as an intermediate host?
- **a.** *T. saginata*
- **b.** *D. caninum*
- **c.** *H. diminuta*
- **d.** *H. nana*

2. Which of the following can bypass the need for an intermediate host?
- **a.** *D. latum*
- **b.** *D. caninum*
- **c.** *H. diminuta*
- **d.** *H. nana*

3. Which eggs are passed unembryonated and may have a small knob at the end of the operculum?
- **a.** *D. latum*
- **b.** *D. caninum*
- **c.** *H. diminuta*
- **d.** *H. nana*

4. Which tapeworm cannot be identified to the species level based on its egg morphology; instead, proglottids must be examined?
- **a.** *Diphyllobothrium*
- **b.** *Dipylidium*
- **c.** *Hymenolepis*
- **d.** *Taenia*

5. Which of the following are treatment(s) of choice for tapeworm infection?
- **a.** Praziquantel
- **b.** Niclosamide
- **c.** Both A and B
- **d.** None of the above

6. Which of the following is not an appropriate prevention measure for cestodes?
- **a.** Controlling the flea and rat population
- **b.** Avoiding the consumption of raw meat or fish
- **c.** Immunization
- **d.** Practicing good hygiene

7. True or False

_____ *Diphyllobothrium latum* is the only cestode to have an aquatic life cycle.

_____ *Hymenolepis diminuta,* also known as the dwarf tapeworm, may reach up to 4 cm in length.

_____ Food is absorbed from the host through the worm's scolex.

_____ Humans are infected with *T. saginata* by eating cysticerci in raw or undercooked beef.

_____ All *Taenia* species are indistinguishable morphologically requiring detailed genotypic analysis

8. Matching: *Match each term with the appropriate description.*

_____ cestode
_____ scolex
_____ proglottids
_____ rostellum
_____ integument
_____ hexacanth embryo
_____ bothria

a. oncosphere
b. crown of scolex
c. head
d. shallow sucking grooves
e. tapeworm
f. outer covering
g. segments

54

Tissue Cestodes

OBJECTIVES

1. Describe and compare the life cycles of the tissue cestodes, including reservoir and intermediate hosts.
2. Describe the clinical manifestations and complications of cysticerci in the human host.
3. List the various methods used to diagnose cysticercosis infection.
4. Define and describe the morphologic characteristics of the following: oncosphere, brood capsule, hydatid cyst, and hydatid sand.
5. Describe hydatid disease, including laboratory diagnosis and the best course of treatment.
6. Compare and contrast the pathogenesis and spectrum of disease associated with direct tissue damage versus the immune response to *Echinococcus* spp.
7. Describe the tapeworm that causes coenurosis, including hosts and symptoms of disease.
8. Describe the preventive measures recommended to prevent infection with tissue cestodes.

PARASITES TO BE CONSIDERED

Cestodes (Tapeworms)

Tissue (Larval Forms)

Taenia solium
Echinococcus granulosus complex
  E. granulosus sensu stricto
  E. equinus
  E. ortleppi
  E. canadensis
Echinococcus multilocularis
Echinococcus oligarthrus
Echinococcus vogeli
Taenia multiceps
Taenia serialis
Spirometra mansonoides

Tissue cestodes do not reach the adult stage in the human host. The organisms infect the human in their intermediate or cyst stage. These infections are much more serious than those caused by adult tapeworms. The parasites can cause serious disease or even death. Larval cestodes cause infection after accidental ingestion of eggs excreted from the intermediate host (Table 54.1) and release embryos that migrate and lodge in various organs and tissues in the human body. Diagnosis of larval infections can be problematic.

Taenia solium

General Characteristics

Taenia solium, also known as the pork tapeworm, causes an intestinal infection contracted when a person eats contaminated pork, as discussed in Chapter 53. The adult worm usually causes no clinical disease. Humans may accidentally become the intermediate host by ingesting eggs from human feces. This typically occurs when an individual is already infected with adult *T. solium.* Autoinfection occurs when the individual swallows eggs after improper hand washing. Humans may develop the larval infection, which could result in cysticercosis. Cysticercosis is usually asymptomatic unless larvae invade the central nervous system (CNS), the globe of the eye, or other muscle and tissues.

Epidemiology

T. solium is found worldwide, with a higher incidence in Latin America. The larval form of the infection rarely occurs in the United States but may be found among immigrants from Mexico. After ingestion of *T. solium* eggs, the oncospheres hatch in the intestine and invade the intestinal wall. Once the larvae invade the tissue, the organism is capable of spreading systemically by migration to the brain, liver, and other tissues, causing human cysticercosis. Cysticercosis is defined as larval forms distributed throughout the body. Human cysticercosis may also occur when reverse peristalsis returns gravid segments into the intestine, where the eggs hatch and release oncospheres. Cysticerci develop and may live many years. Cysticerci will eventually die and may calcify, which will aid in diagnosis.

Pathogenesis and Spectrum of Disease

Clinical signs and symptoms depend on the location, viability, and number of the **cysticerci** present. Cysticerci can develop in any organ or tissue of the body. The severity of the symptoms depends on the body site involved; symptoms may not appear for years after the initial infection. The most severe cases are found in the CNS and the eye. Once cysticerci localize in the brain, the organism causes a condition referred to as **neurocysticercosis.** Infection can cause epileptic-type seizures, headaches, mental disturbances, meningitis, or sudden death. Cysticerci can also be

TABLE 54.1 **Common Human Parasites, Diagnostic Specimens, Tests, and Positive Findings**

Organism	Acquired Infection	Location in Host	Diagnostic Specimen	Diagnostic Test	Positive Specimen	Comments
Tissue cestodes	Source					
Echinococcus granulosus complex	Eggs from dog tapeworm	Liver, lung, etc.	Serum, hydatid cyst aspirate; biopsy	Serology, centrifugation of fluid; histology	Positive serology; hydatid sand, tapeworm tissue	*E. granulosus* (enclosed cyst)
E. oligarthrus	Eggs from a wild dog tapeworm	Definitive: Intestine Intermediate: cysts within various tissues and organs	Serum, scans, biopsy,	Serology, microscopic and confirmation with ELISA and PCR	Tapeworm tissue, positive serology	The cysts resemble those of *E. vogeli*. Exogenous proliferation has not been reported. Unicystic single or multiple metacestodes
E. vogeli	Eggs from a bush dog tapeworm	Definitive: Intestine Intermediate: cysts found primarily in the liver and lungs	Serum, scans, biopsy	Serology, microscopic and confirmation with ELISA and PCR	Tapeworm tissue, positive serology	These cysts are often interconnected and can have multiple chambers, resulting in multichambered cysts as well as endogenous daughter cysts. These proliferating cysts are similar to those of *E. multilocularis*
Echinococcus multilocularis	Eggs from fox tapeworm	CNS, subcutaneous tissues	Serum, scans, biopsy	Serology, films, histology	Positive serology, positive scans, tapeworm tissue	*E. multilocularis* (cyst develops throughout tissue)
Taenia solium (pork)	Eggs from human tapeworm					Small, enclosed cysticerci (cysticercosis)
Taenia multiceps	Eggs from a dog tapeworm	Definitive: Intestine Intermediate: CNS, subcutaneous tissues	Scans, Coenurosis	Biopsy of coenurosis in subcutaneous tissue Serology, confirmation with ELISA and PCR	Positive scans, presence of oncosphere induced coenurosis	Coenurosis most commonly affects the brain, eyes, and subcutaneous tissues
Taenia serialis	Eggs from a dog tapeworm	Definitive: Intestine Intermediate: Various subcutaneous tissues	Scans, coenurosis	Biopsy of coenurosis in subcutaneous tissue	Positive scans, presence of multiple protoscoleces within the coenurosis	Usually identified postmortem
Spirometra mansonoides	Eggs from dog and cat tapeworm	Any organ/tissue in the body	Scans, serum, tissue biopsy	Serology, films, histology, ELISA	Positive serology, positive scans, tapeworm tissue	Adult worm has no scolex, which can help differentiate *Spirometra* from *T. solium*

CNS, Central nervous system; *ELISA*, enzyme-linked immunosorbent assay; *PCR*, polymerase chain reaction.

found in the eye and must be removed to prevent permanent eye damage, including blindness. Much of the damage from cysticercosis is caused by the severe inflammatory host response that occurs after the cysticerci have died. Antibodies are produced and offer the patient secondary immunity.

Laboratory Diagnosis

Cysticercosis can be difficult to diagnose. *T. solium* eggs are found in stools in fewer than half of the patients with cysticercosis. Demonstration of eggs or proglottids in the feces is an indication of *Taenia* infection but does not provide a diagnosis for cysticercosis. Definitive diagnosis usually requires the identification of cysticercus in the tissue. The organism is surgically removed and microscopically examined for the presence of suckers and hooks on the scolex. The cysticercus is round to oval, translucent, and about 5 mm or more in diameter. The organism has a scolex with four suckers and a rostellum with a circle of hooks. Fine-needle aspiration cytology may be helpful in the diagnosis and eliminates the need for surgical biopsy. Diagnosis may also be made using computed tomography (CT) scans and magnetic resonance imaging (MRI). Radiographs may also be useful in detecting calcifying cysticerci within tissue. Ocular cysticercosis may be diagnosed by visual identification of the larval worm. A highly specific and sensitive enzyme-linked immunoelectrotransfer blot assay is available from the Centers for Disease Control and Prevention (CDC). The assay has demonstrated 100% specificity and 98% sensitivity for the identification of antibodies using serum or CSF, primarily for diagnosis of neurocysticercosis. The assay uses purified antigen from *T. solium* containing seven different major glycoproteins. In all patients, regardless of their clinical presentation, the immunoblot assay is slightly more sensitive in serum than in CSF specimens; consequently, there is no need to obtain CSF solely for use in the immunoblot assay. Currently available antibody detection tests for cysticercosis do not distinguish between active and inactive infections and thus have not been useful in evaluating the outcomes and prognoses of treated patients. Nucleic acid–based methods and species-specific polymerase chain reaction (PCR) have been described to differentiate *Taenia* species in CSF, but these are not widely used for clinical laboratory diagnosis of neurocysticercosis.

Therapy

Cysticercosis should be treated with corticosteroids, anticonvulsants, and surgery if deemed appropriate. Treating nonviable cysticerci in the brain of asymptomatic patients has not been proven necessary. Not all patients respond to treatment and not all patients must be treated, because the inflammatory response as a result of the treatment may be more serious than the disease. Symptomatic neurocysticercosis should be managed using treatment that decreases the patient's symptoms. When treatment is suggested, albendazole is the drug of choice. If praziquantel is used, it should be combined with corticosteroids to reduce the inflammatory response and should not be used for ocular or spinal cord infections. Surgery may be required for ocular, spinal, or brain involvement.

Prevention

Education, meat inspection, and improvement of sanitation measures are the key preventive measures. Other prevention methods are discussed in Chapter 53.

Echinococcus granulosus Complex

General Characteristics

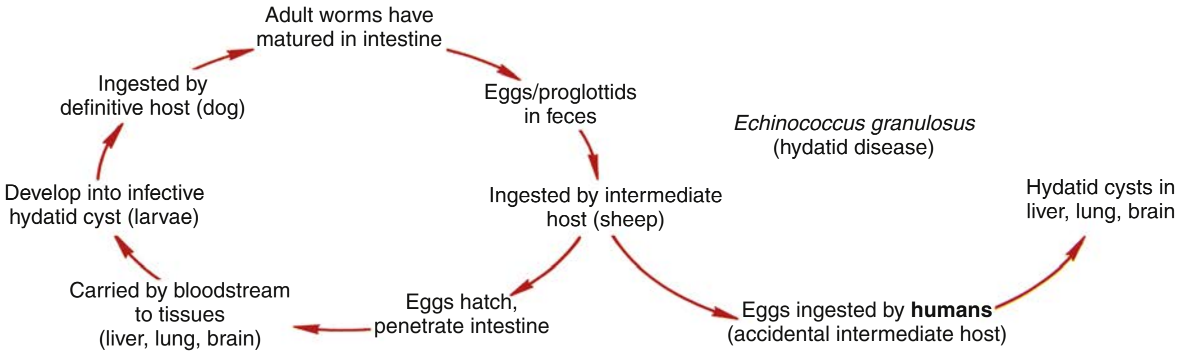
Echinococcus is the smallest of all tapeworms (3 to 9 mm long) with three to five proglottids. It contains a scolex with four suckers and a rostellum with hooks to attach to the intestinal wall. *Echinococcus granulosus sensu lato* can be used as a general term for all of these species and strains. The tapeworm is found in the small intestine of the definitive host, the canine. Eggs are ingested by the intermediate hosts, which include a variety of mammals including sheep (*E. granulosus sensu stricto*), cattle (*E. ortleppi*), moose (*E. canadensis*), horse (*E. equinus*), and humans. Of the several strains of *E. granulosus* that have been identified, the dog-sheep strain is the most common. Regardless of the strain, humans are typically accidental hosts and are considered a dead end, because the life cycle of the organism is unable to continue in a human host. Oncospheres hatch in the intestine of the intermediate host and invade the circulatory system, where they develop into **hydatid cysts.** Disease symptoms vary with the site and size of the cyst. Echinococcosis (**hydatid disease**) results from the presence of one or more cysts, which can develop in any tissue.

Epidemiology

E. granulosus complex is most common in cool, damp areas where the mammalian hosts are prevalent, such as southern South America, Russia, East Africa, and the western United States. The eggs in the definitive host are passed through the feces and contaminate soil, water, or food. The eggs are able to survive freezing conditions and can remain viable within the environment for several years. Adult worms are found only in the definitive canine hosts (Fig. 54.1).

Pathogenesis and Spectrum of Disease

Hydatid disease in humans is potentially dangerous, depending on the size and location of the cyst. Some cysts may remain undetected for many years until they grow large enough to affect other organs. Many people never know they are infected. The cyst is very slow growing in humans. It is usually fluid-filled and has a germinal layer from which many thousands of scolices are budded. These are known as daughter cysts (**brood capsules**), which attach to the germinal layer or free-float in the cyst. The scolices in the hydatid fluid resemble grains of sand and are called **hydatid sand** (Figs. 54.2A and 54.3). The result is a unilocular cyst containing



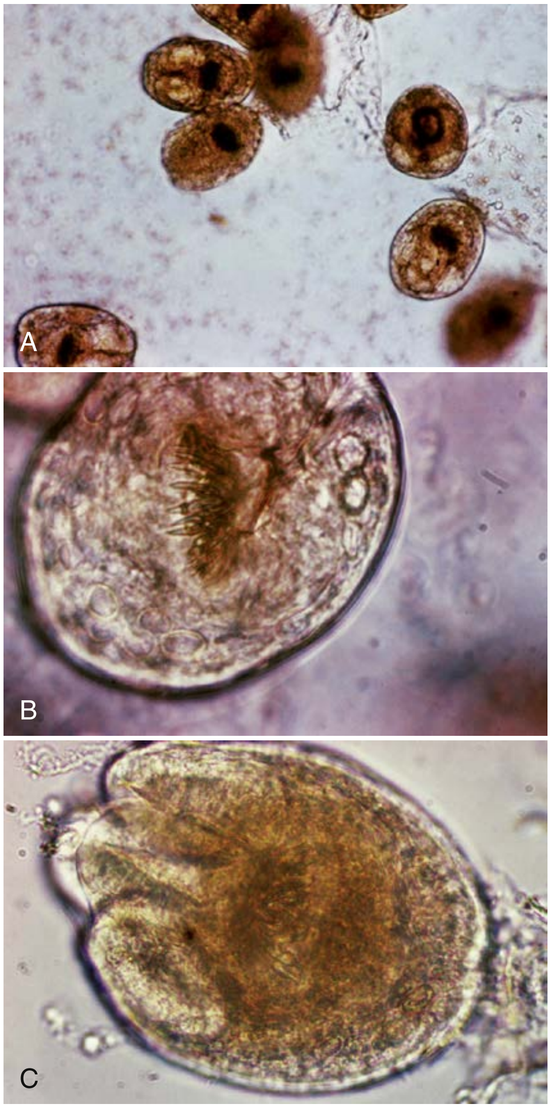
Adult worms have matured in intestine
Eggs/proglottids in feces
Ingested by intermediate host (sheep)
Eggs hatch, penetrate intestine
Carried by bloodstream to tissues (liver, lung, brain)
Develop into infective hydatid cyst (larvae)
Ingested by definitive host (dog)
Echinococcus granulosus (hydatid disease)
Eggs ingested by **humans** (accidental intermediate host)
Hydatid cysts in liver, lung, brain

• **Fig. 54.1** Life cycle of *Echinococcus granulosus* (hydatid disease).

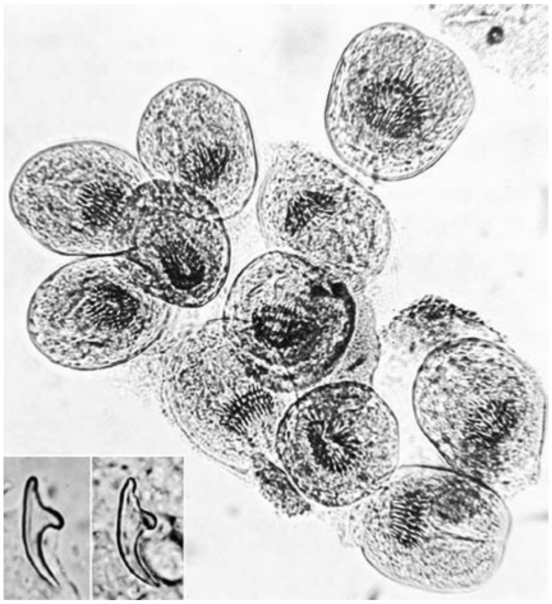
future adult worms. The cyst may resemble a slow-growing tumor. Infection in the liver or lungs may be asymptomatic for many years, but the pressure eventually causes noticeable symptoms. Most hydatid cysts occur within the liver. Cysts within the liver cause chronic abdominal pain and allergic reactions and may result in **cholangitis** (infection of the common bile duct) and **cholestasis** (interference with the flow of bile from the liver). Cysts that develop in the lungs may cause infections and abscesses and result in chronic cough, shortness of breath, and chest pain. During the life cycle of the cyst, there may be occasional seepage of fluid into the host tissue and circulation, causing sensitization or activation of the immune response from the presence of the parasite. The rupture and release of the fluid of a hydatid cyst may cause anaphylactic shock as a result of the primary sensitization in a previously asymptomatic individual. If a cyst bursts within the human body, many new cysts may be released that are typically eliminated via the host's cellular immune response. Leaking fluid from a cyst may cause notable eosinophilia.

Laboratory Diagnosis

Clinical symptoms of a slow-growing abdominal tumor with or without eosinophilia are suggestive of infection. Human infection ranges from asymptomatic to severe, including death. Diagnosis of echinococcosis is made through the identification of cysts in the infected organ, accompanied by positive serologic tests. Immunodiagnostic tests can be very helpful in the diagnosis of echinococcal disease and should be used before invasive methods. A variety of serologic tests, including enzyme-linked immunosorbent assay (ELISA) and Western blot serology, are available at the CDC in the United States. However, false-positive reactions may occur in persons with other helminthic infections, cancer, and chronic immune disorders. Negative test results do not rule out echinococcosis because some carriers do not have detectable antibodies. The presence of detectable antibodies in a patient depends on the physical location, integrity, and vitality of the larval cyst. Cysts in the liver are more likely to elicit an antibody response than cysts in the lungs, and, regardless of localization, antibody detection tests are least sensitive in patients with intact hyaline cysts. Cysts in the lungs, brain, and spleen are associated with lowered serodiagnostic reactivity, whereas those in bone appear to regularly stimulate a detectable antibody response. Fissuration or rupture of a cyst is followed by an abrupt antibody response. A patient with senescent, calcified, or dead cysts is generally found to be seronegative. Indirect hemagglutination (IHA), indirect fluorescent antibody (IFA) tests, and enzyme immunoassays (EIAs) are sensitive tests for detecting antibodies in serum of patients with cystic disease; sensitivity rates vary from 60% to



• **Fig. 54.2** (A) *Echinococcus* granules. (B) Ovum. (C) Scolex. (Courtesy Dr. Henry Travers, Sioux Falls, SD.)



• **Fig. 54.3** *Echinococcus granulosus,* hydatid sand (300×). *(Inset)* Two individual hooklets (1000×).

90%, depending on the characteristics of the cases. At present, the best available serologic diagnosis is obtained by using a combination of tests. EIA or IHA is used to screen all specimens; a positive reaction is confirmed by immunoblot assay or any gel diffusion assay. Although these confirmatory assays give false-positive reactions with sera of 5% to 25% of persons with neurocysticercosis, the clinical and epidemiological presentation of neurocysticercosis is rarely confused with that of cystic echinococcosis.

Antibody responses are also useful in monitoring treatment in some cases. Following successful radical surgery, antibody titers decline and sometimes disappear; titers rise again if secondary cysts develop. Tests for Arc 5 or IgE antibodies appear to reflect antibody decline during the first 24 months postsurgery, whereas the IHA and other tests remain positive for at least 4 years. Consistent declines in antibody titers do not follow chemotherapy. Consequently, the usefulness of serology to monitor the course of disease is limited; imaging techniques provide a more accurate assessment of the patient's condition.

Ultrasound, MRI, and CT have improved the diagnosis and may provide visualization of the fluid-filled cysts. Calcified cysts can be visualized using conventional x-ray. Cysts from different species can also be distinguished by the morphology of the protoscolices, if they are present. Microscopic examination of the cyst fluid for the identification of the scolices can be useful in diagnosis. A 1% eosin stain may be added to the fluid to assist in the visualization and determination of whether the cyst is viable. Nonviable scolices will stain with the eosin; viable scolices will not.

Therapy

PAIR (puncture, aspiration, infection, and reinjection) is used for the inactivation of hydatid sand by injecting the cyst with a cysticidal agent (hypertonic 30% saline, 0.5% cetrimide, or 70% to 95% ethanol) if surgical removal is not feasible. In other cases, the cysts may be surgically removed after thirty minutes of instillation with one of the previously noted chemical treatments. Albendazole or albendazole plus praziquantel have been used effectively to kill the scolices within the cyst, reduce the size of the cyst, and prevent recurrence. Cystic lesions have been known to resolve in some patients without the need for therapy.

Prevention

Preventive measures include avoiding contact with infected dogs, and deworming animals regularly. Effective control includes educating the population concerning the danger and means of transmission of hydatid disease as well as maintaining good hygiene and practicing safe disposal of dog feces. Slaughtered animals must be disposed of properly to prevent dogs from being exposed to contaminated materials, thus interrupting the *Echinococcus* life cycle.

Echinococcus multilocularis

General Characteristics

Although rarely found in the brains of humans, *Echinococcus multilocularis* causes alveolar hydatid disease, which is a fatal form of **echinococcosis.** It is the most lethal of all helminthic diseases. The cyst is extremely dangerous because it lacks a laminated membrane and develops a series of connected chambers. The chambers contain little or no fluid and rarely contain a scolex. The morphology of the cyst is very similar to that of *E. granulosus,* but the adult organisms are much smaller (1.2 to 3.7 mm). The cysts are very resistant to cold temperatures.

Epidemiology

E. multilocularis is found in Asia, Europe, and northern North America, including areas such as Alaska, Montana, and Minnesota. Foxes, coyotes, and dogs are the definitive host for *E. multilocularis,* whereas rodents are the intermediate host. The parasite is occasionally transmitted to humans through the ingestion of contaminated food or water and by handling infected animals. Fur trappers and veterinarians are at an increased risk of infection because of exposure to infected animals. The life cycle of *E. multilocularis* is essentially identical to that of *E. granulosus.*

Pathogenesis and Spectrum of Disease

Alveolar hydatid disease is a highly lethal, destructive disease. The cyst of *E. multilocularis* grows slowly and may take years to produce clinical symptoms. Many cysts are asymptomatic during the life of the infected individual and are sometimes found during autopsy, surgery, or imaging scans related to other clinical conditions. The severity of symptoms depends on the location of the cyst and the size, as seen with *E. granulosus.* Cysts form primarily in the liver and metastasize to the lung or brain. Cysts in the liver are not restricted with a laminated cyst wall and are capable of expansion into a multicystic structure. This **multilocular** (many chambers) **hydatid cyst** is often mistaken for a hepatic sarcoma, making diagnosis difficult. This disease is often fatal.

Laboratory Diagnosis

Ultrasound, CT, and MRI are used to visualize the cyst and can be supported with serologic testing. Serologic tests, such as ELISA, are sensitive and highly specific. Most patients with alveolar disease have detectable antibodies in serologic tests using heterologous *E. granulosus* or homologous *E. multilocularis* antigens. With crude *Echinococcus* antigens, nonspecific reactions create the same difficulties as described previously with *E. granulosus* complex. However, immunoaffinity-purified *E. multilocularis* antigens (Em2) used in EIA demonstrate positive antibody reactions in more than 95% of alveolar cases. Using a comparison of serologic reactivity to Em2 antigen with that of antigens containing components from both *E. multilocularis* and *E. granulosus* differentiates alveolar from cystic disease. Combining two purified *E. multilocularis* antigens (Em2 and recombinant antigen II/3-10) in a single immunoassay optimizes the sensitivity and specificity. These antigens are commercially available as an EIA kit in Europe, but not in the United States. As in cystic echinococcosis, Em2 tests are more useful for postoperative follow-up than for monitoring the effectiveness of chemotherapy.

Therapy

The most common treatment is to remove the parasite surgically; however, the disease is usually diagnosed late, when it is inoperable and results in a high rate of fatality. Presurgical treatment with albendazole is recommended to reduce the size of the cyst before surgical removal. For inoperable cases, life-long treatment with mebendazole and albendazole has been used successfully and may be the preferred treatment in many cases.

Prevention

Controlling rodents is an important means of prevention, along with educating the public at risk to avoid exposure to infective feces. Practicing good hygiene and periodically deworming household pets are also helpful.

Echinococcus oligarthrus and *Echinococcus vogeli*

General Characteristics

Infections with *E. vogeli* and *E. oligarthrus* are usually known as polycystic echinococcosis (or neotropical polycystic echinococcosis), from the form of the disease that is identified in the intermediate hosts. Because *E. oligarthrus* manifests as a single or discrete cyst in humans, this disease has also been called unicystic echinococcosis.

Epidemiology

Many strains of *Echinococcus* are distributed worldwide; however, *E. vogeli* and E. *oligarthrus* have been found only in Central and South America.

Pathogenesis and Spectrum of Disease

The definitive hosts for *E. vogeli* are bush dogs *(Speothos venaticus)* and the intermediate hosts are South American rodents, especially pacas *(Cuniculus paca)*. Dogs, which may be given the entrails from pacas after a hunt, can also act as definitive hosts. The metacestode is found primarily in the liver of the intermediate host, but it can also occur in the lungs and other organs. In pacas, *E. vogeli* cysts are fluid-filled, usually 0.5 cm to 6 cm in diameter, and can occur singly or as aggregates. These cysts are often interconnected and can have multiple chambers. *E. vogeli* undergoes exogenous proliferation in accidental hosts such as primates, resulting in multichambered cysts as well as endogenous daughter cysts. These proliferating cysts, like those of *E. multilocularis*, are invasive. Exogenous proliferation does not seem to occur in the natural host.

The definitive hosts for *E. oligarthrus* are wild felids, and the intermediate hosts are rodents. This species can mature in experimentally infected housecats. In the intermediate host, cysts develop in the muscles, subcutaneous tissues, and internal organs such as the heart and lungs. The cysts resemble those of *E. vogeli* and can reach up to 5 cm in diameter. Exogenous proliferation has not been reported. In human infections, unicystic single or multiple metacestodes were found behind the eye or in the heart.

E. oligarthrus has not been documented in domesticated intermediate mammalian hosts. Two outbreaks caused by *E. vogeli*, one affecting nutrias and the other in nonhuman primates, have been reported in zoos. Orangutans and gorillas developed severe clinical signs including very pendulous abdomens. A number of animals died or had to be euthanized. In pacas, *E. vogeli* does not seem to be symptomatic unless the cysts become very large.

Laboratory Diagnosis

Echinococcus eggs are morphologically indistinguishable from *Taenia* spp., and the tiny proglottids are rarely noticed in feces. ELISAs that detect *Echinococcus* antigens in fecal samples (coproantigen ELISA) can be used to screen definitive hosts. This assay can detect both prepatent and patent infections. A PCR assay designed for fecal samples (copro-DNA assay) is mainly used to confirm the infection or to identify eggs from the feces. *Echinococcus* adults or their proglottids can also be found in the definitive host after purgation with arecoline compounds. *E. oligarthrus* and *E. vogeli* adults usually have three segments. Direct examination of the intestines at necropsy may be used in some circumstances; however, subtle differences are present in the mature proglottids. *E. oligarthrus* is approximately 2 to 3 mm long and *E. vogeli* is 3.9 to 5.6 mm long. In addition to these characteristics, *Echinococcus* species can also be distinguished by PCR followed by sequencing or restriction fragment length polymorphism analysis.

Therapy

In the definitive host, *Echinococcus* spp. can be treated with antihelminthic drugs. Praziquantel, which is effective against both juvenile and adult parasites, is often used. In intermediate hosts, surgery is often the treatment of choice. Long-term antihelminthic treatment may also suppress some cysts. Long-term daily albendazole treatment, after surgical resection of the cyst masses, has suppressed parasite growth in some patients.

Prevention

Preventive measures include avoiding contact with infected dogs and deworming animals regularly. Effective control includes educating the population concerning the danger and routes of transmission associated with the disease as well as maintaining good hygiene and safe disposal of dog feces. Slaughtered animals must be disposed of properly to prevent dogs from being exposed to contaminated materials.

Taenia multiceps and Other Species

General Characteristics

Taenia multiceps is the most common canid tapeworm that causes **coenurosis** in humans. Additional dog tapeworm species, *Taenia crassiceps* and *Taenia serialis,* have also been associated with human coenurosis (Chapter 53). The **coenurus** (larval form) may cause destructive damage or death but is an extremely rare disease in humans. The coenurus cyst is a unilocular cyst that contains a transparent fluid, similar to cysticercus, although the worm has multiple scolices. Daughter cysts may also be seen. The adult tapeworm of *T. multiceps* is 5 to 6 cm long and consists of 200 to 250 segments. The scolex has four suckers and a **proboscis** (tubular appendage) or rostellum with 22 to 32 hooks arranged in two rows.

Epidemiology

T. multiceps is most often found in Africa, although it may be seen in South America, the United States, and Canada. The adult worm is typically found in dogs and other canids. Many animals serve as the intermediate host, such as sheep, cattle, and deer. The animals become infected through the ingestion of eggs while grazing. Humans can also serve as an intermediate host. Human infection occurs from accidental ingestion of dog feces containing the eggs.

Pathogenesis and Spectrum of Disease

The oncosphere hatches and penetrates the intestinal wall of the intermediate host. The embryo is carried via the bloodstream to various parts of the body including the brain, eyes, and CNS, where the organism lodges and the coenurus develops. The coenurus develops into multiple daughter cysts. Symptoms include headache, vomiting, paralysis, and blindness. The coenurus causes a serious disease in sheep and in dogs that have eaten the brains of infected sheep. Infected sheep lose their balance and rotate in circles until they fall (screw disease). The human clinical condition is known as gid, sturdy, or staggers.

Laboratory Diagnosis

Diagnosis is similar to that for *Echinococcus* infection. CT and MRI may be useful for detecting the cysts. Microscopic identification can be used if the cyst has been removed surgically. A serologic test available from the CDC provides additional clinically significant information in combination with imaging studies to establish a diagnosis.

Nucleic acid–based methods have also been used for the diagnosis of *T. multiceps* infections.

Although different serological methods, including ELISA and indirect hemagglutination assay, have been developed to diagnose coenurosis, the antigens used in these assays are natural worm extracts and cannot be produced commercially. Indirect ELISA assays using stable recombinant antigens Tm7 and heat shock protein 70 have been successfully developed for the diagnosis of coenurosis. Although PCR may be useful to detect nucleic acid in CSF, the current complexity of the concentration, extraction, and amplification process prevent routine use in clinical laboratories.

Therapy

Treatment is similar to that for *Echinococcus.* The most common treatment is surgery if possible, although the drugs used for cysticercosis may also be effective against coenurus infection.

Prevention

Dogs associated with sheep and other livestock should not be fed the brain or spinal cord from infected animals and should be dewormed regularly. Good hygiene should be practiced and care taken not to eat or drink anything contaminated with dog feces.

Taenia serialis

General Characteristics

T. serialis has been found in a number of locations, including North America, South America, Europe, and Africa.

Epidemiology

T. serialis, also known as a canid tapeworm, are parasites of carnivores, particularly dogs, with herbivorous animals such as rabbits serving as intermediate hosts. Humans become accidental hosts when eggs are ingested from food or water contaminated with infected dog feces.

Pathogenesis and Spectrum of Disease

Hatching of the *T. serialis* usually occurs only if the eggs have been exposed to gastric secretions. The oncospheres hatch in the intestine, invade the intestinal wall, and are carried in the blood throughout the tissues. Within the tissues, the larvae (called metacestodes) develop into cysticerci or coenuri, which are larvae that group within cysts.

The infection with the metacestode larval form (coenurus) of *T. serialis* is called coenurosis. When humans ingest these eggs from the infected tissue of a definitive host, the eggs develop into coenuri. These coenuri can occur in humans within muscle, brain, eye, or subcutaneous connective tissue. The symptoms are variable, and depend on the location and number of larvae. Coenuri in the skin or subcutaneous tissue usually present as painless nodules. The lesions are often fluctuant and tender. Most subcutaneous nodules manifest on the trunk, sclera, subconjunctiva, neck, shoulders, head, and limbs. Coenuri in the neck may affect movement and swallowing. Clinically, coenuri can mimic lymphomas, lipomas, pseudotumors, or neurofibromas. Coenuri in the CNS cause headache, fever, and vomiting. Localizing neurologic symptoms may also develop, including nerve palsies, Jacksonian epilepsy, pachymeningitis, obstructive or communicating hydrocephalus, and intracranial arteritis with transient hemiparesis. Coenuri in the eye can cause both intraocular and orbital infections, and patients may present with varying degrees of visual impairment. If not removed, coenuri in the eye can result in painful inflammation, glaucoma, and eventual blindness.

Laboratory Diagnosis

Diagnosis is made by the observation of coenuri in tissue biopsy or autopsy specimens. Coenuri are usually readily distinguished from cysticerci by the presence of multiple protoscoleces (infective form of the immature developing scolex).

Therapy and Prevention

Surgical removal or antiparasitic agents can be used to treat coenurus. Oral epsiprantel, praziquantel, or fenbendazole can be used to treat coenuri infection. Discretion should be used when treating this evolving cestode as the dead parasite may cause a significant inflammatory response in the host. The inflammation can be managed with the use of corticosteroids. In many cases surgical removal of the coenurus is a safer option, as leakage of fluid from the cyst during surgery is unlikely to cause a new cyst. Surgical excision is often curative.

Prevention is similar to that for *T. multiceps.* Good hygiene is essential to prevent contamination of food and the environment with feces from infected animals. Proper food preparation is also essential to avoid consumption of infected raw or undercooked meat.

Spirometra mansonoides

General Characteristics

Sparganosis is an infection caused by the plerocercoid larvae of *Spirometra.* The larvae (**spargana**) are white, wrinkled, and ribbon-shaped. They may be 3 mm wide and up to 30 cm long. The sparganum has bothria (longitudinal grooves) instead of suckers. No scolex is present, which can help differentiate *Spirometra* from *T. solium.*

Epidemiology

Spirometra is found worldwide; most human cases of sparganosis are found in Asia. Sparganosis is endemic in animals throughout North America but rare in humans. Adult *Spirometra* live in the intestine of dogs and cats. Eggs are shed in feces, hatch in water, and release free-swimming ciliated coracidia. The coracidia are then ingested by copepods, which become infected. Reptiles, fish, and amphibians ingest infected copepods containing the procercoid (elongated and globular) larvae. The procercoid larvae develop into plerocercoid (pseudosegmented with a scolex) larvae in the second intermediate host. Humans are accidental hosts; they acquire sparganosis after ingestion of contaminated water or by consuming undercooked fish. The life cycle is identical to that of the broad fish tapeworm, *Diphyllobothrium* spp. Humans are unable to serve as the definitive host for *Spirometra.* However, spargana can live up to 20 years in the human host.

Pathogenesis and Spectrum of Disease

Spargana migrate and lodge anywhere in the human body. Clinical symptoms depend on which organs or tissues are involved. Spargana can live for several years before symptoms develop. Sparganosis is usually asymptomatic until the larvae grow and cause an inflammatory reaction. Painful nodules can develop in the tissues. A variety of symptoms may occur, including seizure, weakness, headache, and eye pain that can lead to blindness if left untreated.

Laboratory Diagnosis

Definitive diagnosis is usually made by removal and identification of the sparganum from infected tissue. Serodiagnosis utilizing ELISA methodology can be used to target anti-sparganum IgG antibodies within the blood. ELISA may be positive around 10 to 12 days postinfection and is almost 100% effective at detecting the anti-sparganum antibodies at 14 to 22 days post infection. Clinical history, ELISA, MRI, and CT can all be used together to presumptively diagnose sparganosis. Eosinophilia may also be present.

Therapy

Praziquantel has been used with limited success. Injection of ethanol into the nodule along with surgical removal of the complete sparganum is the treatment of choice.

Prevention

Prevention strategies should include safe drinking water practices and awareness of the dangers of consuming raw fish and amphibians. Water in contaminated areas should be boiled before it is consumed.

Visit the Evolve site for a complete list of procedures, review questions, and case studies.

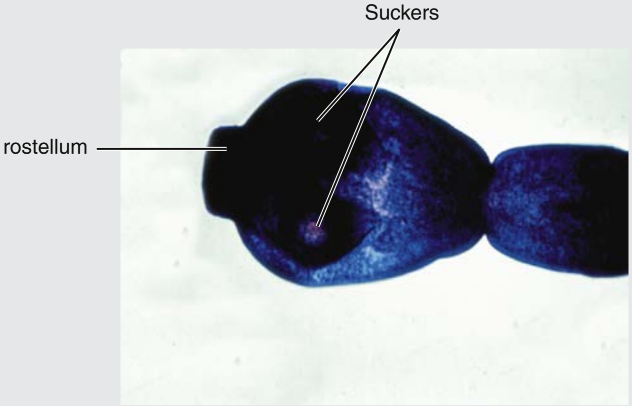
CASE STUDY 54.1

A 65-year-old man from Montana was admitted to the emergency department in a local hospital. The patient is a sheepherder and owns dogs. He claims to have no travel history outside the local area. He enjoys hunting and trapping in the area and frequently enjoys eating his venison. He was admitted with upper right quadrant pain and vomiting. An abdominal mass was felt and an MRI ordered. MRI showed a 5-cm mass in the liver. Fluid-filled cysts and a scolex were surgically removed (Fig. 54.4).

Questions

1. What parasite should be considered?
2. What additional testing should be performed to aid in diagnosis?
3. Which preventive measures should be used to control the spread of this parasite?



• **Fig. 54.4** Scolex collected from patient's liver biopsy. (Courtesy Dr. Henry Travers, Sioux Falls, SD.)

Chapter Review

1. Which of the following is a characteristic of *Echinococcus*?
   - **a.** Longest tapeworm found in humans
   - **b.** Vitamin B_{12} deficiency
   - **c.** Hydatid cysts
   - **d.** Cysticercus
2. Which of the following cysts is not encased in a capsule?
   - **a.** *T. solium*
   - **b.** *T. multiceps*
   - **c.** *Mansonoides*
   - **d.** *E. multilocularis*
3. What is the drug of choice for treating hydatid cysts?
   - **a.** Albendazole and praziquantel
   - **b.** Praziquantel
   - **c.** Mebendazole
   - **d.** Niclosamide
4. Surgery may be the best course of treatment for which tapeworm?
   - **a.** *E. granulosus*
   - **b.** *E. multilocularis*
   - **c.** *T. multiceps*
   - **d.** All of the above
5. Human cysticercosis occurs when:
   - **a.** *T. solium* eggs are ingested
   - **b.** Reverse peristalsis returns gravid segments into the intestine
   - **c.** Humans ingest contaminated pork
   - **d.** All of the above
6. Cysticercosis develops:
   - **a.** In any organ or tissue in the body
   - **b.** After ingesting contaminated beef
   - **c.** And will die and calcify in 2 to 3 weeks
   - **d.** All of the above
7. Neurocysticercosis is defined as:
   - **a.** Cysticerci localized in the liver
   - **b.** Cysticerci localized in the brain
   - **c.** Cysticerci localized in the eye
   - **d.** All of the above
8. Definitive diagnosis of cysticercus is made by:
   - **a.** Identification of cysticerci in tissue
   - **b.** CT or MRI
   - **c.** Immunoblot assay
   - **d.** All of the above
9. The cyst of *E. multilocularis:*
   - **a.** Grows quickly and produces many clinical symptoms
   - **b.** Is most commonly found in the southern United States
   - **c.** Is capable of forming a multicystic structure attributable to lack of a laminated membrane
   - **d.** Causes coenurus in humans
10. Humans become infected with *E. multilocularis* when they:
    - **a.** Ingest an oncosphere from an infected deer
    - **b.** Ingest coracidia from an infected copepod
    - **c.** Ingest eggs from an infected fox
    - **d.** Ingest eggs from human feces
11. Humans acquire sparganosis by:
    - **a.** Accidental ingestion of dog feces
    - **b.** Handling infected animals
    - **c.** Consuming procercoid larvae in undercooked fish
    - **d.** Ingesting human feces

12. True or False

______ Hydatid disease results when humans become the accidental host of *T. solium* cysts.

______ The presence of a scolex differentiates *Spirometra* from *T. solium.*

______ The rupture of a hydatid cyst may cause anaphylactic shock.

______ The cyst of *T. solium* lacks a laminated membrane.

13. Matching: *Match each term with the correct description.*

______ neurocysticercosis	a. daughter cysts
______ hydatid disease	b. many-chambered cysts
______ hydatids	c. longitudinal grooves
______ brood capsules	d. echinococcosis
______ hydatid sand	e. magnetic resonance imaging
______ multilocular	f. *T. multiceps* larval form
______ coenurus	g. cysticerci localized in brain
______ bothria	h. computed tomography
______ CT	i. scolices in hydatid fluid
______ MRI	j. cysts

Intestinal Trematodes

OBJECTIVES

1. List the clinically significant intestinal trematodes.
2. Describe the general life cycle of the intestinal trematodes, and identify the life cycle stage that is infective for humans.
3. Describe the diagnostic methods used to identify intestinal trematodes.
4. Explain the pathogenesis of intestinal trematode infections.
5. List the drugs of choice for intestinal trematode infections.
6. Describe the natural environment or habitat of intestinal trematodes, the route of transmission, and preventive measures.

PARASITES TO BE CONSIDERED

Helminths
Trematodes (flukes)
Intestinal
  Echinostoma ilocanum
  Fasciolopsis buski
  Gastrodiscoides hominis
  Heterophyes heterophyes
  Metagonimus yokogawai
  Centrocestus spp.
  Haplorchis spp.
  Stellantchamus spp.
  Pygidiopsis spp.

The intestinal trematodes (flukes) are members of the phylum Platyhelminthes (flatworms), are dorsoventrally flattened, and require at least one intermediate host (a freshwater snail). Human infection occurs by ingestion of **metacercariae** (tailless encrusted larvae) encysted on freshwater vegetation or fish. Most trematodes are hermaphroditic (both ovaries and testes are contained within each adult worm). The parasites are typically identified from eggs shed in the feces.

The adult worms are located in the small intestine, where they lay eggs that may be embryonated or remain unembryonated until shed from the body via feces. The egg continues developing after reaching the water, and a ciliated, free-swimming **miracidium** larva is released. The miracidium enters a snail host and develops into a **redia** (cylindrical larvae), followed by development into tailed **cercariae.** The cercariae emerge from the snail and encyst as a metacercariae on water plants or fish. A human host ingests raw or undercooked plants *(Fasciolopsis buski)*, fish *(Heterophyes, Metagonimus yokogawai),* or freshwater mollusks or fish (*Echinostoma* spp.) containing the metacercariae, which excyst in the intestinal tract, attach, and mature into adults. A representative life cycle for *M. yokogawai* is shown in Fig. 55.1.

Echinostoma spp.

General Characteristics

Varieties of species of echinostomes have been reported that infect humans including *E. hortense*, *E. ilocanum*, *E. macrorchis*, *E. perforatum*, and *E. revolutum*. The majority of human infections are caused by *E. ilocanum*. *E. ilocanum* adult flukes are elongated, leaflike, and approximately 1 cm in length and 0.2 cm in width. Both ends are attenuated, and the posterior end may be slightly pointed. Approximately 50% of adult worms demonstrate 49 to 53 collar spines arranged in alternating rows around the oral sucker. The eggs are passed in the feces of infected patients and are large and oval, with a relatively narrow operculum and small abopercular wrinkles at the posterior end. The eggs measure 89 to 112 µm long and 58 to 69 µm wide.

Epidemiology

Echinostomes infect freshwater mollusks, primarily snails. Infections are common in Russia, Southeast Asia, and the Far East. Rats and dogs serve as reservoir hosts in endemic areas.

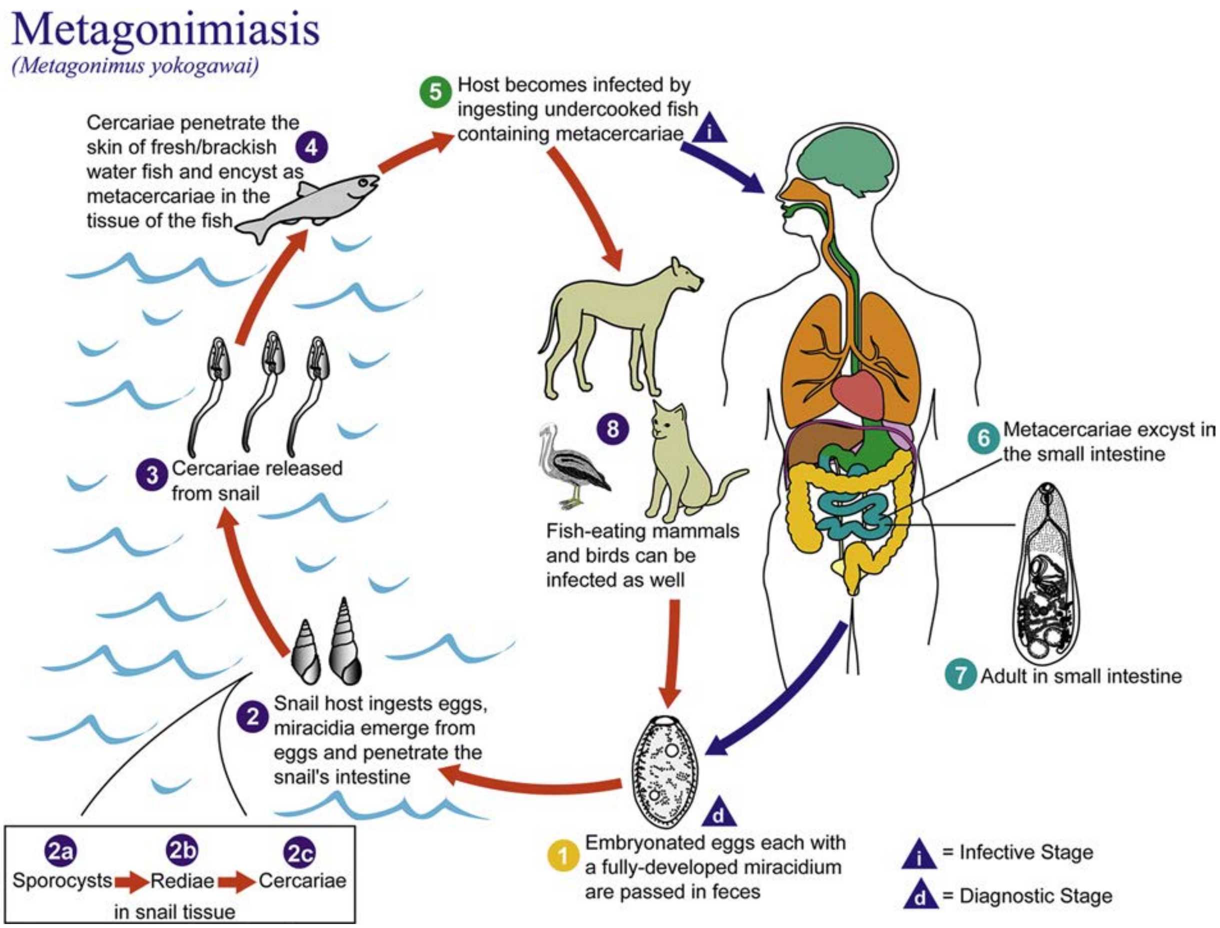
Pathogenesis and Spectrum of Disease

Echinostome infections can cause severe clinical manifestations, particularly in cases with heavy worm burdens. Infections can induce mucosal ulceration and bleeding in the duodenum and jejunum through mechanical irritation of the worms (using collar spines, and oral and ventral suckers) leading to severe gastrointestinal discomforts, including epigastric or abdominal pain accompanied by diarrhea, easy fatigue, and malnutrition, for several months' duration.

Patients may appear asymptomatic in light infections and experience mild abdominal pain and diarrhea.

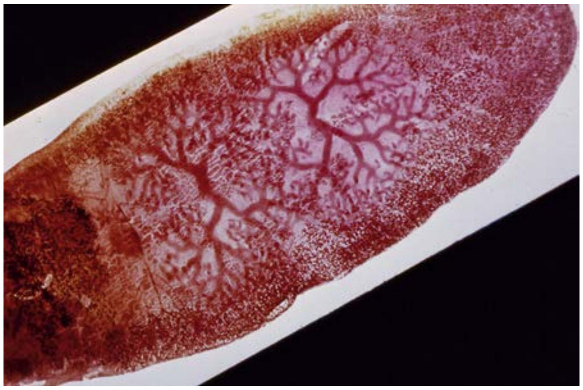
Therapy and Prevention

Praziquantel is the drug of choice for echinostomiasis although it is not included in the US product labeling for



Metagonimiasis
(Metagonimus yokogawai)
5 Host becomes infected by ingesting undercooked fish containing metacercariae
i
Cercariae penetrate the skin of fresh/brackish water fish and encyst as metacercariae in the tissue of the fish 4
3 Cercariae released from snail
8
Fish-eating mammals and birds can be infected as well
6 Metacercariae excyst in the small intestine
7 Adult in small intestine
2 Snail host ingests eggs, miracidia emerge from eggs and penetrate the snail's intestine
2a Sporocysts
2b Rediae
2c Cercariae
in snail tissue
d
1 Embryonated eggs each with a fully-developed miracidium are passed in feces
i = Infective Stage
d = Diagnostic Stage

• **Fig. 55.1** This is an illustration of the life cycle of the parasitic trematode, *Metagonimus yokogawai*, the causal agent of metagonimiasis. (Photo Courtesy the Division of Parasitic Diseases/Centers for Disease Control and Prevention.)



• **Fig. 55.2** Whole mount of *Fasciolopsis buski*. (Courtesy Dr. Henry Travers, Sioux Falls, SD.)

these infections. Although a single dose of 25 mg/kg of praziquantel is the recommended dose for treatment of intestinal fluke infection, echinostome infections can be treated with a slightly lower single oral dose of 10 to 20 mg/kg praziquantel. Proper food preparation and avoiding the consumption of raw, undercooked, or freshly pickled fish prevents infection. Praziquantel is the drug of choice for treatment. In addition, albendazole may also be used.

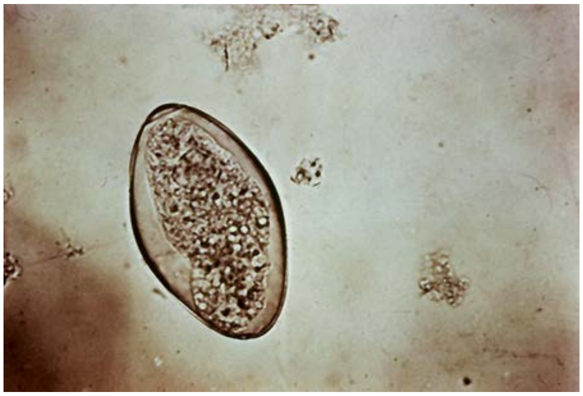
Fasciolopsis buski General Characteristics

The adults of *F. buski* have an elongated shape and range from 20 to 75 mm long and approximately 8 to 20 mm wide (Fig. 55.2). They have an oral sucker at the anterior end and a ventral sucker located about midway to the posterior end. The eggs, which are indistinguishable from those of *Fasciola hepatica* (Fig. 55.3), are oval and elongated, transparent, and yellow-brown with an operculum (lid) at one end, and they range in size from 130 to 140 mm long and 80 to 85 mm wide and may be unembryonated.

Epidemiology

F. buski is found in Bangladesh, Cambodia, China, India, Indonesia, Laos, Malaysia, Pakistan, Taiwan, Thailand, and Vietnam and is prevalent in school-aged children. Contaminated feces drain into the water from farmland, where feces is used for fertilization, or defecation occurs in or near water sources. Reservoir hosts include pigs, dogs, and rabbits.

F. buski is the largest of the intestinal trematodes, and infection is acquired by ingestion of raw water chestnuts or caltrop (plants with spiny heads or fruit). The definitive host is the pig, and fish-eating wild and domestic animals may



• **Fig. 55.3** *Fasciola* egg. The eggs of *Fasciolopsis buski* and *Fasciola hepatica* are indistinguishable morphologically. (Courtesy Dr. Henry Travers, Sioux Falls, SD.)

serve as reservoir hosts. The water vegetation may become contaminated when feces is used for fertilization or where disposal of farm animal feces is inadequate.

Pathogenesis and Spectrum of Disease

The intestinal attachment site of the adult worms often becomes locally inflamed and ulcerated and may hemorrhage. Moderate to heavy infections may cause abdominal pain, diarrhea, intestinal obstruction, and edema of the abdomen and lower extremities and may result in inadequate absorption of vitamin B_{12}. Eosinophilia is common.

Therapy and Prevention

The current treatment of choice for *F. buski* infection is praziquantel; single dose up to three times a day of niclosamide has been reported to have some *in vitro* efficacy. Infection can be prevented by immersing water plants in boiling water for a few seconds before peeling, and properly cooking water plants and fish before they are eaten. In addition, changes are needed in agricultural practices and health education in the endemic areas.

Gastrodiscoides hominis

General Characteristics

The natural habitat for *G. hominis*, also known as the colonic fluke, is the colon of pigs. The adult worm is vase-shaped and bright pink, averaging 5 to 8 mm long and 3 to 5 mm wide. The anterior region has a prominent oral sucker. The posterior portion is discoidal, and the ventral sucker is close to the posterior end. The tegument is smooth and contains a series of concentric folds bearing numerous tightly packed tubercles. Ciliated and non-ciliated papillae are arranged around the oral sucker on the ventral surface of the worm. Eggs measure approximately 146 by 66 µm, are rhomboidal (parallelogram shape), transparent, and green in color. Each egg contains about 24 vitelline (yolk sac–like) cells and a central unembryonated ovum.

Epidemiology

Human gastrodiscoidiasis is endemic in Southeast Asia, as well as the Philippines, Guyana, India, and Assam. High incidence can be attributed to low standards of sanitation in regions such as rural farms and villages, where night soils are used for fertilizer. Infection in both humans and animals results from the ingestion of contaminated vegetation. Transmission to humans occurs when undercooked or raw infected fish are ingested. Reservoir hosts include rats and deer mice. Humans are an accidental host with pigs serving as the definitive host.

Pathogenesis and Spectrum of Disease

Gastrodiscoidiasis as an infection in the definitive host is usually mild to asymptomatic. Following ingestion by a human host the metacercaria travel through the digestive tract into the duodenum to the cecum, where the larvae self-fertilize and lay eggs. Disease presentation is dependent on the worm burden. Patients may be asymptomatic, but heavy infections cause diarrhea, fever, abdominal pain, colic, malnutrition, and anemia. In severe cases, where there are large numbers of eggs present, papular lesions and desquamation lead to necrosis. Inflammatory reactions can occur in the heart or mesenteric lymphatic system.

Therapy and Prevention

Praziquantel is the treatment of choice for infections. Changes in agricultural practices, health education, and proper hygiene can prevent transmission in the endemic areas. The preferred drug, praziquantel, eliminates the parasite with three doses at 25 mg/kg in 1 day. Prevention of this disease is not difficult when simple sanitary measures are taken. Night soil should never be used as a fertilizer because it could contain any number of parasites. Vegetables should be washed thoroughly, and meat properly cooked.

Heterophyes: Metagonimus yokogawai, Centrocestus spp., *Haplorchis* spp., *Stellantchamus* spp., and *Pygidiopsis* spp.

General Characteristics

There are 22 genera in the family *Heterophyidae,* with six medically relevant genera. *Heterophyes* and *M. yokogawai* are the most prominent. Additional genera included in the family include *Centrocestus* spp., *Haplorchis* spp., *Stellantchamus* spp., and *Pygidiopsis* spp.

Heterophyes heterophyes

Adult *H. heterophyes* worms range in size from 1.0 to 1.7 mm in length and 0.3 to 0.4 mm in width and have a broadly rounded posterior. The adult *H. heterophyes* also has an additional sucker, the genital sucker, which surrounds the genital pore. The eggs are small, yellow-brown, embryonated, and operculated and may have minimal opercular shoulders. Eggs range in size from 26 to 30 mm long and 15 to 17 mm wide and may be indistinguishable from *M. yokogawai*.

Epidemiology

H. heterophyes is distributed throughout China, Egypt, India, Iran, Israel, Japan, Korea, Sudan, the Philippines, Tunisia, and Turkey. Reservoir hosts include cats, dogs, and birds. Snails serve as the intermediate host and a variety of freshwater fish serve as the second intermediate host. This very small trematode is acquired through ingestion of pickled, raw, or inadequately cooked fish.

Metagonimus yokogawai

Adult

M. yokogawai adult worms range in size from 1.0 to 2.5 mm long and approximately 0.4 to 0.8 mm wide. The eggs are small, yellow-brown, embryonated, and operculated, and may have minimal opercular shoulders. Eggs range in size from 26 to 30 mm long and 15 to 17 mm wide and may be indistinguishable from *H. heterophyes.*

Epidemiology

M. yokogawai is found in the Balkans (a cultural region of southeastern Europe), China, Indonesia, Israel, Japan, Korea, Russia, Spain, and Taiwan and is considered the most common intestinal fluke infection in the Far East. Reservoir hosts include cats, dogs, and birds. Freshwater snails serve as the intermediate host, and a variety of freshwater fish serve as the second intermediate host. This very small trematode is acquired through ingestion of pickled, raw, or inadequately cooked fish.

Centrocestus spp.

Adult worms range in size from 280 to 330 µm long and approximately 150 to 180 µm wide. The body is covered in scalelike tegumental spines. The worm has a terminal oral sucker with 32 circumoral spines arranged in two rows and a small ventral sucker. The eggs are oval, yellowish brown, with a distinct operculum. The shell surface appears to have a lattice design. The eggs are approximately 33 µm long and 17 µm wide.

Epidemiology

Centrocestus spp. is an intestinal foodborne trematode that parasitizes birds and mammals, including humans. The species is native to Asia, with worldwide distribution. The primary molluscan intermediate host, *Melanoides* spp., is reported to be present in more than 10 countries throughout Asia and the Americas. Many species of fish are the second intermediate hosts. Metacercariae encyst in the gills of the fish causing pathological developmental delay and death, giving rise to economic losses in the fish farming industry.

Haplorchis spp.

The adult worms of *Haplorchis* are characterized by the presence of a small, armed ventral sucker and a single testis, which differentiates it from *Metagonimus* and *Heterophyes*. A distinct morphological feature of *Haplorchis* is the ventral sucker that has a semi-lunar (half-moon shaped) group of 12 to 16 long, crescentic, and hollow spines and a sinistral (left side) patch of very minute solid spines. The eggs are oval with a convex operculum. The eggs are very similar in shape, size, and morphology to *Opisthorchis viverrini* and cannot be morphologically differentiated.

Epidemiology

Human infections with *Haplorchis* spp. are prevalent in Southeast Asia, including countries located in the Indochina Peninsula, Taiwan, the Philippines, and Egypt. The intermediate host is freshwater snails, *Melania* spp. Fish are the second intermediate hosts, and dozens of species of birds and fish-eating mammals, including dogs, cats, and humans, serve as definitive hosts.

Stellantchamus spp.

The adult flukes are pyriform with a small submedian ventral sucker and an expulsor-type elongated saclike seminal vesicle. Eggs are elongated, ovoid, and slender, from 25.3 to 29.2 µm long and 11.1 to13.4 µm wide.

Epidemiology

Human infections with *Stellantchamus* spp. are prevalent in Southeast Asia, including Korea, Japan, and Kuwait. The intermediate host is the brackish water snail, *Melanoides* spp. The second intermediate hosts are brackish water fish, primarily mullets. Additional freshwater fish, including the half-beaked fish and climbing perch, can also serve as the second intermediate host. Natural definitive hosts include cats, dogs, pigs, rats, humans, and birds.

Pygidiopsis spp.

The adult flukes have a small concave body with a medial ventral sucker. The worm has a unique ventrogenital apparatus (having two groups of spines around the genital pore; 5 to 6 right side and 7 to 9 left side). The two testes are side by side. The worm produces small (19.8 to 22.9 µm long and 11.1 to 13.4 µm wide), ovoid, pyriform eggs with no distinct pattern on the shell.

Epidemiology

Human infections with *Pygidiopsis* spp. are prevalent in Southeast Asia and other regions, including Korea, Japan, Vietnam, and Egypt. The primary intermediate host is the brackish water snail, *Melanoides* spp. The second intermediate host is brackish water fish. The definitive hosts include wolves, cats, dogs, foxes, shrews, rats, pelicans, kites, ducks, and cormorants.

Pathogenicity and Spectrum of Disease

Infections with a small number of worms from any of the heterophyid genera may be asymptomatic. Symptoms in heavy infections may include abdominal pain, diarrhea with a large amount of mucus, and ulceration of the intestinal wall. Eggs may gain entry into the intestinal capillaries and the lymphatic system, where they can be carried to the heart, brain, spinal cord, or other tissues, causing emboli or granuloma formation.

Prevention

Infection can be prevented by avoiding ingestion of raw, inadequately cooked, and pickled or salted fish. The risk of infection could be reduced with improved sanitary conditions and health education programs.

Laboratory Diagnosis

Identification of the intestinal trematodes is made by recovery of eggs, or in rare cases adults, from stool specimens using a sedimentation method such as formalin-ethyl acetate. The sediment may be examined in a wet mount with or without iodine. The eggs of *F. buski* are identical to those of *F. hepatica*, *E. ilocanum,* and *G. hominis;* and those of *H. heterophyes* and *M. yokogawai* are very similar. Diagnosis of heterophyid infections may also require assessment of symptoms, obtaining a travel history, and/or recovery of adult worms.

Nucleic Acid Detection

Various polymerase chain reaction (PCR) methods have shown potential in detecting intestinal flukes. These methods take advantage of the different types of DNA nucleotide sequence variations demonstrated by the different species within a particular genus. Multiplex qPCR has been developed to detect the presence of the major intestinal parasites known to cause gastroenteritis, including the trematodes *C. sinensis* and *M yokogawai*. The assays reportedly exhibit 100% sensitivity and 100% specificity.

Polymerase chain reaction–restriction fragment length polymorphism (PCR-RFLP) and simple sequence repeat anchored PCR have been reported to be useful in distinguishing species of the *Metagonimus* genus (including *M. yokogawai*). Information derived from RFLP involving specific sites in ribosomal RNA and mitochondrial cytochrome oxidase I (mtCOI) genes may help to differentiate *M. yokogawai* from other Metagonimus species. Six members of the *Heterophyidae* family can be distinguished with PCR assays based on variations in rDNA polymorphisms among the species.

Treatment

The drug of choice for treatment of intestinal trematode infection is praziquantel, an isoquinoline derivative administered orally in three doses for 1 day. There may be some mild side effects, but these usually disappear within 48 hours and may be more severe in those with heavy infections. An alternative drug is niclosamide and is administered for 1 to 2 days.

CASE STUDY 55.1

The husband of a 32-year-old woman is employed in the foreign service, and the couple has recently been on assignment to Africa. The wife complained of a 2-month history of abdominal pain, vomiting, diarrhea, and weight loss. While in Africa, she had eaten the locally grown watercress. A stool specimen was collected for culture, ova, and parasite examination. The bacterial culture was negative. A wet mount made during the parasite examination showed large, oval, operculated, and unembryonated helminth eggs.

Questions

1. What parasite is the probable cause of the patient's symptoms?
2. Another parasitic worm has indistinguishable eggs. How would the infections caused by these two worms differ?
3. How did the patient most likely acquire this infection?
4. What would be the preferred treatment for this infection?

Chapter Review

1. Fluke eggs are equipped with a lid at the top of the shell called a/an:
a. Egress
b. Operculum
c. Nodule
d. Button

2. The infective life cycle stage of a fluke is the:
a. Miracidium
b. Cercariae
c. Metacercariae
d. Pleurocercariae

3. What intermediate host is required in the life cycle of all trematodes?
a. Freshwater snail
b. Crayfish
c. Aquatic vegetation
d. Freshwater crab

4. Which two of the following are small flukes whose eggs are generally indistinguishable?
a. *Fasciolopsis*
b. *Heterophyes*
c. *Metagonimus*
d. *Paragonimus*

5. What laboratory finding is common in *F. buski* infections?
a. Increased levels of vitamin B_{12}
b. Increased serum bilirubin levels
c. Decreased number of red blood cells
d. Increased number of eosinophilia

6. The drug of choice for an intestinal trematode infection is:
a. Niclosamide
b. Praziquantel
c. Albendazole
d. Tiabendazole

56

Liver and Lung Trematodes

OBJECTIVES

1. List the clinically significant trematodes capable of infecting the liver and lungs.
2. Describe the general life cycle of the liver and lung flukes and identify the infective stage for humans.
3. Describe the diagnostic methods used to identify the liver and lung flukes, including the microscopic differentiation of eggs and serologic methods.
4. Describe the pathogenesis of the liver and lung flukes, including location and associated disease manifestations.
5. List the drug of choice for infections with liver and lung flukes.
6. Describe the transmission of the liver and lung flukes and discuss how infection may be prevented.

PARASITES TO BE CONSIDERED

Trematodes (Flukes)

Liver/Lung
Clonorchis sinensis
Opisthorchis felineus
Opisthorchis viverrini
Fasciola gigantica
Fasciola hepatica
Paragonimus africanus
Paragonimus caliensis
Paragonimus heterotremus
Paragonimus kellicotti
Paragonimus mexicanus
Paragonimus miyazakii
Paragonimus skrjabini
Paragonimus uterobilateralis
Paragonimus westermani

The parasites within this chapter are typically foodborne and may have serious economic implications. *Clonorchis* spp., *Opisthorchis* spp., and *Fasciola* spp. live in the biliary ducts of humans. *Paragonimus* spp. are found in the lungs and in other body sites.

The Liver Flukes

General Characteristics

The adults of these trematodes live in the biliary ducts and may be found in the gallbladder in heavy infections. Three of these, *Clonorchis sinensis* (the Chinese liver fluke), *Opisthorchis felineus,* and *Opisthorchis viverrini* (the Southeast Asian liver fluke), are elongated and narrow and much smaller than *Fasciola* (the sheep liver fluke). These flukes also all require a freshwater snail as an intermediate host.

Epidemiology and Life Cycle

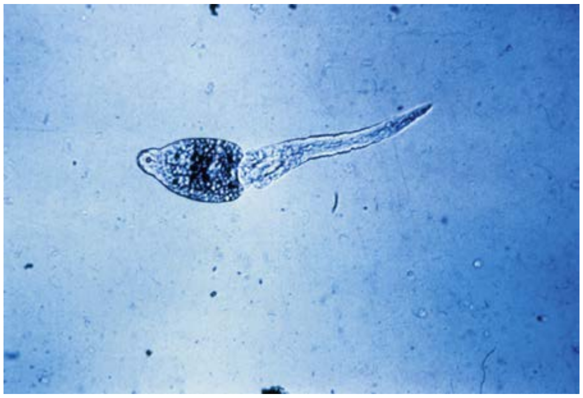
C. sinensis is distributed throughout China, Japan, Korea, Taiwan, and Vietnam. *O. viverrini* is found in Cambodia, Laos, Thailand, and Vietnam, and *O. felineus* is found in Northern Europe and Asia. Reservoir hosts include dogs and cats. *Fasciola* spp. cause very similar disease, differing primarily in geographic distribution, with *F. hepatica* occurring in Europe and North and South America, and *F. gigantica* in Asia and Africa. *Fasciola* spp. affect the economics of the sheep and cattle industries. Reservoir hosts include dogs, hogs, cats, martens, badgers, minks, weasels, pigs, equines, and rats. Infected feces enter the water system because of improper drainage and unsanitary practices.

The life cycle of the liver flukes is very similar to that of the intestinal flukes. The adult worms produce eggs in the biliary ducts that are then excreted from the body in the feces. The free-swimming miracidium is released from the egg in fresh water and enters the snail host, where it develops into a redia and then cercariae, which leaves the snail and enters the water (Fig. 56.1). The cercariae of *Clonorchis* and *Opisthorchis* are ingested by a second intermediate host, a freshwater fish. The cercariae then encyst and develop into the metacercariae within the intermediate host. The metacercaria is the infective stage for humans. When infected freshwater fish are eaten raw or undercooked, the metacercariae will excyst in the duodenum and then travel to the bile duct, where they mature. The cercariae of *Fasciola* encyst on freshwater vegetation, such as watercress and water chestnuts, and develop into metacercariae. When the infected vegetation is eaten raw, the metacercariae will excyst in the duodenum and then travel to the bile duct and mature. Fig. 56.2 depicts the general life cycles of the liver and lung flukes.

Pathogenesis and Spectrum of Disease

Light infections with *C. sinensis* or *Opisthorchis* spp. are most common and may be asymptomatic. Heavier infections with these flukes may present with fever, abdominal pain, and jaundice. Eosinophilia and increased serum levels of immunoglobulin E (IgE) may occur. Severe infections may cause obstruction of the biliary ducts, resulting in enlargement and tenderness of the liver, cirrhosis, cholecystitis (inflammation of the gallbladder), and cholangiocarcinoma (cancerous growth in bile duct epithelium).

Even light infections with *Fasciola* may cause fever, abdominal pain, nausea, diarrhea, enlargement and tenderness of the liver, jaundice, nonproductive cough, eosinophilia, and elevated serum IgE levels. Leukocytosis, eosinophilia and mild to moderate anemia may also be present. More severe infections may result in obstruction of the biliary ducts, cirrhosis, cholecystitis, and cholangiocarcinoma. During migration in the human body, the larvae may penetrate the peritoneal cavity, and adult flukes may be found in the intestinal walls, lungs, heart, or brain. Many symptoms of infection disappear when the parasite has lodged in the biliary passages resulting in chronic infection. The chronic phase presents with liver abnormalities and eosinophilia. In chronic infections, worms have been identified in the intestinal wall, brain, heart, lungs, and skin.



• **Fig. 56.1** Cercaria of a liver fluke. (Photo courtesy Dr. Henry Travers, Sioux Falls, SD.)

Laboratory Diagnosis

Identification of the liver flukes is primarily made by recovery of the eggs in feces using a sedimentation method and a wet mount with or without iodine staining.

The adult worms of *Clonorchis* are elongated and narrow and a transparent reddish-yellow color. Adult *Clonorchis* may vary in size from 10 to 25 mm × 3 to 5 mm. The eggs

6 Adults in biliary duct

• **Fig. 56.2** Life cycle of the trematode, *Clonorchis sinensis,* the causal agent of clonorchiasis. (Courtesy Division of Parasitic Diseases/Centers for Disease Control and Prevention.)

of *Clonorchis* are 28 to 30 µm × 14 to 18 µm. The eggs have shouldered opercula and a small knob at the end opposite the operculum, are yellow-brown in color, and are embryonated when they leave the body (Fig. 56.3A). Diagnosis is based on microscopic identification of eggs in stool specimens. However, the eggs of *Clonorchis* are practically indistinguishable from those of *Opisthorchis*. The adult fluke can also be surgically recovered.

Like *Clonorchis,* the adult worms of *Opisthorchis* are elongated and narrow and a transparent reddish-yellow color. Adult worms of *Opisthorchis,* however, are much smaller: 5 to 10 mm × 0.8 to 1.9 mm. The adult worm of *O. felineus* is lancet-shaped and is larger than *O. viverrini.* The size of *Opisthorchis* eggs is slightly smaller than *Clonorchis; Opisthorchis* eggs are 19 to 29 µm × 12 to 17 µm. Also like *Clonorchis,* the eggs have shouldered opercula and a small knob at the end opposite the operculum, are yellow-brown in color, and are embryonated when they leave the body (Fig. 56.3). Diagnosis is made by detecting eggs in a duodenal aspirate (bile fluid), the recovery of adult worms, or by clinical history. Eggs are not excreted in patients with biliary obstruction, requiring needle aspiration, surgery, or an autopsy specimen for confirmation.

The adult worm of *Fasciola* is much larger (2 to 5 cm × 0.8 to 1.3 cm) (Fig. 56.3C), with a cephalic cone at the anterior end, that contains the oral sucker. The adult fluke of *F. gigantica* is similar to *F. hepatica*; however, it is somewhat more lancet-shaped and has a less distinct cephalic cone. The eggs are 130 to 150 µm × 70 to 90 µm, operculated, brownish-yellow, and unembryonated when they leave the body. The eggs of *F. gigantica* tend to be somewhat larger (160 to 190 µm by 70 to 90 µm). Because the eggs of *Fasciola* spp. and *Fasciolopsis* are virtually indistinguishable, it may also be necessary to recover eggs from bile specimens or to recover adult worms. The diagnosis of *F. gigantica* is the same as *F. hepatica*; however, eggs may even be less likely to be identified in the stool of infected patients. Definitive identification of *Fasciola* is important, because the treatment is different from that for *Fasciolopsis.* Fig. 55.3 shows the eggs of *Fasciola hepatica,* and Fig. 55.2 is a *Fasciolopsis buski* adult fluke.

Serologic Testing

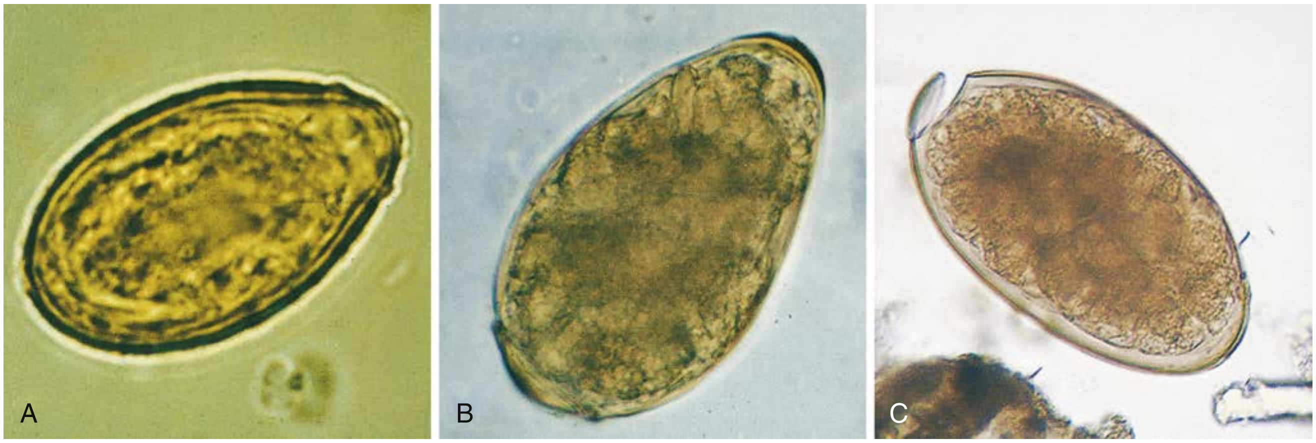
C. sinensis and *O. viverrini* infections elicit a strong immune response. IgE levels are elevated in infections, and IgM is detectable in acute infections, followed by an increase in IgA and IgG. In chronic infections, the IgA level returns to normal, but IgG and IgM remain elevated. Serological diagnosis has been successful for *C. sinensis*; using ELISA is sensitive and demonstrates low cross-reactivity to related organisms. However, this means of diagnosis is not available for *O. viverrini* due to a lack of standardization and false-positive results; this is caused by cross-reactivity with other parasitic diseases. ELISA has been successful using excretory and secretory antigens from adult worms of *O. felineus* cultivated *in vivo.*

Serologic testing is available for the diagnosis of *Fasciola* spp. Serologic testing can be useful in the acute phase of infection because specific antibodies to *Fasciola* may become detectable 2 to 4 weeks following infection, whereas egg production typically is not apparent until 3 to 4 months after exposure. Serologic testing can also be of value for cases of chronic *Fasciola* infection in persons with low-level or sporadic egg production, as well as in persons with ectopic infection. It may also help rule out pseudofascioliasis associated with ingestion of parasite eggs in sheep or beef liver.

The immune diagnosis of human *F. hepatica* infection includes an enzyme immunoassay (EIA) with excretory-secretory (ES) or recombinant antigens and confirmatory testing of EIA-positive specimens with an immunoblot assay. Enzyme-linked immunosorbent assay (ELISA) serum IgG antibody testing may demonstrate cross-reactivity with other trematodes, such as the schistosomes.

Nucleic Acid Detection

A variety of PCR-based methods including loop-mediated isothermal amplification (LAMP) have been developed for the detection of the liver flukes, including *F. hepatica*. These



• **Fig. 56.3** Trematode eggs. (A) *Clonorchis sinensis*. (B) *Paragonimus westermani*. (C) *Fasciola hepatica* (note the partially open operculum). (From Centers for Disease Control and Prevention. DPDx-Laboratory Identification of Parasitic Diseases of Public Health Concern.)

methods demonstrate a high sensitivity and specificity for the diagnosis of *F. hepatica* infection in comparison to routine fecal and indirect serological tests. The LAMP detects DNA of *C. sinensis* and *O. viverrini* in freshwater snails, the second intermediate fish hosts, and patient feces. In human fecal samples, LAMP-based technology detects *C. sinensis* in human infection with as low as 1 egg per 100 mg of feces. Further evaluation of the LAMP-based diagnosis test showed a sensitivity of 97.1% and specificity of 100%.

Similar LAMP assays are also available for *O. viverrini*, with the variation of sensitivity and specificity relating to the repetition of different target genes when detecting DNA. A multiplex PCR assay has been used to detect *C. sinensis* and *Opisthorchis* in fish and infected patients in endemic areas. A single-step duplex real-time fluorescence resonance energy transfer (FRET) real-time PCR has been developed to diagnose and differentiate *C. sinensis* and *Opisthorchis* infections in human fecal samples. The assay differentiates the two species with 100% specificity and sensitivity. Despite the clinical utility of nucleic acid methods for the detection of the liver flukes, they are not generally available in routine laboratories, even in endemic regions.

Therapy and Prevention

The drug of choice for treatment of infections with *Clonorchis* and *Opisthorchis* is praziquantel (25 mg/kg) given orally three times per day for 2 days. The drug of choice for the treatment of *Fasciola* spp. is triclabendazole (praziquantel is not as effective). Infections with *Opisthorchis* often require additional treatment with antibiotics due to secondary bacterial infections.

Human infection can be prevented by ensuring that fish and aquatic vegetation are properly cooked before consumption, as well as by the improvement of sanitary conditions, along with good personal hygiene.

The Lung Flukes

General Characteristics

The genus *Paragonimus* contains approximately 15 species known to infect humans. *Paragonimus westermani* is the most common and widely distributed lung fluke. *P. mexicanus* is located in Central and South America, and *P. kellicotti* is found in North and South America. Both are important human pathogens. The adult worms live in the lungs and produce eggs that may be present in sputum, or if expectorated and swallowed may be present in feces. Like other trematodes, a freshwater snail is required as an intermediate host.

Epidemiology and Life Cycle

Paragonimiasis is found primarily in the Far East, in India, the Philippines, China, Japan, Korea, Manchuria, Papua New Guinea, and Southeast Asia, following ingestion of uncooked crabs, crayfish, freshwater shrimp, mussels, and paratenic hosts. Reservoir hosts for *P. westermani* include dogs and cats, and those for *P. mexicanus* include domestic and wild pigs, dogs, and rodents. Species of *Paragonimus* may also be found in other freshwater crab- or crayfish-eating mammals. *P. kellicotti* is becoming an increasing concern in the United States. It is widely distributed throughout North America and is found in cats, dogs, bobcats, raccoons, foxes, skunks, minks, and coyotes. Transmission in the United States is associated with behavioral activities that include alcohol consumption, dares, and the demonstration of outside survival skills.

The adult worms, encapsulated in the lungs, produce eggs that leave the lung via the bronchioles, stimulating a cough response. The eggs are swallowed and eventually excreted in the feces. Egg size varies with species from approximately 80 to 120 μm long and 45 to 70 μm wide (Fig. 56.3B). The free-swimming miracidium is released from the egg in fresh water and enters the snail host, where it develops into a redia and then cercariae, which leaves the snail and enters the water. The cercariae then enter a second intermediate host, a crab or crayfish, where they encyst and develop into metacercariae. The metacercaria is the infective stage for humans. When infected freshwater crabs and crayfish are eaten raw or undercooked, the metacercariae will excyst in the duodenum and then migrate through the intestinal wall, and eventually through the diaphragm and into the lungs where they encapsulate (usually in pairs) and mature (Fig. 56.2).

Pathogenesis and Spectrum of Disease

Light infections may be asymptomatic. The migration of the metacercariae through muscle and tissue may cause local pain and an immune response to the tissue damage. In the lungs, the immune response causes infiltration of eosinophils and neutrophils. Serum IgE levels are usually elevated. Eventually the adult worms are encapsulated in a granuloma. Presence of the worms in the lungs usually results in a chronic cough, with possible production of blood-tinged sputum. The cough provides a mechanism to transport eggs up into the throat, where they are swallowed and then may be excreted in the feces. The larvae of *P. mexicanus, P. skrjabini, P. heterotremus,* and *P. hueitungensis* may migrate to other areas of the body, commonly causing subcutaneous or lower abdominal nodules to form. The larvae of *Paragonimus* may enter other sites such as the liver, intestinal wall, muscles, peritoneum, and the brain, where they can cause severe damage. These ectopic infections are generally associated with *P. heterotremus, P. mexicanus*, and *P. westermani.* Computed tomography (CT) and magnetic resonance imaging (MRI) may be used to reveal cysts with edema, migration tracks, and nodules in various areas of the body including the brain, liver, and lungs.

Laboratory Diagnosis

The adult worms of *Paragonimus* vary in size, 10 to 25 mm × 3 to 5 mm, and are a reddish-brown color. The eggs of *P. westermani* measure 80 to 120 µm × 45 to 60 µm, and those of *P. mexicanus* are approximately 80 µm × 40 µm. The eggs are unembryonated when they leave the body, operculated with opercular shoulders, thick-shelled, and brownish-yellow. The eggs of *Paragonimus* are similar to those of *Diphyllobothrium* (freshwater fish tapeworm) and can be differentiated by the operculum, opercular shoulders, and thickened shell at the end opposite the operculum.

Paragonimus eggs may be recovered from sputum, pleural effusions, and occasionally in feces using a sedimentation concentration method. The eggs may be observed in a wet mount (with or without iodine stain) (Fig. 56.4). **Charcot-Leyden crystals** may also be observed in sputum or lung tissue specimens. Charcot-Leyden crystals are slender and pointed at both ends. The crystals normally appear colorless and stain purplish to red with trichrome. Elevated levels of eosinophils may be present in whole blood, and elevated IgE levels may be present in serum. Lesions in the lungs may be observed by x-ray.

Serologic Testing

Serologic testing is available in the United States for the diagnosis of *P. westermani* and *P. kellicotti.* EIA tests and immunoblot (IB) assays and hemagglutination tests can be used to diagnose active infections. Antibody levels detected by EIA and IB do decline after chemotherapy and death of the worms. Pleural effusion samples are more suitable for the detection of antibodies than serum. The Division of Parasitic Disease at the Centers for Disease Control and Prevention (CDC) performs serum IgG EIA and immunoblot testing. Cross-reactivity with other species and trematodes may occur.

Nucleic Acid Detection

The conventional immunological diagnosis is sensitive in human paragonimiasis but unsustainable in epidemiological surveys. A LAMP assay has successfully amplified the gene sequence of *P. westermani* eggs in sputum and pleural fluid from patients, as well as metacercariae in freshwater crabs and crayfish. LAMP demonstrates a detection limit of 1 ×

10^{-8} ng/µL, approximately 100 times more sensitive than PCR. The LAMP method also yields positive and negative results coinciding with those from parasitology tests, making it an excellent candidate for field surveys and clinical diagnoses of paragonimiasis.

Treatment and Prevention

The drug of choice for treatment of *Paragonimus* infections is praziquantel given three times a day for 2 to 3 consecutive days. Triclabendazole in a single- or two-dose regimen is also effective but is not available in the United States.

Human infection can be prevented by not eating pickled, raw, or undercooked crabs or crayfish. Crustaceans should be cooked to an internal temperature of 145°F. Care should also be taken to properly clean utensils used in the preparation of these foods. Improvement of sanitary conditions and practices may also help to reduce the prevalence of these infections.

CASE STUDY 56.1

A 50-year-old male visiting from Japan complained of fever, abdominal pain, and jaundice. A stool specimen was collected for ova and parasite examination. A blood specimen was also collected and sent to a clinical laboratory for testing. The blood work showed a slightly increased serum bilirubin level. The parasite examination showed small, oval, operculated eggs (approximately 80 μm × 45 μm), with opercular shoulders and a knob on the opposite end.

Questions

1. What parasite is the probable cause of this infection?
2. Another parasitic worm has eggs that are almost identical. What fact about the patient can aid in deciding which worm is responsible for his infection?
3. What other complications might be expected with this infection?
4. What would be the preferred treatment for this infection?

Chapter Review

1. Which of the following flukes has an operculated flask-shaped egg with prominent shoulders and a knob at the opposite end?
a. *Opisthorchis*
b. *Paragonimus*
c. *Fasciola*
d. *Fasciolopsis*

2. For which one of the following flukes would sputum be the diagnostic specimen?
a. *Opisthorchis*
b. *Paragonimus*
c. *Fasciola*
d. *Clonorchis*

3. The eggs of *Fasciola hepatica* are indistinguishable from those of:
a. *Clonorchis sinensis*
b. *Heterophyes heterophyes*
c. *Opisthorchis viverrini*
d. *Fasciolopsis buski*

4. Where might *Clonorchis* be found that *Opisthorchis* is not found?
a. Vietnam
b. Thailand
c. Korea
d. Cambodia

5. Infection with *Clonorchis* or *Opisthorchis* may result from eating raw or undercooked:
a. Aquatic vegetation
b. Crabs
c. Crayfish
d. Freshwater fish

6. What laboratory finding may be observed in *Paragonimus* infections?
a. Increased number of eosinophils
b. Decreased serum bilirubin level
c. Decreased vitamin B_{12} level
d. Increased number of red blood cells

7. The drug of choice for treatment of *Fasciola hepatica* infections is:
a. Albendazole
b. Triclabendazole
c. Niclosamide
d. Praziquantel

Blood Trematodes

OBJECTIVES

1. List the clinically significant blood trematodes.
2. Describe the general life cycle of the blood trematodes and how human infection occurs.
3. Explain the diagnostic methods used to identify blood trematodes.
4. Differentiate the eggs of the five species of schistosomes.
5. Describe the pathogenesis of the blood trematodes.
6. List the drugs of choice for treatment of blood trematode infections.
7. Describe the natural habitat for blood trematodes and how infection may be prevented.

PARASITES TO BE CONSIDERED

Trematodes

Blood

Schistosoma guineensis
Schistosoma haematobium
Schistosoma intercalatum
Schistosoma japonicum
Schistosoma malayensis
Schistosoma mansoni
Schistosoma mattheei
Schistosoma mekongi
Schistosoma spp.

There are five main species of blood flukes that are primarily associated with disease in humans (known as **schistosomiasis, bilharziasis,** or snail fever), all belonging to the genus *Schistosoma.* These species are *Schistosoma haematobium, Schistosoma mekongi, Schistosoma intercalatum, Schistosoma japonicum* (Oriental blood fluke), and *Schistosoma mansoni.* Seven additional species are rarely associated with human infection and have limited geographic distribution. The blood flukes differ in morphology and life cycle characteristics from the other trematodes. They are similar, however, by requiring a freshwater snail as the intermediate host.

General Characteristics

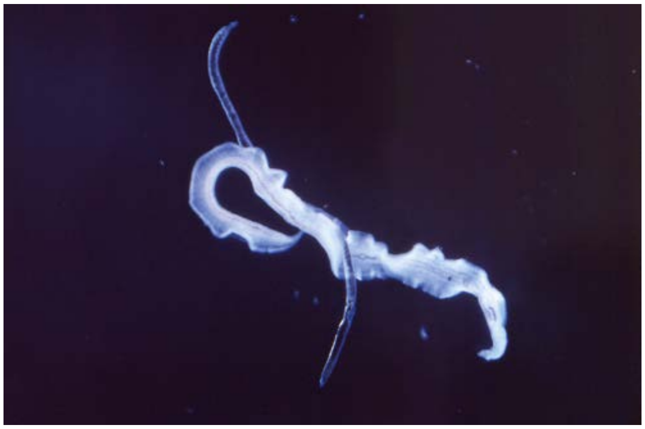
Unlike the other trematodes, adult schistosomes are not flattened, but are rather long, thin, and rounded in shape. There is an oral sucker surrounding the mouth and a ventral sucker located just slightly below the oral sucker. The adult male averages 1.5 cm in length and is wider than the female, having a ventral fold that wraps around the female when they mate (Fig. 57.1). The adult female averages 2 cm in length and is very thin.

The eggs of each species are distinct and can be distinguished by size, spine morphology, and sometimes specimen type (Fig. 57.2). The size range for eggs of *S. haematobium* is 110 to 170 μm long by 40 to 70 μm wide, and they have a sharply pointed terminal spine. They are fully embryonated without an operculum. The size range for the eggs of *S. japonicum* is 70 to 100 μm long by 50 to 65 μm wide, and they have a small lateral spine that is sometimes difficult to detect (Fig. 57.3). *S. mekongi* eggs are smaller than those of *S. japonicum,* ranging in size from 50 to 65 μm long by 30 to 55 μm wide. They are fully embryonated without an operculum and have a small lateral spine. The size range for eggs of *S. mansoni* is 115 to 180 μm long by 40 to 75 μm wide, and they have a large lateral spine. *S. mansoni* eggs are inoperculate, immature when released, and take up to 8 to 10 days to develop a miracidium. *S. intercalatum* eggs are fully embryonated without an operculum, have a terminal spine, and range in size from 140 to 240 μm long by 50 to 85 μm wide. *S. intercalatum* eggs resemble those of *S. haematobium* and can be differentiated by Ziehl-Neelsen acid-fast positivity. In addition, *S. intercalatum* eggs are only found in feces, not in urine specimens. Table 57.1 provides a comparison of the schistosome eggs.

One of the main differences between the schistosomes and other trematodes is that instead of being hermaphroditic, there are separate male and female adult worms. In human infection, the adult worms live in either the veins that supply the intestine (*S. japonicum, S. intercalatum, S. mekongi*, and *S. mansoni*) or the veins that supply the urinary bladder *(S. haematobium).* The eggs are passed from the body in either feces or urine. To reach the inside of the intestine or bladder, the eggs must penetrate the tissue from the veins. This is accomplished via a spine that is distinctive among the major species. The embryonated egg releases the miracidium. once it reaches fresh water, where it enters the snail host and develops into the infectious cercaria. The free-swimming cercariae are capable of penetrating through human skin and do not encyst on aquatic vegetation or within other aquatic wildlife. The cercariae penetrate host tissue until they reach a vein; then they travel to capillaries near the lungs and then to the portal vein of the liver, where they mature. When they are mature, the adult males pair with females and then travel to veins of either the intestine or the bladder, where eggs are produced.

Epidemiology

Schistosomes have a worldwide distribution from Egypt and China to Africa and the Americas. *S. haematobium* is found in Africa and the Arabian Peninsula and has no reservoir hosts. *S. mansoni* and *S. guineensis* are found in Africa, the Arabian Peninsula, and Brazil. Reservoir hosts include wild rodents and marsupials. *S. japonicum* is found in China, Indonesia, and the Philippines. Many domestic animals (cats, dogs, cattle, horses, pigs) serve as reservoir hosts, as do some wild animals. *S. mekongi* primarily exists in the lower Mekong River basin in southern Laos, Cambodia, and Thailand. Reservoir hosts include dogs and domestic pigs. *S. intercalatum* and *S. guineensis* are primarily found in central and western Africa. Reservoirs include rodents, marsupials, and nonhuman primates. Human schistosome infection is caused by fecal (and urine) contamination of small bodies of water that favor the growth of the snail hosts. Infection with *S. japonicum* is especially prevalent in areas where humans work in rice paddies.

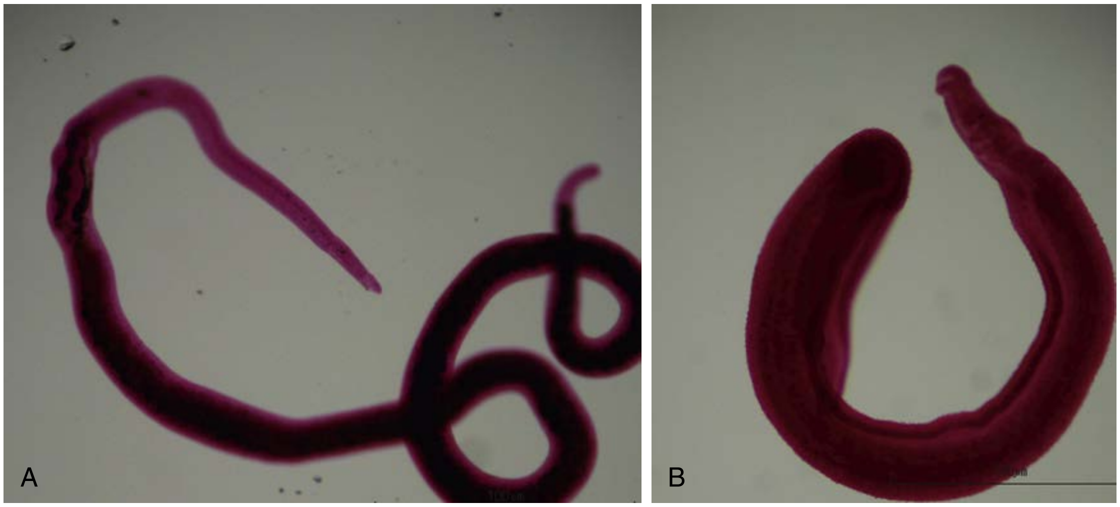


• **Fig. 57.1** This low-power photomicrograph reveals some of the ultrastructural morphology exhibited by coupled male and female *Schistosoma mansoni* parasites. Unlike the flukes, adult schistosomes are either male or female, with the female residing in a gynecophoral canal within the male. Male worms are robust, tuberculate, and measure 6 to 12 mm in length. Females are longer (7 to 17 mm in length) and slender. Adult *S. mansoni* reside in the venous plexuses of the colon and lower ileum and in the portal system of the liver of their host. (Courtesy Division of Parasitic Diseases/Centers for Disease Control and Prevention.)

Reports have indicated that *S. haematobium* is capable of cross-breeding with other species. This phenomenon has been identified between *S. haematobium* and *S. bovis,* as well as between *S. guineensis* and *S. intercalatum.* This is important when considering epidemiology and identification of these parasites

Pathology and Spectrum of Disease

Infection with only a small number of worms may be asymptomatic. A variety of species cause acute toxemic schistosomiasis resembling serum sickness. *S. japonicum* causes significant hepatointestinal disease resulting in portal hypertension and splenic and hepatic enlargement. *S. intercalatum* is primarily associated with rectal schistosomiasis in regions of Africa. *S. haematobium* is the only species that causes urinary schistosomiasis. Quite often, penetration of the skin by cercariae causes localized swelling and itching (cercarial dermatitis). The migration of the larvae through the body may cause transient symptoms of fever, malaise, cough (when they migrate in the lungs), or hepatitis (when in the liver). The adults are able to acquire some host antigens on their outer surface, and so may not elicit an immune response, although the eosinophil count



• **Fig. 57.2** (A) *Schistosoma mansoni* adult female; note the long pointed end (400× total magnification). (B) *Schistosoma mansoni* adult male. Males are shorter and wider to accommodate the insertion of the female during copulation. (400× total magnification.)

may be high. Severe tissue damage, with associated pain, fever, and chills, may occur when the eggs travel through tissue to reach the intestines or bladder. There may also be bloody diarrhea or blood in the urine (hematuria). Necrosis, lesions, and granulomas may develop, as well as obstruction of the bowel or ureters. Urinary schistosomiasis may give rise to calcifications in the bladder and renal failure. *S. intercalatum* and *S. guineensis* tend to produce milder symptoms. Eggs are primarily deposited in the colon, resulting in blood and mucus in the stool.

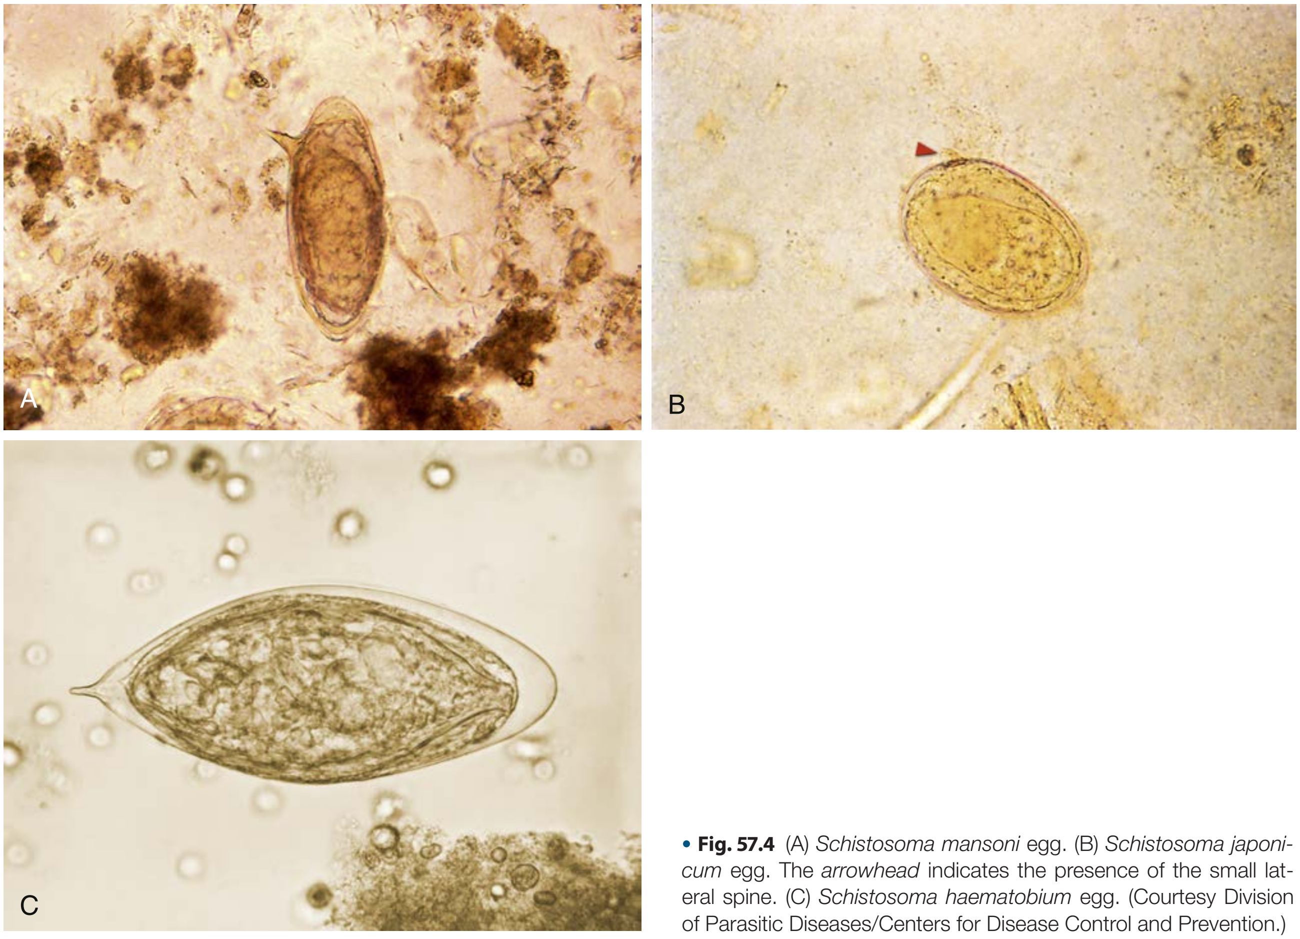
TABLE 57.1 **Diagnostic Characteristics of the Blood Trematodes**

Blood Trematode	Adult Location	Size of Egg	Description of Egg
Schistosoma haematobium	Veins surrounding bladder	110–170 µm × 40–70 µm	Pointed terminal spine, no operculum, embryonated
Schistosoma intercalatum/guineensis	Venules of colon	140–240 µm × 50–85 µm	Resembles egg of *S. haematobium,* but acid-fast positive
Schistosoma japonicum	Venules of small intestine	70–100 µm × 50–65 µm	Small lateral spine, no operculum, embryonated
Schistosoma mansoni	Venules of large intestine	115–180 µm × 40–75 µm	Large lateral spine, no operculum, embryonated
Schistosoma mekongi	Venules of small intestine	50–65 µm × 30–55 µm	Resembles egg of *S. mansoni,* but much smaller



• Fig. 57.4 (A) *Schistosoma mansoni* egg. (B) *Schistosoma japonicum* egg. The *arrowhead* indicates the presence of the small lateral spine. (C) *Schistosoma haematobium* egg. (Courtesy Division of Parasitic Diseases/Centers for Disease Control and Prevention.)

Penetration of human skin by the cercariae of blood flukes that commonly infect other mammals or aquatic birds may cause a schistosomal dermatitis known as "swimmer's itch." Erythema, edema, and intense itching may develop that usually disappear within 1 week. The cercariae of these species are not able to complete their life cycle by entering the human bloodstream and are destroyed by the host immune system.

Laboratory Diagnosis

The standard method of diagnosis is by the detection of characteristic eggs in feces or rectal biopsy for *S. japonicum, S. mekongi, S. mansoni, S. intercalatum,* and *S. guineensis* (and perhaps *S. haematobium* if these worms have migrated to a bladder vein that is close to the intestine) and in urine (usually concentrated before examination) or bladder tissue biopsy for *S. haematobium.* A wet mount with or without iodine from a sedimentation or concentration method can be examined for eggs. Fig. 57.4A–C provides images of three different schistosome eggs. To optimize recovery of *S. haematobium* in urine, the specimen should be collected between noon and 2 p.m.

Antigen Detection

Two circulating schistosome antigens, the anodic and cathodic antigens, can be detected in the urine of patients with schistosomiasis. A lateral flow rapid detection kit is available for the circulating cathodic antigen and is commercially available. This rapid diagnostic test (RDT) has been used widely in Africa and Brazil but is not FDA approved. Another flow assay is under development for the detection of *S. japonicum* and *S. haematobium.*

Serologic Testing

There are serologic assays that are available for diagnosis of schistosomal IgG antibody (enzyme immunoassay [EIA], enzyme-linked immunosorbent assay [ELISA], and immunoblot), but these methods cannot distinguish between current and previous infections. This type of assay may, however, be useful for travelers who have returned from endemic areas. These assays lack sensitivity and specificity during the early stages of disease, or for detecting persistence of antibodies after treatment for schistosomiasis. These assays are performed at the Division of Parasitic Disease at the Centers for Disease Control and Prevention (CDC) and may be available at some private reference laboratories.

Several nucleic acid–based methods have been developed that demonstrate high sensitivity and specificity using genomic or mitochondrial sequences. In addition, schistosome DNA has been identified in plasma using real-time polymerase chain reaction (PCR). Generally, an etiological method or a simple PCR method cannot distinguish between the species of *Schistosoma*. Repetitive sequences utilizing nested PCR to identify genes located within the parasitic chromosomes aid in detecting schistosomiasis. Various highly repetitive sequences have been successfully used to identify schistosomiasis: *SjR2* for *S. japonicum*, *SM1-7* for *S. mansoni*, and the *Dra I* for *S. haematobium.* In addition, the ribosomal RNA sequences are highly repetitive and conserved in the DNA of schistosomes. Both the 18S and 28S rDNA sequences have been used to detect parasite-derived DNA in fecal, serum, and urine samples in either monoplex or multiplex real-time PCR assays.

Eukaryotic organisms, such as schistosomes, contain mitochondria in their cells. Mitochondria contain their own circular DNA molecule and replicate independently of the cell nucleus in a eukaryotic cell. A novel real-time PCR technique was developed that can identify the nicotinamide adenine dinucleotide hydrogen (NADH) 1 and 2, *nad1* and *nad2*, specific for *S. japonicum*. This method successfully identified *S. japonicum* DNA in human stool samples with low-intensity infections. Another PCR assay has been used to detect the *nad3* in urine samples of patients infected with schistosomes. This approach can accurately differentiate *S. haematobium* from other schistosomes. Additional genes commonly used for identification of *S. japonicum* and *S. mansoni* include *cox2* and *nad6*. A multiplex PCR assay for the cytochrome C oxidase subunit I, *cox1*, of several human schistosomes was developed that can differentiate *S. mansoni, S. haematobium*, *S. japonicum*, and *S. mekongi* infections.

Nucleic acid–based tests are highly sensitive and specific; however, costs associated with instrumentation and reagents in endemic areas limit use. Improved methods and tools are needed for broad implementation. Recent reports have shown that loop-mediated isothermal amplification (LAMP), a highly sensitive amplification technique that does not require thermal cycling (and its associated costs and equipment), can detect parasite DNA in a variety of platyhelminth- and nematode-infected hosts, including those with schistosome infections.

Therapy

The drug of choice for treatment of schistosome infections is praziquantel, given in two or three doses daily.

Prevention

Because human infection is through direct penetration by the cercariae, prevention of schistosome infection is more difficult to achieve. Educational programs are required to help people in endemic areas understand how to help prevent infection. Sanitary conditions need to be improved, with proper disposal not only of human waste but also that of domestic animals (in areas with *S. japonicum* and *S. mekongi*). A safe water supply for bathing and washing clothes is also necessary. Various snail control methods have been implemented in endemic regions, but these methods are very costly and would need to be repeated on a regular basis to have the desired effect.

CASE STUDY 57.1

An 18-year-old male had recently been on a 1-month long trip to Brazil with a group of volunteer workers, where he had enjoyed swimming in a nearby river with the local teenage volunteers. He complained of crampy abdominal pain and twice noticed a small amount of blood in his feces. A stool specimen was collected for ova and parasite examination. A blood specimen was also collected and sent to a clinical laboratory for testing. The results of the blood tests showed increased eosinophil and IgE levels. The parasite examination showed large (115 µm × 75 µm), inoperculate, oval eggs with large lateral spines.

Questions

1. What parasite is the probable cause of this infection?
2. Where in the human host would the adults of this parasite be found?
3. What recent activity of this patient is probably responsible for his infection?
4. What is the drug of choice for treatment of infection with this parasite?

Chapter Review

1. The mode of transmission of schistosomal infection is by:
  a. Ingestion of contaminated aquatic vegetation
  b. Direct penetration of the skin by cercariae
  c. Ingestion of raw fish
  d. Mosquito bite

2. A diagnostic characteristic of the egg of *S. mansoni* is:
  a. A large lateral spine
  b. No spine
  c. A pointed terminal spine
  d. A small lateral spine

3. Infection with *S. haematobium* may present with which of the following?
  a. Nausea
  b. Basophilia
  c. Hematuria
  d. Jaundice

4. The drug of choice for treatment of schistosome infections is:
  a. Metrifonate
  b. Praziquantel
  c. Bilarcil
  d. Niclosamide

5. Which of the following is a major contributing factor to infection with *S. japonicum*?
  a. Absence of animal reservoir hosts
  b. Easily controlled snail population
  c. Easily passed from person-to-person
  d. Large number of humans working in rice paddies

6. **Matching:** *Match the location in the body with the adult schistosome worm:*

______ *S. mansoni*
______ *S. haematobium*
______ *S. japonicum*
______ *S. mekongi*
______ *S. intercalatum*

a. veins surrounding the bladder
b. venules of the small intestine
c. venules of the large intestine
d. venules of the colon

58

Overview of Fungal Identification Methods and Strategies

OBJECTIVES

1. Define the terms mycology; saprophytic; dermatophyte; and polymorphic, dimorphic, and thermally dimorphic fungi.
2. Define and differentiate superficial, cutaneous, subcutaneous, and systemic mycoses, including the tissues involved.
3. Differentiate the colonial morphology of yeasts and filamentous fungi (molds).
4. Define and differentiate anamorph, teleomorph, and synanamorph.
5. Describe three ways in which fungi reproduce.
6. List the media used for optimal recovery of fungi, including their incubation requirements.
7. List the common antibacterial agents used in fungal media.
8. Explain and differentiate the characteristic colonial morphology of fungi, including topography (rugose, umbonate, verrucose), texture (cottony, velvety, glabrous, granular, wooly) and surface described (front, reverse).
9. Describe and differentiate the sexual and asexual reproduction of the *Ascomycota*.
10. Define and differentiate rapid, intermediate, and slow growth rates with regard to fungal reproduction and cultivation.
11. Describe the proper method of specimen collection for fungal cultures, including collection site, acceptability, processing, transport, and storage.
12. Give the advantages and disadvantages of using screw-capped culture tubes, compared with agar plates, in the laboratory.
13. Describe the chemical principle and methodologies used to identify fungi, including calcofluor white–potassium hydroxide preparations, hair perforation, cellophane (Scotch) tape preparations, saline/wet mounts, lactophenol cotton or aniline blue, potassium hydroxide, Gram stain, India ink, modified acid-fast stain, periodic acid–Schiff stain (PAS), Wright's stain, Papanicolaou stain, Grocott-Gomori methenamine silver (GMS), hematoxylin and eosin (H&E) stain, Masson-Fontana stain, tease mount, and microslide culture.

Mycology is a specialized discipline in the field of biology concerned with the study of fungi, including their taxonomy, environmental impact, and genetic and biochemical properties. These microorganisms are recognized as important causes of disease, from superficial infections to those that are life threatening and rapidly fatal. Because of the change in patient profiles, particularly the increase in immunocompromised individuals and the increased use of antifungals, a number of fungal species normally found in the environment have been recognized as important causes of human disease. In addition, the implementation of genome-sequencing technology and the ability to identify polymerase chain reaction (PCR)-generated amplicons from nonculturable clinical isolates continually identifies new organisms and increases the understanding of the diversity of fungal infections associated with human disease. It is estimated that more than one billion people worldwide suffer from fungal infections. The modern clinical laboratory, therefore, must provide methods for isolating and identifying the causes of fungal disease. Susceptibility testing of these isolates may also be necessary.

This chapter is designed to assist clinical laboratory professionals and microbiologists with the basics of diagnostic clinical mycology and is not considered inclusive. The field of clinical mycology is rapidly evolving with the implementation of new molecular methods for classification and identification. Therefore, it is often necessary to consult other references for more detailed information within this vast field of study.

Epidemiology

Fungal infections are an increasing threat to individuals. The number of nosocomial, health care–associated, and community-associated infections has increased dramatically. The major factors responsible for the increase in the number of fungal infections are alterations in the host, particularly the growing number of immunocompromised individuals and the increasing use of antifungal medications. Whether associated with the use of antifungal medications, immunosuppressive agents, or serious underlying diseases, these factors may lead to infection by organisms normally nonpathogenic or part of the patient's normal microbiota. These infections may occur in patients with debilitating diseases, such as progressive infection with the human immunodeficiency virus (HIV) or diabetes mellitus or in patients with impaired immunologic function resulting from corticosteroid or antimetabolite chemotherapy. Other common predisposing factors include complex surgical procedures and antibacterial therapy. More than 135,000 valid species of fungi exist, but it is estimated that the number of undiscovered species ranges from 1 to 10 million with about 1000 to 1500 new species identified annually. With the implementation of molecular technology, the number of clinically relevant fungi and pathogenic species will continue to grow. Many of these organisms normally live a **saprophytic** existence (living on dead or decayed organic matter) in nature and persist in the environment.

Fungal infections generally are not communicable in the usual sense, through person-to-person transmission. Humans become accidental hosts for fungi by inhaling spores or through the introduction of fungal elements into tissue by trauma. Except for disease caused by the dimorphic fungi, healthy individuals are relatively resistant to most infections caused by fungi. Classic infections are now appearing in new forms in patients, and the old "harmless" saprophytic molds are implicated in serious diseases. This ability of normally saprophytic fungi to cause disease in patients means that laboratories must be able to identify and report a wide array of fungi.

The primary fungal pathogens appear to have well-defined geographic locations. An example of this is the dimorphic fungi *Coccidioides* spp. *Coccidioides* is usually found only in the Southwest United States in the desert, northern Mexico, and Central America. Opportunistic pathogens such as *Candida* and *Aspergillus* spp. are found all over the world.

General Features of the Fungi

Fungi seen in the clinical laboratory generally can be categorized into two groups based on the appearance of the colonies formed. The **yeasts** are unicellular organisms (Chapter 62) and produce moist, creamy, opaque, or pasty colonies on media, whereas the **filamentous fungi** or **molds** produce multicellular structures (Chapters 59 and 60) and demonstrate fluffy, cottony, woolly, or powdery colonies. Several systemic fungal pathogens that exhibit either a yeast or yeastlike phase and filamentous forms are referred to as **dimorphic.** When dimorphism is temperature-dependent, the fungi are designated as **thermally dimorphic.** In general, these fungi produce a mold form in the environment or when cultured on routine artificial mycology agar at 25°C to 30°C and are yeastlike in tissue or when cultured on enriched artificial medium at 35°C to 37°C.

The medically important dimorphic fungi are *Histoplasma* sp., *Blastomyces* spp., *Coccidioides* spp., *Cokeromyces recurvatus, Emergomyces* spp., and *Paracoccidioides* spp. Additionally, some of the medically important yeasts, particularly the *Candida* species, may produce yeast forms, pseudohyphae, and/or true hyphae (Chapter 62). Fungi that have more than one independent form or spore stage in their life cycle are called **polymorphic** fungi. The polymorphic features of this group of organisms are not temperature dependent.

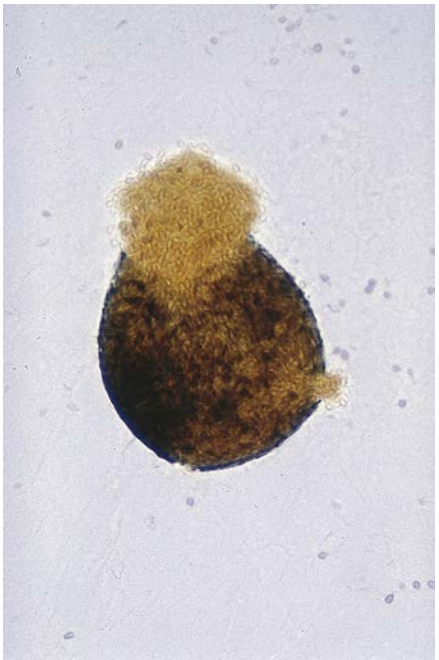
Taxonomy of the Fungi

Fungi are composed of a vast array of organisms that are unique compared with plants and animals. They are heterotrophic (saprophytic) and require preformed organic carbon for nutrition. Included among these are the mushrooms, rusts and smuts, molds and mildews, and yeasts. Despite their great variation in morphologic features, most fungi share the following characteristics:

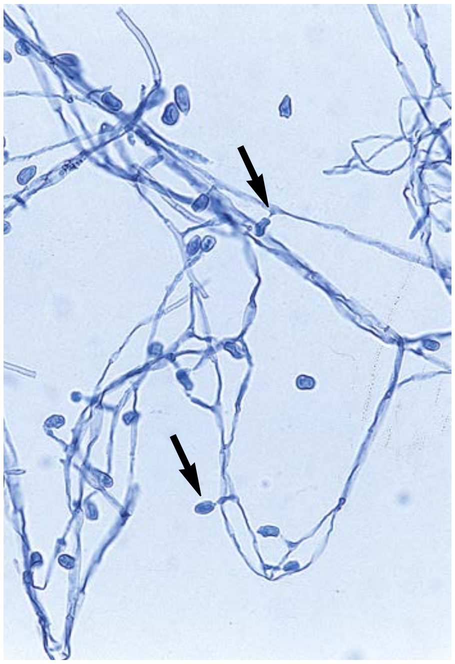
- Chitin in the cell wall
- Ergosterol in the cell membrane
- Reproduction by means of spores, produced asexually or sexually
- Lack of chlorophyll
- Lack of susceptibility to antibacterial antibiotics

Significant changes have resulted in the organization of the groups, taxonomy, and nomenclature within the fungi due to the introduction of molecular methods. Traditionally, the fungi have been categorized based on phenotypic traits, which vary based on temperature, atmospheric conditions, nutrient availability, and humidity, to name a few. Because of this variation, phenotypic classification is unclear, complex, and variable. Molecular analysis of these organisms, which includes extensive DNA sequencing, is now considered the gold standard to determine taxonomic designation and classification. In addition, fungal taxonomy has been complicated by fungi names that describe the sexual (**teleomorph**) or asexual (**anamorph**) stage. This system has become obsolete. The International Botanical Congress adopted a one-fungus, one-name policy, published in the International Code of Nomenclature, Article 59.

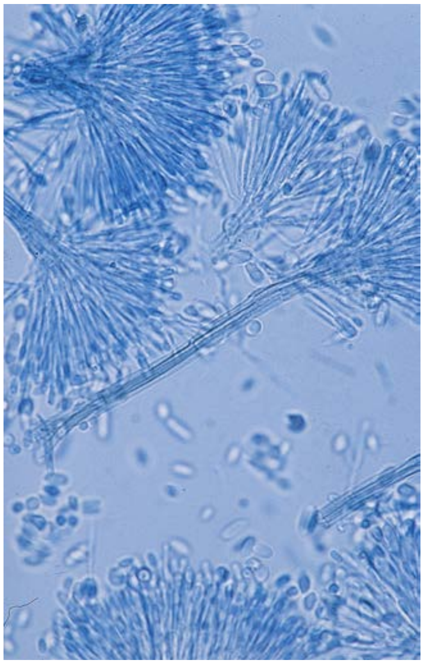
The implementation of DNA sequencing for the classification and taxonomy of fungi is not without challenges. As with other microorganisms, fungi have the ability to exchange genetic material and demonstrate evidence of recombination among populations, making speciation difficult. Currently, no standard exists that provides for a definition of the amount of genetic diversity that is allowable, or that limits the species level in taxonomy of fungi. Some clinically relevant fungi have been identified that include **molecular siblings.** A molecular sibling is an organism that cannot be distinguished based on phenotypic, metabolic, and clinical presentation but is recognized as a different



• **Fig. 58.1** A cleistothecium of *Pseudallescheria boydii* that has opened and is releasing numerous ascospores (×750).



• **Fig. 58.2** *Scedosporium apiospermum* showing asexually produced conidia borne singly on conidiophores (anellophores *[arrows]*) (×430).



• **Fig. 58.3** Anamorph form of *Pseudallescheria boydii* (×500).

species based on molecular analysis. Molecular siblings that do not differ in traditional characteristics, including disease presentation, are often considered a **species complex.** The use of the term "complex" does not hold any taxonomic relevance; it provides a system to limit organism identification within the clinical laboratory. Clinical laboratories may choose to report species complexes as preliminary identifications until further studies can be performed on the isolate, including antifungal susceptibility profiles when appropriate.

Historically, the fungi were categorized into three well-established phyla: Zygomycota, Ascomycota, and Basidiomycota. The previous phylum, Zygomycota, contained a very diverse group of organisms. Zygomycota has now been replaced with the subphyla Mucoromycotina and Entomophthoromycotina. The subphyla Mucoromycotina includes the order Mucorales and the genera *Lichtheimia, Mucor, Rhizomucor,* and *Rhizopus*; the Entomophthoromycotina, order Entomophthorales, includes the genera *Basidiobolus* and *Conidiobolus.* These two subphyla include organisms that produce **aseptate** or sparsely **septate hyphae** and exhibit asexual reproduction by **sporangiospores.** Some species may reproduce sexually and form **zygospores** in culture.

The Ascomycota include many fungi that reproduce asexually by the formation of **conidia** (asexual spores) and sexually by the production of **ascospores.** The filamentous ascomycetes are ubiquitous in nature and produce true septate hyphae. They may exhibit a sexual form (teleomorph) but also exist in an asexual form (anamorph) (Figs. 58.1 to 58.3). Fungi that have different asexual forms of the same fungus are called **synanamorphs**. An example of a clinically important fungus that belongs to the phylum Ascomycota is *Histoplasma capsulatum*. Numerous opportunistic fungi such as *Aspergillus,* the atypical fungi, *Pneumocystis*, and yeast such as the *Saccharomyces, Saprochaete*, and *Candida,* also belong to the Ascomycota.

The phylum Basidiomycota includes fungi that reproduce sexually through the formation of **basidiospores** on a specialized structure called the **basidia.** Medically relevant basidiomycetous yeasts include the genera *Cryptococcus, Malassezia, Pseudozyma, Rhodotorula, Sporobolomyces*, and *Trichosporon.* The filamentous Basidiomycetes are uncommon causes of human respiratory and systemic disease in immunocompetent and immunosuppressed patients and are poorly characterized. In addition, several organisms that are pathogenic to humans and have been classified as fungal or parafungal organisms that phenotypically resemble protozoans or yeast and remain unculturable are included in Chapter 61.

Clinical Classification of the Fungi

The complexity associated with the taxonomic classifications of fungi makes the identification of clinically relevant organisms to the species level inherently difficult. For clinicians, dividing the fungi into four categories of mycoses according to the type of infection in combination with macroscopic and microscopic characteristics is used to provide a systematic approach to identification. The clinical categories of fungi are separated as follows:

- **Superficial (cutaneous) mycoses**
- **Subcutaneous mycoses**
- **Systemic mycoses**
- **Opportunistic mycoses**

The superficial, or cutaneous, mycoses are fungal infections that involve hair, skin, or nails without direct invasion of deeper tissue. The fungi in this category include the dermatophytes (agents of ringworm, athlete's foot) and agents of infections such as tinea, tinea nigra, and piedra. All of these infect keratinized tissues.

Some fungi cause infections that are confined to the subcutaneous tissue without dissemination to distant sites. Examples of subcutaneous infections include chromoblastomycosis, mycetoma, and phaeohyphomycotic cysts (Chapter 60).

Some of the agents of systemic fungal infections include the genera *Blastomyces, Coccidioides, Histoplasma, Cokeromyces, Talaromyces, Sporothrix, Emergomyces,* and *Paracoccidioides.* Infections caused by most of these organisms involve the lungs but also may become widely disseminated and involve any organ system.

Any of the fungi could be considered an opportunistic pathogen in the appropriate clinical setting. The list of uncommon fungi found to cause disease in humans expands every year. Fungi previously thought to be nonpathogenic may be the cause of infections. The infections these organisms cause occur primarily in patients with some type of compromise of the immune system. This may occur secondary to an underlying disease process, such as diabetes mellitus, or prolonged use of an immunosuppressive agent. Although any fungus potentially can cause disease in these patients, the most commonly encountered genera in this group are *Aspergillus, Candida,* and *Cryptococcus,* among others. All of these organisms may cause disseminated (systemic) disease. Some of the dematiaceous fungi may cause deeply invasive phaeohyphomycoses (i.e., produce brown-pigmented structures) in this patient population.

Classification by type of infection allows the clinician to attempt to categorize organisms in a logical fashion into groups by clinical relevance. Table 58.1 presents an example of a classification of infections and their etiologic agents that is useful to clinicians.

The identification of organisms in clinical samples requires examination of the macroscopic and microscopic characteristics of the fungal culture. Although

TABLE 58.1 General Clinical Classification of Pathogenic Fungi

Cutaneous	Subcutaneous	Opportunistic	Systemic
Superficial mycoses	Chromoblastomycosis	Aspergillosis	Aspergillosis
Tinea	Sporotrichosis	Candidosis	Blastomycosis
Piedra	Mycetoma (eumycotic)	Cryptococcosis	Candidosis
Candidosis	Phaeohyphomycosis	Geotrichosis	Coccidioidomycosis
Dermatophytosis		Mucormycosis	Adiaspiromycosis
		Fusariosis	Emmonsiosis

			Sporotrichosis
			Pseudoallescheriosis/scedosporiosis
			Mucormycosis
			Entomophthoromycosis
			Fusariosis
			Trichosporonosis

[a] Virtually any fungus may cause disease including systemic infection in a profoundly immunocompromised host.

the macroscopic characteristics may be suggestive of particular genera of fungi, the microscopic characteristics tend to provide a more reliable method for identification. This requires a microscopic examination of the isolate for the appearance of hyphal elements, including the presence, absence, and number of septa. If the hyphae appear to be broad and predominantly **nonseptate** (i.e., cells are not separated by a septum or wall), Mucoromycetes, Basidiobolomycoses, or Entomophthoromycoses should be considered. If the hyphae are septate, they must be examined further for the presence or absence of pigmentation. If a dark pigment is present in the hyphae, the organism is considered to be **melanized** (dematiaceous), and the conidia are then examined for their morphologic features and their arrangement on the hyphae. If the hyphae are nonpigmented, they are considered to be **hyaline.** The fungi are then examined for the type and the arrangement of the conidia produced. The molds are identified by recognition of their characteristic microscopic features.

It is important that the clinical laboratory evaluate the isolation of a fungus from a clinical sample, because it may be regarded as a contaminant acquired during collection, transportation, processing, or incubation. It is important to consider that all contaminating fungi may be considered pathogenic in the appropriate clinical setting. Each isolate should be carefully evaluated on a case-by-case basis.

Pathogenesis and Spectrum of Disease

Fungal infection is caused by either primary pathogens or opportunistic pathogens. Infections caused by primary pathogens can occur in immunocompetent hosts, are not always as virulent, and may lead to subclinical disease. Opportunistic pathogens primarily infect immunocompromised hosts. Opportunistic pathogens include almost any fungus present in the environment. An increase in the identification of opportunistic fungal infections in humans is in large part a result of the immunocompromised nature of the host but also the increasing use of antifungals and improved diagnostic methods. In addition, organism-specific factors, called **virulence factors,** make invading tissues and causing disease easier. Some virulence factors include:

- The organism's size (with inhalation, the organism must be small enough to reach the alveoli)
- The organism's ability to grow at 37°C at a neutral pH
- Conversion of the dimorphic fungi from the mycelial (mold) form into the corresponding yeast or spherule form in the host
- Toxin production

Most of the fungi exist in environmental niches as saprophytic organisms (Table 58.2). Perhaps the fungi that cause disease in humans have developed various mechanisms that allow them to establish disease in the human host. Table 58.3 describes some of the known or speculative virulence factors of the fungi known to be pathogenic for humans.

Laboratory Diagnosis

Collection, Transport, and Culturing of Clinical Specimens

The diagnosis of fungal infections depends entirely on the selection and collection of an appropriate clinical specimen for microscopic analysis and culture. Many fungal infections are similar clinically to mycobacterial infections, and often the same specimen is cultured for both fungi and mycobacteria. If a fungal clinical infection is suspected, the sample should always be cultured on fungal media. If the specimen quantity is insufficient for microscopy and culture, the culture should be performed. Many infections have a primary focus in the lungs; respiratory tract secretions are usually included among the specimens selected for culture. It should be emphasized that dissemination to distant body sites may occur, and fungi may be recovered from nonrespiratory sites.

Proper collection of specimens and rapid transport to the clinical laboratory are crucial to the recovery of fungi. Specimens often contain not only the etiologic agent but also contaminating bacteria or fungi that rapidly overgrow some of the slower-growing pathogenic fungi. The viability of fungi decreases over time. Specimens should be processed within 2 hours of receipt. Most fungal specimens can be maintained at room temperature. If processing of intravascular catheter tips, other medical devices (stents, surgical implants, replacement joints, etc.), lower respiratory tract or urine specimens will be delayed, the samples can be refrigerated for a short time. Dermatologic specimens (skin, hair, nails) are very sensitive to cold temperatures. Yeasts (e.g., *Candida* spp.) commonly are recovered on routine bacteriology media and fungal culture media. A few specific comments concerning specimen collection and culturing are discussed later in this chapter. Additional information on specimen collection is included in Table 5.1.

Lower Respiratory Tract Secretions

Respiratory tract secretions (sputum, induced sputum, bronchial washings, bronchoalveolar lavage, and tracheal aspirations) are perhaps the most common specimens collected for fungal culture. Viscous lower respiratory tract specimens should be pretreated with a mucolytic agent and concentrated by centrifugation. The sediment should then be plated to media without antibiotic and a media containing antibacterial antibiotics to prevent overgrowth by contaminants and ensure optimal recover of fungi. The antifungal agent cycloheximide prevents overgrowth by rapidly growing molds and should be included in at least one of the culture media. As much specimen as possible (0.5 mL) should be used to inoculate each medium. Two fungal organisms commonly isolated from cystic fibrosis (CF) patients include *Candida* spp. and *Scedosporium* spp. Therefore, it is recommended that selective and differential chromogenic medium for the isolation of *Candida* spp. and *Scedosporium*-selective medium containing antifungal

TABLE 58.2 **Summary of Common Pathogens**

Organism	Natural Habitat	Infectious Form	Mode of Transmission	Common Sites of Infection	Clinical Form
Aspergillus spp.	Ubiquitous, plants	Conidia	Inhalation	Lungs, eyes, skin, nails	Hyphae
Blastomyces spp.	Unknown, possibly soil/wood in moist areas	Probably conidia	Usually inhalation	Lungs, skin, long bones	Yeast
Candida spp.	Human microbiota	Yeast, pseudohyphae, and true hyphae	Direct invasion/dissemination	GI and GU tracts, nails, viscera, blood	Yeast, pseudohyphae, and true hyphae
Coccidioides spp.	Soil of many arid regions	Arthroconidia	Inhalation	Lungs, skin, meninges	Spherules, endospores
Cryptococcus spp.	Bird feces, soil	Yeast[a]	Inhalation	Lungs, skin, meninges	Yeast
Histoplasma capsulatum	Bat and bird feces	Conidia	Inhalation	Lungs, bone marrow, blood	Yeast
Paracoccidioides spp.	Possibly soil, plants	Conidia	Inhalation/trauma	Lungs, skin, mucous membranes	Yeast
Sporothrix spp.	Soil, plants	Conidia/hyphae	Trauma/rarely inhalation	Skin and lymphatics, lungs, meninges	Yeast
Dermatophytes	Human disease, animals, soil	Conidia/hyphae	Contact	Skin, hair, or nails	Hyphae

[a] Possibly the conidia of the teleomorphic stage.
GI, Gastrointestinal; *GU*, genitourinary.

agents dicloran and benomyl should be added to respiratory cultures of CF patients to improve the isolation of these organisms. Specimens may be stored at room temperature if processing is completed within 2 hours; if processing is delayed, specimens should be refrigerated at 4°C.

Sterile Body Fluids Including Cerebrospinal Fluid

Most sterile body fluids are generally collected in heparin blood tubes to prevent clotting. Lysis centrifugation tubes may also be used for the collection of sterile body fluids. Cerebrospinal fluid lumbar puncture tubes collected for culture should be concentrated by centrifugation and the concentrated sediment used to inoculate the culture medium. Cultures should be examined daily. It is recommended that ≥2 mL of specimen should be centrifuged and up to 0.5 mL of sample be inoculated onto each type of fungal culture medium. If less than 1 mL of specimen is submitted for culture, following centrifugation, 1-drop aliquots of the sediment should be placed on several areas on the agar surface. Many laboratories utilize screw-cap tubes containing slants or culture vials to avoid contamination of fungal cultures. Media used for the recovery of fungi from sterile fluids should contain no antibacterial or antifungal agents. *Cryptococcus* spp., a pathogenic encapsulated yeast associated with meningitis, is inhibited by the antifungal agent cycloheximide.

Once submitted to the laboratory, sterile body fluid specimens should be processed promptly. If prompt processing is not possible, samples should be kept at room temperature. Sterile body fluid specimens should never be refrigerated.

Blood and Bone Marrow

Disseminated fungal infections are a major cause of morbidity and mortality in hospitalized patients, and blood cultures provide an accurate method for determining the cause in many instances. Currently several automated blood culture systems that utilize fungal medium modifications for the isolation of fungi, including the BACTEC (Becton Dickinson, Sparks, MD), BacT/ALERT 3D (bioMérieux, Durham, NC), and VersaTREK (Thermo Scientific, Oakwood Village, OH), are adequate systems for the recovery of yeasts, except *Malassezia* spp.

Laboratories that frequently recover dimorphic fungi and molds from blood or bone marrow are encouraged to use the lysis-centrifugation system, the Isolator. A heparinized syringe or pediatric Isolator tube

TABLE 58.3 **Virulence Factors of Medically Important Fungi**

Fungal Pathogen	Putative Virulence Factor
Aspergillus spp.	Elastase-serine protease Proteases Toxins (gliotoxin, fumagillin, helvolic acid) Elastase-metalloprotease Aspartic acid proteinase Aflatoxin Catalase Lysine biosynthesis *p*-aminobenzoic acid synthesis
Blastomyces spp.	Cell wall alpha-1,3-glucan BAD-1 an adhesion and immune modulator
Coccidioides spp.	Extracellular proteinases
Cryptococcus spp.	Capsule Phenoloxidase melanin synthesis Varietal differences
Dematiaceous fungi	Phenoloxidase melanin synthesis
Histoplasma capsulatum	Cell wall alpha-1,3-glucan Intracellular growth Thermotolerance CBP, binds calcium
Paracoccidioides spp.	Estrogen-binding proteins Cell wall components Beta-glucan Alpha-1,3-glucan
Sporothrix spp.	Thermotolerance Extracellular enzymes

is recommended for the collection of bone marrow samples. The Isolator has been proven optimal for the recovery of *H. capsulatum* and other filamentous fungi. Special automated fungal media such as the BACTEC MYCO/F lytic medium or BacT/ALERT media may also be used for the isolation of filamentous molds from blood samples. With this system, red blood cells and white blood cells, which may contain the microorganisms, are lysed, and centrifugation concentrates the organisms before culturing. The concentrate is inoculated onto the surface of appropriate culture media, and most fungi are detected within the first 4 days of incubation. However, occasional isolates of *H. capsulatum* may require approximately 10 to 14 days for recovery. In addition to the lysis-centrifugation system, special automated fungal media such as the BACTEC MYCO/F lytic medium or BacT/ALERT media may also be used for the isolation of filamentous molds to improve the recovery from blood. Bone marrow samples should not be placed in automated blood culture media. The optimal temperature for fungal blood cultures is 30°C, and the suggested incubation time is 21 days.

Eye (Corneal Scrapings or Vitreous Humor)

Corneal scrapings collected by a physician should be placed directly onto microscopic slides and inoculated onto noninhibitory media such as Sabouraud dextrose agar, in either an X- or C-shaped pattern. Vitreous humor aspiration should be concentrated by centrifugation, similar to processing a cerebrospinal fluid (CSF) sample, and the sediment should be used for smears and culture. Specimens should be inoculated onto a noninhibitory media, inhibitory mold agar, and brain-heart infusion (BHI) agar with 10% sheep blood. Samples should be processed as soon as possible and stored at room temperature. Media containing cycloheximide should be avoided to prevent inhibition of potential isolates.

Hair, Skin, and Nail Scrapings

Specimens of hair, skin scrapings or biopsies, and nail clippings are usually submitted for dermatophyte culture and are contaminated with bacteria or rapidly growing fungi or both. Samples collected from lesions may be obtained by scraping the skin or nails with a scalpel blade or microscope slide; infected hairs are removed by plucking them with forceps. Only the leading edge of skin lesions should be sampled, because the centers often contain nonviable organisms. These specimens should be placed in a sterile container; they should not be refrigerated. Hair samples may be cut into 1 mm pieces and applied to the medium using a sterile forceps. Skin and nail samples should be cut into smaller pieces, placed on the medium using a sterile forceps and pressed slightly into the agar. **Mycosel agar,** which contains chloramphenicol and cycloheximide, is satisfactory for the recovery of dermatophytes. If infection with *Malassezia furfur* is suspected, olive oil or an olive oil–saturated paper disk should be placed in the first quadrant of the agar plate. Cultures should be incubated for a minimum of 21 days at 30°C before being reported as negative.

Vaginal

Candida spp. are considered normal vaginal flora, and therefore, identification without symptoms is not significant. Vaginal lesions may also be present with histoplasmosis or paracoccidioidomycosis. Vaginal samples should be transported to the laboratory within 24 hours of collection using culture transport swabs. Swabs should be kept moist in sterile tubes. This method of collection provides a specimen suitable for a wet preparation. Both selective and inhibitory agars should be plated. Vaginal cultures should be screened for yeasts using chromogenic agars for *Candida* spp.

Urine

First morning, clean-catch, suprapubic or direct catheterized urine samples are recommended for fungal culture. Urine samples should be processed as soon after collection as possible. The 24-hour urine and Foley catheter samples are unacceptable for culture. Quantitative cultures are not useful. All urine samples should be centrifuged and the sediment cultured using a loop to provide adequate isolation of colonies. Because urine often is contaminated with gram-negative bacteria, media containing antibacterial agents must be used to ensure the recovery of fungi. If processing is completed within 2 hours, samples may remain at room temperature. However, if processing is delayed, specimens should be refrigerated at 4°C. If a urine transport system is used, samples may be stored at room temperature for up to 72 hours.

Tissue

All tissues should be processed before culturing by mincing; it is critical not to grind them. Grinding will disrupt, and may damage, a fungal isolate resulting in no growth; except when *H. capsulatum* is suspected. This pathogen is intracellular, requiring homogenization to release the fungal cells to ensure growth. Tissue pieces should be pressed into the appropriate culture media or partially embedded to provide an oxygen tension gradient, and the cultures should be incubated at 30°C for 21 days (incubation may be extended if clinical suspicion of a mycotic disease is high).

Culture Media and Incubation Requirements

A number of fungal culture media are satisfactory for use in the clinical microbiology laboratory (Table 58.4). Most are adequate for the recovery of fungi. For optimal recovery, a battery of media should be used; the following are recommended:

- Media with and without cycloheximide to prevent the overgrowth of slow-growing fungi by more rapidly growing species. It is important to note that cycloheximide may also be inhibitory to some fungi.
- Media with and without an antibacterial agent (media with an antibacterial agent are used for specimens likely to contain contaminating bacteria; they are not necessary for specimens from sterile sites).
- Inhibitory agar controls bacterial contamination more effectively than Sabouraud dextrose agar.
- Chloramphenicol is an inhibitory agent for the growth of contaminating bacteria; however, it is important to note that it is also inhibitory to *Nocardia* and other aerobic actinomycetes.
- Growth of dimorphic fungi is enhanced on enriched media such as BHI containing antibiotics and 5% to 10% sheep blood. This enhances growth but inhibits sporulation. Once isolated, the fungi should be immediately subcultured to blood-free enriched media for identification.
- Birdseed agar may be used for the cultivation of *Cryptococcus* spp. from CSF, pleural fluid, bone marrow, tissue, and lower respiratory specimens.
- Specific chromogenic agar may be used to identify some species of yeast.
- Additional specialized media may be required for additional fungal isolates that have unique nutritional or incubation requirements.

Agar plates (petri dishes), rectangle agar vials, or screw-capped agar tubes are satisfactory for the recovery of fungi; however, plates or vials are preferred, because they provide better aeration of cultures and a large surface area for better isolation of colonies. Agar plates provide greater ease of handling by laboratory professionals when making microscopic preparations for examination. Agar tends to dehydrate during the extended incubation period required for fungal recovery, but this problem can be minimized by using agar plates or vials containing at least 40 mL of agar and placing them in a humidified incubator. Agar plates should be opened and examined in a certified biologic safety cabinet (BSC). Many laboratories discourage the use of agar plates because of safety considerations; however, the advantages outweigh the disadvantages.

Compared with agar plates, screw-capped culture tubes are more easily stored, require less space for incubation, and are easily handled. In addition, they have a lower dehydration rate, and most laboratory workers believe cultures are less hazardous to handle when in tubes. However, disadvantages, such as relatively poor isolation of colonies, a reduced surface area for culturing, and a tendency to promote anaerobiosis, discourage routine use in most clinical microbiology laboratories. If culture tubes are used, the tube should be as large as possible to provide an adequate surface area for isolation. After inoculation, tubes should be placed in a horizontal position for at least 1 to 2 hours to allow the specimen to absorb to the agar surface and prevent settling at the bottom of the tube.

Cultures should be incubated at room temperature, or preferably at 30°C, for 21 to 30 days before they are reported as negative. A relative humidity in the range of 40% to 50% can be achieved by placing an open pan of water in the incubator. Cultures should be examined at least three times weekly during incubation.

As previously mentioned some clinical specimens are contaminated with bacteria or rapidly growing fungi or both, requiring the use of antifungal and antibacterial agents. The addition of 0.5 μg/mL of cycloheximide and 16 μg/mL of chloramphenicol to media traditionally has been advocated to inhibit the growth of contaminating molds and bacteria, respectively. However, better results have been achieved using a combination of 5 μg/mL of gentamicin and 16 μg/mL of chloramphenicol as antibacterial agents. Ciprofloxacin at a concentration of 5 μg/mL may be used.

Cycloheximide may be added to any of the media that contain or lack antibacterial antibiotics. However, if cycloheximide is included in the battery of culture media, a medium lacking this ingredient should also be included. Pathogenic fungi, such as *Cryptococcus* spp., *Candida krusei* and other *Candida* spp., *Trichosporon* spp., *P. boydii,* and *Aspergillus* spp., are partially or completely inhibited by cycloheximide.

Direct Microscopic Examination

Direct microscopic examination of clinical specimens has been used for many years; however, its usefulness should be reemphasized. Because the mission of a clinical microbiology laboratory is to provide a rapid and accurate diagnosis, the mycology laboratory can provide this service in many cases by direct examination (particularly with the

TABLE 58.4 **Fungal Culture Media: Indications for Use**

Media	Indications for Use	Media Composition	Mode of Action
Primary Recovery Media			
Brain-heart infusion agar	Primary recovery of saprobic and pathogenic fungi	Brain-heart infusion, enzymatic digest of animal tissue, enzymatic digest of casein, dextrose, sodium chloride	The agar provides a rich medium for bacteria, yeast, and pathogenic fungi.
Brain-heart infusion agar (fungal formulation) with antibiotics	Primary recovery of pathogenic fungi exclusive of dermatophytes	Brain-heart infusion, enzymatic digest of animal tissue, enzymatic digest of casein, dextrose, sodium chloride, 10% sheep blood, antibiotics (chloramphenicol, cycloheximide, and gentamicin)	The agar provides a rich medium for yeast and pathogenic fungi, including systemic dimorphic fungi.
Chromogenic agar	Isolation and presumptive identification of yeast and filamentous fungi	Chromopeptone Glucose Chromogen mix Chloramphenicol	Chromogen mix contains substrates that react with enzymes produced by different organisms that result in the production of characteristic color changes.
Dermatophyte test medium	Primary recovery of dermatophytes; recommended as screening medium	Soy, peptone, dextrose, cycloheximide, gentamicin, chloramphenicol, phenol red	Dermatophytes produce alkaline metabolites, which raise the pH and change the medium from red to yellow.
Inhibitory mold agar	Primary recovery of pathogenic, cycloheximide sensitive fungi exclusive of dermatophytes	Chloramphenicol, casein, dextrose, starch, sodium phosphate, magnesium sulfate, sodium chloride, manganese sulfate	Examine plates for growth. Chloramphenicol inhibits bacterial growth.
Potato flake agar	Primary recovery of saprobic and pathogenic fungi and the stimulation of conidia formation.	Potato flakes, glucose, cycloheximide, chloramphenicol, bromthymol blue	Growth is enhanced by a pH alkaline reaction of fungus. Chloramphenicol and antibiotics inhibit the growth of bacteria and nonpathogenic fungi.
Mycobiotic or mycosel agar	Primary recovery of dermatophytes but may also be used for the recovery of other pathogenic fungi.	Pancreatic digest of soybean meal and dextrose with cycloheximide, chloramphenicol.	Inhibits bacteria and saprophytic fungi
Sabouraud dextrose with brain-heart infusion (SABHI) agar	Primary recovery of saprobic and pathogenic fungi	Sabouraud dextrose, brain-heart infusion agar. With chloramphenicol, cycloheximide, penicillin, and/or streptomycin. 10% sheep blood may be added.	Isolates and enhances growth of all fungi including the yeast phase of dimorphic fungi.
Yeast-extract phosphate agar with ammonia	Primary recovery of pathogenic fungi exclusive of dermatophytes	Yeast extract, dipotassium phosphate, chloramphenicol. 1 drop of ammonium hydroxide is applied to the agar surface prior to inoculation and allowed to diffuse into the medium.	Enhances the recovery and sporulation of *Blastomyces* and *Histoplasma capsulatum* from contaminated specimens
Differential Test Media			
Acetate Ascospore agar	Detection of ascospores in ascosporogenous yeasts (e.g., *Saccharomyces* spp.)	Potassium acetate, yeast extract, dextrose	Potassium acetate is necessary, and yeast extract increases the sporulation of yeasts.

Continued

TABLE 58.4 **Fungal Culture Media: Indications for Use—cont'd**

Media	Indications for Use	Media Composition	Mode of Action
Christensen's urea agar	Identification of *Cryptococcus, Trichosporon*, and *Rhodotorula* spp. Separation of *Trichophyton mentagrophytes* from *Trichophyton rubrum*	2% urea, phenol red	Produces urease and a change in the pH.
Cornmeal agar with Tween 80 and trypan blue	Differentiation of *Candida* spp. by chlamydospore production	Cornmeal, Tween 80, cornmeal infusion, and trypan blue	Addition of Tween 80 enhances the production of chlamydospores, pseudohyphal and arthrospore formation. The addition of trypan blue provides a contrasting background for observing the morphologic features of yeasts.
Czapek's agar	Differential identification of *Aspergillus* spp.	Sodium nitrate, sucrose, yeast extract	Produces characteristic features of yeast and fungus of any organism that can use sodium nitrate.
Niger seed agar (birdseed agar)	Identification of *Cryptococcus* spp., particularly *Cryptococcus neoformans* and *Cryptococcus gattii*	*Guizotia abyssinica* seeds or niger seeds, dextrose, creatinine, chloramphenicol	*C. neoformans* and *C. gattii* produce the enzyme phenol oxidase, resulting in a brown pigment through metabolism of caffeic acid. Creatinine enhances the melanization of some strains of *C. neoformans.*
Potato dextrose agar	Demonstration of conidia formation and the pigment production by *Trichophyton rubrum;* preparation of microslide cultures and sporulation of dermatophytes	Potato infusion, dextrose, tartaric acid **Note:** Some laboratories use potato flake agar, because it may be more stable.	Carbohydrate and potato infusion promotes the growth of yeasts and molds, and the low pH (tartaric acid) partially inhibits bacterial growth.
Trichophyton agars 1–7	Identification of *Trichophyton* spp.	Dextrose, monopotassium phosphate, magnesium sulfate, amino acids 1. Casamino acids; vitamin free 2. Casamino acids plus inositol 3. Casamino acids plus inositol and thiamine 4. Casamino acids plus thiamine 5. Casamino acids plus niacin 6. Ammonium nitrate 7. Ammonium nitrate plus histidine	*Trichophyton* spp. may be differentiated by growth in the presence of different amino acids.
Yeast fermentation broth	Identification of yeasts by determining fermentation	Yeast extract, peptone, bromcresol purple, and a specific carbohydrate (e.g., dextrose, maltose, sucrose)	Most yeasts produce acid, which is indicated by a change in the solution from purple to yellow as a positive fermenter.
Yeast nitrogen-base agar	Identification of yeasts by determining carbohydrate assimilation	Ammonium sulfate, carbon source (e.g., glucose, sucrose, raffinose)	Assimilation of carbon by yeast cells produces a positive result.

Gram stain) of the clinical specimen submitted for culture. Microbiologists are encouraged to become familiar with the diagnostic features of fungi commonly encountered in clinical specimens and to recognize them when stained by various dyes. This important procedure often can provide the first microbiologic proof of the cause of disease in patients with fungal infection and guide the selection of appropriate media to support growth.

Tables 58.5 and 58.6 present the methods available for direct microscopic detection of fungi in clinical specimens and a summary of the characteristic microscopic features of each. Fig. 58.4 presents photomicrographs of some of the fungi commonly seen in clinical specimens.

Traditionally the potassium hydroxide preparation has been the recommended method for direct microscopic examination of specimens in dermatological samples. Calcofluor white (CW) (Evolve Procedure 58.1) and lactophenol blue (LPCB) bind specifically to polysaccharides, chitin, and cellulose present in fungal cell walls. In addition, LPCB contains lactic acid that aids in the preservation of fungal structures and phenol that acts as a killing agent. Slides prepared using these methods may be observed using fluorescent (CW) or bright-field microscopy (LPCB).

Serologic Testing

Molecular diagnostics may eventually replace the use of serologic testing for the diagnosis of fungal infections. These methods currently lack standardization for performance when taken directly from patient specimens. No commercially available procedures exist for serologic testing of most fungi. However, serology testing is a useful tool for the diagnosis of invasive fungal infections with select organisms, such as *Cryptococcus, Coccidioides, Blastomyces, Histoplasma,* and *Aspergillus* spp.

Antibody testing has proven useful but not for immunocompromised patients, who are incapable of producing a measurable humoral response. Acute and convalescent titers need to be monitored during treatment of the fungal infection.

Immunodiffusion testing is a simple, cost-effective procedure. Although it is 100% specific, it is relatively insensitive and is not used as a screening tool. This test also requires 2 to 3 weeks to exhibit a positive result.

Enzyme immunoassays for both antibody and antigen have been used. These tests are also commonly negative in immunocompromised patients, especially early in the infection.

Point-of-care (POC) testing using lateral flow assay-based devices have the potential to improve the diagnosis of fungal infections, especially in developing countries with limited laboratory resources. POC devices generally are inexpensive and portable while providing rapid and reproducible results that are highly sensitive and specific. Undoubtedly, the development of these devices will be useful in monitoring and detecting fungal antibodies.

(1,3)-β-D-Glucan Detection

(1,3)-β-D-Glucan, a polysaccharide present in the cell wall of some fungi, is found in the blood of patients that have invasive fungal infections. Although detection of the polysaccharide has demonstrated success in the diagnosis and monitoring of fungal meningitis, variation in assay sensitivity and specificity, along with the need for what are considered significant levels in the blood of a patient with fungal infections, indicates further studies are necessary.

Molecular Methods

Phenotypic and biochemical identification methods are extremely time-consuming for the identification of fungal pathogens. One of the most critical risk factors associated with mortality from systemic mycoses is the time to diagnosis, making molecular detection methods ideal in the clinical laboratory. In addition to diagnosis, drug resistance among invasive *Candida* and *Cryptococcus* spp. has increased, requiring the development of new assays to detect drug resistance. Ideally, a molecular direct hybridization assay or amplification assay panel of primers specific for the detection of fungi in clinical specimens would include the most common organisms known to cause disease in immunocompromised patients (including the dimorphic fungi and *Pneumocystis* spp.). The current literature contains references to all of the major human fungal pathogens, describing species and strain-specific primers and probes, yet no commercial methods are available to the clinical laboratory. Sequence-based molecular identification of fungal isolates is a useful diagnostic tool and has resulted in the development of commercial diagnostic assays such as the MicroSEQ D2 rDNA Fungal Sequencing Kit (Thermo Fisher, Grand Island, NY). Currently, DNA sequencing technology, including whole genome sequencing, remains confined to research and reference laboratories due to the large capital investment and expertise required for implementation.

Currently, a few FDA-cleared molecular diagnostic assays are available, which include amplification and hybridization techniques. These assays primarily focus on the identification of *Candida, Cryptococcus, Aspergillus* spp., and the systemic dimorphic fungi.

Matrix-Assisted Laser Desorption Ionization Mass Spectrometry

Matrix-assisted laser desorption ionization time-of-flight mass spectrometry (MALDI-TOF MS) is a biophysical method that significantly reduces the time required to specifically identify fungal organisms. The major disadvantage of this technique is the need to have pure cultures of the clinical isolates for sample preparation, adding days and weeks to the process. The protein profiles for fungi also vary significantly based on environmental and culture conditions, making standardization of the analytical process extremely difficult in fungal identification. The level of fungal organisms, such as yeast in the bloodstream and other clinical fluid samples is generally too low for direct detection by

TABLE 58.5 Summary of Methods Available for Direct Microscopic Detection of Fungi in Clinical Specimens

Method	Use	Time Required	Advantages	Disadvantages
Acid-fast stain and partial acid-fast stain	Detection of mycobacteria and *Nocardia* spp., respectively	12 min	Detects *Nocardia* spp.[a] and some isolates of *Blastomyces* spp.	Tissue homogenates are difficult to observe because of background staining.
Alcian blue or mucicarmine stain.	Mucopolysaccharide stains used to visualize the capsule of *Cryptococcus* spp. in histological tissue sections.	30 min	Detects encapsulated yeast in tissue sections	*Blastomyces dermatitidis* and *Rhinosporidium seeberi* may also react positively with this stain.
Auramine-rhodamine stain	Detection of mycobacteria and *Nocardia* spp., respectively	10 min	Excellent screening tool; sensitive and affordable.	Not as specific for acid-fast organisms as Ziehl-Neelsen stain.
Calcofluor white stain	Detection of fungi	1 min	Can be mixed with KOH; detects fungi rapidly because of bright fluorescence.	Requires use of a fluorescence microscope; background fluorescence prominent, but fungi exhibit more intense fluorescence; vaginal secretions are difficult to interpret. Nonspecific reactions may be observed, such as cotton fibers from swabs and brain tumor biopsies, both falsely resembling branching hyphae.
Gram stain	Detection of bacteria	3 min	Commonly performed on most clinical specimens submitted for bacteriology; detects most fungi.	Some fungi stain well, but others (e.g., *Cryptococcus* spp.) show only stippling and stain weakly in some instances; some isolates of *Nocardia* spp. fail to stain or stain weakly.
India ink (nigrosin) stain	Detection of *Cryptococcus* spp. in CSF	1 min	Diagnostic of meningitis when positive in CSF.	Positive in fewer than 50% of cases of meningitis; not sensitive in non–HIV-infected patients. Artifacts such as erythrocytes, leukocytes, and talc particles from gloves or bubbles may mimic yeast, resulting in false positives.
Lactophenol cotton (aniline) blue wet mount	Most widely used method of staining and observing fungi	1 min	Lactic acid and glycerol preserves structures; slides can be made permanent.	Mechanical treatment dislodges fungal structures.
Potassium hydroxide	Clearing of specimen using 10%–20% KOH to make fungi more readily visible	5 min; if clearing is not complete, an additional 5–10 min is necessary	Rapid detection of fungal elements. 0.1% thimerosal (Sigma Chemical Co.) may be added to preserve the specimen.	Requires experience, because background artifacts are often confusing; clearing of some specimens may require an extended time.
Masson-Fontana stain	Examination of melanin pigment in fungal cell walls	1 h, 10 min	Aids differentiation of melanin and hemosiderin pigments.	Difficult to interpret when only rare granular staining is present.

TABLE 58.5 **Summary of Methods Available for Direct Microscopic Detection of Fungi in Clinical Specimens—cont'd**

Method	Use	Time Required	Advantages	Disadvantages
Methenamine silver stain	Detection of fungi in histologic section	1 h	Best stain for detecting fungal elements (black) against a pale green or yellow background.	Requires a specialized staining method that is not usually readily available to microbiology laboratories.
Periodic acid–Schiff (PAS) stain	Detection of fungi	20 min; 5 min additional if counterstain is used	Stains fungal elements well; hyphae of molds and yeasts can be readily distinguished.	*Nocardia* spp. do not stain well. Time-consuming and has been replaced in many laboratories by calcofluor white staining procedures.
Toluidine blue O	Rapid detection of *P. jiroveci* from lung biopsy and BAL specimens.	1 min	Quickly performed, easy, rapid results, and cost-effective.	Trophozoites are not discernable.
Wright's stain	Examination of bone marrow or peripheral blood smears	7 min	Detects *Histoplasma capsulatum* and *Cryptococcus* spp.	Most often used to detect *H. capsulatum* and *Cryptococcus* spp. in disseminated disease.

[a] Partially acid-fast bacterium.
BAL, Bronchoalveolar lavage; *CSF*, cerebrospinal fluid; *HIV*, human immunodeficiency virus; *KOH*, potassium hydroxide.

MALDI-TOF MS. In addition, proteins and hemoglobin tend to interfere with the spectra analytics making identification problematic. Further clinical studies are needed prior to implementation of direct identification using MALDI-TOF MS for systemic fungal infections. An overview of the technique is discussed in more detail in Chapter 7.

General Considerations for the Identification of Yeasts

Most often yeasts are identified through the use of a combination of differential test media (Fig. 58.5). Identification factors and techniques include the following:

- Colonial morphologic features
- Microscopic morphologic features
- Physiologic studies
- Chromogenic agars (presumptive species identification)
- Rapid commercial yeast identification tests or panels
- Nucleic acid–based methods (direct hybridization or amplification methods)
- Matrix-assisted laser desorption/ionization time-of-flight mass spectroscopy (MALDI-TOF MS)

Several key characteristics can be seen macroscopically. Colonies have a wide variety of colors, shapes, and textures. Chromogenic agar or a combination of rapid tests can be used to differentiate some pathogenic yeast presumptively. Presumptive identification is indicated when the test or combination of tests do not identify characteristics that are unique to that species. The results of these tests must be correlated with the macroscopic and microscopic morphological characteristics and the site of infection (i.e., clinical specimen). Wet preps and lactophenol cotton blue stain can aid microscopic identification by improving the visualization of the fungal reproductive structures. Sexual and asexual characteristics are very important. Often a genus can be determined by the microscopic and macroscopic characteristics. India ink stain is useful when *Cryptococcus* spp. are suspected. Because carbon and nitrogen source differences are the key to differentiating yeasts, many automated and semiautomated commercial systems have been designed with assimilation and fermentation tests. Supplemental testing takes advantage of a limited set of characteristics to further aid identification.

The clinical microbiology laboratory has historically operated under the idea that if the identification of the isolate to the species level is incorrect, the patient will not be adversely affected once the susceptibility is completed. This is problematic, when the specific species identifications are used to determine minimum inhibitory concentrations and breakpoints for treatment for bacterial and fungal infections. Treatment failures, along with the increasing occurrence of resistance to echinocandins, fluconazole, and voriconazole, make accurate identification and susceptibility testing required. Molecular diagnostic techniques, proteomic and genomic, clearly demonstrate more accurate and reliable identification for yeasts than conventional biochemical methods. The use of these methods in the routine clinical laboratory is currently limited by the need for standardization and the expansion of the current databases.

TABLE 58.6 Summary of Characteristic Features of Select Fungi Seen in Direct Examination of Clinical Specimens

Morphologic Form Found in Specimens	Organism	Size Range (diameter, mm)	Characteristic Features
Yeastlike	*Histoplasma capsulatum*	2–5	Small; oval to round budding cells; often found clustered in histiocytes; difficult to detect when present in small numbers.
	Sporothrix spp.	2–6	Small; oval to round to cigar-shaped; single or multiple buds present; uncommonly seen in clinical specimens.
	Cryptococcus spp.	2–15	Cells exhibit great variation in size; usually spherical but may be football-shaped; buds single or multiple and "pinched off"; capsule may or may not be evident; occasionally, pseudohyphal forms with or without a capsule may be seen in exudates of cerebrospinal fluid.
	Malassezia furfur (in fungemia)	1.5–4.5	Small; bottle-shaped cells, buds separated from parent cell by a septum; emerge from a small collar.
	Blastomyces spp.	8–15	Cells are usually large, double refractile when present; buds usually single; however, several may remain attached to parent cells; buds connected by a broad base.
	Paracoccidioides spp.	5–60	Cells are usually large and are surrounded by smaller buds around the periphery ("mariner's wheel appearance"); smaller cells may be present (2–5 μm) and resemble *H. capsulatum*; buds have "pinched-off" appearance.
Spherules	*Coccidioides* spp.	10–200	Spherules vary in size; some may contain endospores, others may be empty; adjacent spherules may resemble *Blastomyces* spp.; endospores may resemble *H. capsulatum* but show no evidence of budding; spherules may produce multiple germ tubes if a direct preparation is kept in a moist chamber ≥24 h.
	Rhinosporidium seeberi (protozoan [parafungal] pathogen that is studied in mycology)	6–300	Large, thick-walled sporangia containing sporangiospores are present; mature sporangia are larger than spherules of *Coccidioides*; hyphae may be found in cavitary lesions.

TABLE 58.6 **Summary of Characteristic Features of Select Fungi Seen in Direct Examination of Clinical Specimens—cont'd**

Morphologic Form Found in Specimens	Organism	Size Range (diameter, mm)	Characteristic Features
Yeast and pseudohyphae or hyphae	*Candida* and *Candida dubliniensis*	5–10 (pseudohyphae)	Cells usually exhibit single budding; pseudohyphae, when present, are constricted at the ends and remain attached like links of sausage; hyphae, when present, are septate.
	M. furfur (in tinea versicolor)	3–8 (yeast) 2.5–4 (hyphae)	Short, curved hyphal elements are usually present, along with round yeast cells that retain their spherical shape in compacted clusters; "spaghetti and meatballs."
Pauciseptate hyphae	Mucorales: *Mucor, Rhizopus,* and other genera	10–30	Hyphae are large, ribbonlike, often fractured or twisted; occasional septa may be present; smaller hyphae are confused with those of *Aspergillus* spp., particularly *Aspergillus flavus.*
Hyaline septate hyphae	Dermatophytes, skin and nails	3–15	Hyaline, septate hyphae are commonly seen; chains of arthroconidia may be present.
	Dermatophytes, hair	3–15	Arthroconidia on periphery of hair shaft producing a sheath indicate ectothrix infection; arthroconidia formed by fragmentation of hyphae in the hair shaft indicate endothrix infection. Long hyphal filaments or channels in the hair shaft indicate favus hair infection.
	Aspergillus spp.	3–12	Hyphae are septate and exhibit dichotomous, 45-degree branching; larger hyphae, often disturbed, may resemble those of *Mucorales*.
	Geotrichum spp.	4–12	Hyphae and rectangular arthroconidia are present and sometimes rounded; irregular forms may be present.
	Trichosporon spp.	2–4 by 8	Hyphae and rectangular arthroconidia are present and sometimes rounded; occasionally, blastoconidia may be present.
Dematiaceous septate hyphae	*Bipolaris* spp., *Cladophialophora* spp., *Cladosporium* spp., *Curvularia* spp., *Exophiala* spp., *Exserohilum* spp., *Hortaea werneckii*, *Phialophora* spp., and other genera.	2–6	Dematiaceous polymorphous hyphae are seen; budding cells with single septa and chains of swollen rounded cells are often present; occasionally, aggregates may be present in infection caused by *Phialophora* and *Exophiala* spp.
Sclerotic bodies	*Cladophialophora* (formerly *Cladosporium) carrionii* *Fonsecaea* spp., *Phialophora verrucosa,* and *Rhinocladiella aquaspersa*	5–20	Brown, round to pleomorphic, thick-walled cells with transverse septations; commonly, cells contain two fission planes that form a tetrad of cells (sclerotic bodies).

Continued

TABLE 58.6 **Summary of Characteristic Features of Select Fungi Seen in Direct Examination of Clinical Specimens—cont'd**

Morphologic Form Found in Specimens	Organism	Size Range (diameter, mm)	Characteristic Features
Granules	*Acremonium* spp.	200–300	White, soft granules without a cementlike matrix.
	Aspergillus *Aspergillus nidulans*	500–1000	Black, hard grains with a cementlike matrix at the periphery.
	Curvularia *Curvularia geniculata* *Curvularia lunata*	65–160	White, soft granule without a cementlike matrix.
	Exophiala *Exophiala jeanselmei*	200–300	Black, soft granules, vacuolated, without a cementlike matrix, made of dark hyphae and swollen cells.
	Fusarium *Fusarium verticillioides* (formerly *F. moniliformis)*	200–500	White, soft granules without a cementlike matrix.
	Fusarium solani	300–600	
	Trematosphaeria grisea (formerly *Madurella grisea*)	350–500	Black, soft granules without a cementlike matrix; the periphery is composed of polygonal swollen cells, and the center has a hyphal network.
	Madurella mycetomatis	200–900	Black to brown, hard granules; two types: (1) rust-brown, compact, filled with cementlike matrix; (2) deep brown, filled with numerous vesicles, 6–14 μm in diameter, cementlike matrix in periphery, central area of light-colored hyphae.
	Neotestudina *Neotestudina rosatii*	300–600	White, soft granules with cementlike matrix at the periphery.
	Pseudallescheria *Pseudallescheria boydii*	200–300	White, soft granules composed of hyphae and swollen cells at the periphery in a cementlike matrix.

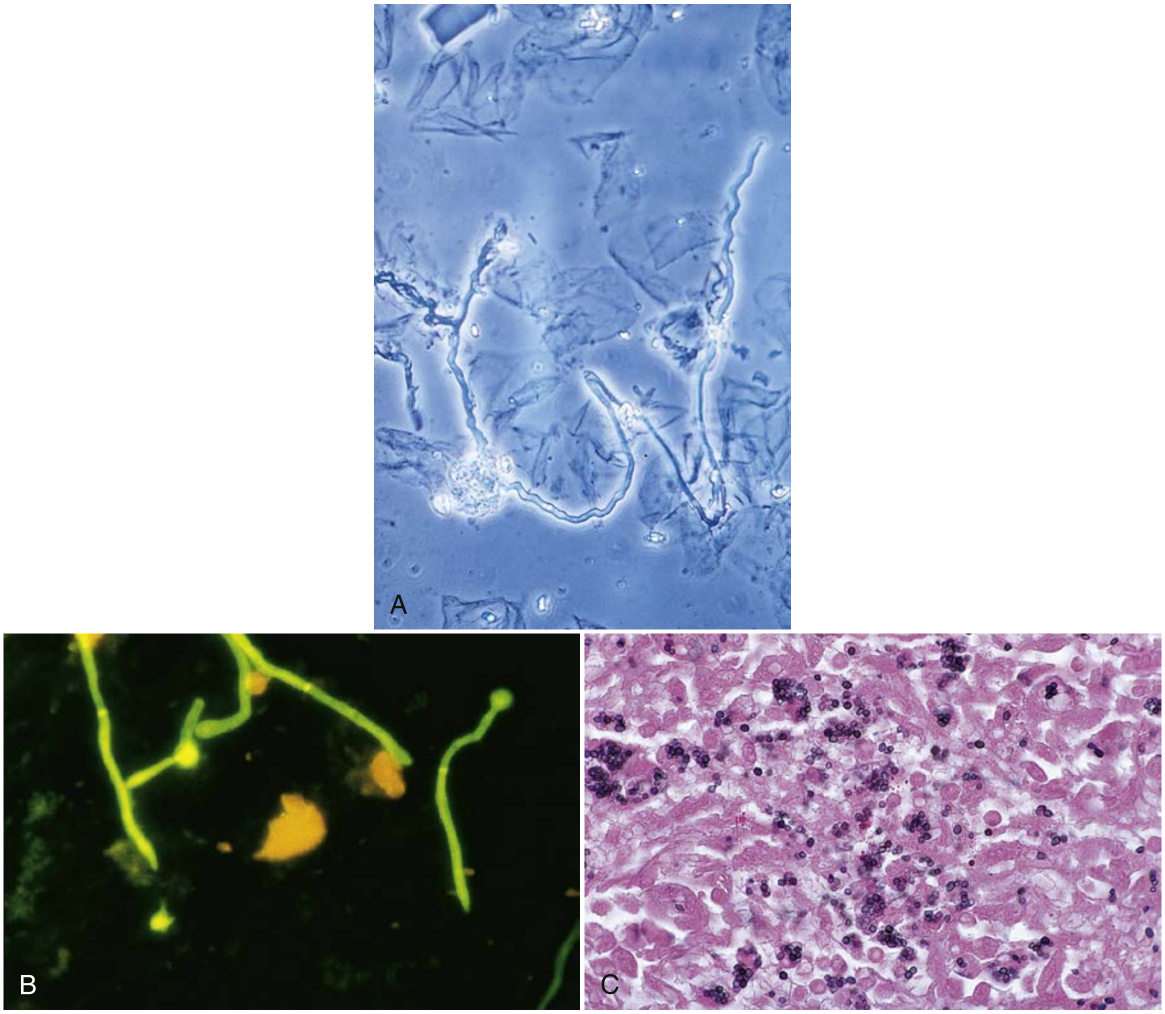
General Considerations for the Identification of Molds

Filamentous fungi are also identified by a combination of tests (Fig. 58.6). Molds are identified using a combination of the following:

- Growth rate
- Colonial morphologic features
- Microscopic morphologic features

In most cases, the microscopic morphologic features provide the most definitive means of identification. Determination of the growth rate can be most helpful when a mold culture is examined. However, this may have limited value, because the growth rate of certain fungi varies, depending on the amount of inoculum present in a clinical specimen. **Slow growers** form mature colonies in 11 to 21 days, and **intermediate growers** form mature colonies in 6 to 10 days. **Rapid growers** form mature colonies in 5 days or less.

The growth of *Coccidioides* is often rapid and is hazardous to microbiologists. In general, the growth rate for the dimorphic fungi, *Blastomyces dermatitidis, H. capsulatum,* and *P. brasiliensis,* is slow; 1 to 4 weeks usually are required before colonies become visible. In some instances, cultures of *B. dermatitidis, Talaromyces marneffei,* and *H. capsulatum* may be detected within 3 to 5 days. This is a somewhat uncommon circumstance, encountered only when large numbers of the organism are present in the specimen. Colonies of *Mucorales* may appear within 24 hours, whereas the other hyaline and melanized (dematiaceous) fungi often exhibit growth in 1 to 5 days. The growth rate of an organism therefore is important, but it must be used in combination with other features before a definitive identification can be made.



• Fig. 58.4 Fungi commonly seen in clinical specimens. (A) This potassium hydroxide preparation of a skin scraping from a patient with a dermatophyte infection shows septate hyphae intertwined among epithelial cells. (Phase-contrast microscopy; ×500.) (B) This calcofluor white stain of urine demonstrates *Candida albicans.* (C) The deeply staining, small, uniform yeast cells in this histologic section of lung tissue are typical of *Histoplasma capsulatum*. (Methenamine silver stain; ×430.)

The colonial morphologic features may have limited value for identifying molds because of natural variation among isolates and colonies grown on different culture media. Although common organisms recovered repeatedly in the laboratory may be more easily recognized, colonial morphology is an unreliable criterion that should be used to supplement the microscopic morphologic features of the organism.

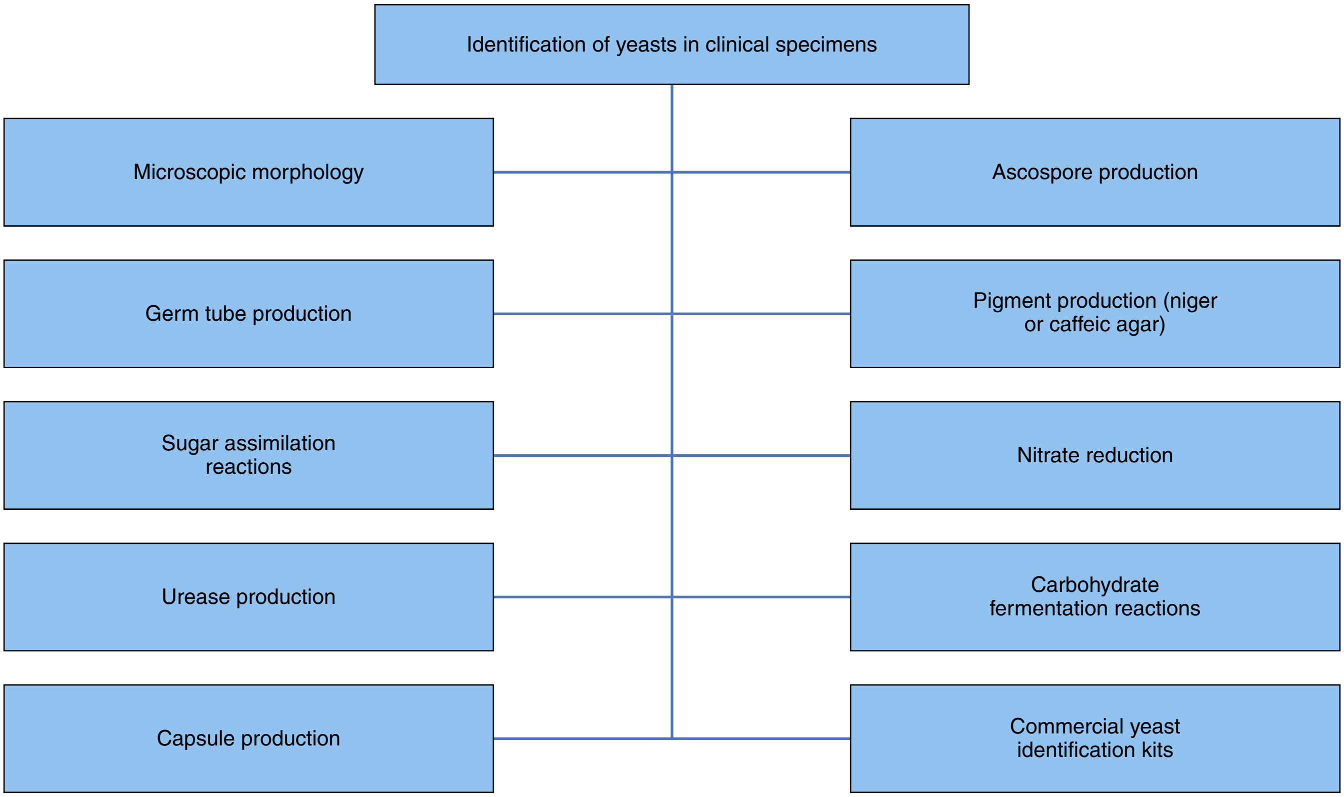
The color of the colony and uniformity of the color can be important, along with the presence of diffusible pigments in the media. The examiner must be sure to note the color of both the front and reverse sides of the culture. The colony topography describes the various elevations of the colony on the agar plate. Topography can be described as **verrucose** (furrowed or convoluted), **umbonate** (slightly raised in the center), or **rugose** (furrows radiate out from the center).

The colony's texture should also be noted. Various textures can be seen, such as **cottony** (loose, high aerial mycelium), **velvety** (low aerial mycelium resembling a velvet cloth), **glabrous** (smooth surface with no aerial mycelium), **granular** (dense, powdery, resembling sugar granules), and **wooly** (high aerial mycelium that appears slightly matted down).

Incubation conditions and culture media must also be considered. For example, *H. capsulatum* appears as a white-to-tan fluffy mold on BHI agar and may have a yeastlike appearance when grown on the same medium containing blood enrichment.

In general, the microscopic morphologic features of the molds are stable and show minimal variation. Definitive identification is based on the characteristic shape, method of reproduction, and arrangement of spores; however, the size of the hyphae also provides helpful information. The large, ribbonlike, **pauciseptate hyphae** of the *Mucorales* are easily recognized; small hyphae, approximately 2 µm in diameter, may suggest the presence of one of the dimorphic fungi or a dermatophyte.

The fungi may be prepared for microscopic observation using several techniques. The procedure traditionally used by most laboratories is the cellophane tape preparation (Evolve Procedure 58.2; Fig. 58.7). It can be prepared



Identification of yeasts in clinical specimens
Microscopic morphology
Germ tube production
Sugar assimilation reactions
Urease production
Capsule production
Ascospore production

Nitrate reduction
Carbohydrate fermentation reactions
Commercial yeast identification kits

• **Fig. 58.5** Traditional identification of yeasts in clinical specimens. Manual methods, kits, and panels have been predominantly replaced with proteomic and genomic methods.

easily and quickly and often is sufficient to make the identification for most fungi. However, some laboratories prefer the wet mount (Evolve Procedure 58.3; Fig. 58.8) or tease mount (Evolve Procedure 58.4). A microslide culture method (Evolve Procedure 58.5; Fig. 58.9) may be used when greater detail of the morphologic features is required.

General Morphologic Features of the Molds

Specialized types of vegetative hyphae may be helpful for categorizing an organism into a certain group. For example, dermatophytes often produce several types of hyphae, including **antler hyphae,** so named because they are curved, freely branching, and have the appearance of antlers (Fig. 58.10). **Racquet hyphae** are enlarged, club-shaped structures (Fig. 58.11). In addition, certain dermatophytes produce **spiral hyphae** that are coiled or exhibit corkscrewlike turns in the hyphal strand (Fig. 58.12). These structures are not characteristic for any certain group; however, they are found most commonly in dermatophytes.

Some species of fungi (Ascomycota) produce sexual spores in a large, saclike structure called an **ascocarp** (Fig. 58.13). The ascocarp contains smaller sacs, called **asci,** each of which contains four to eight ascospores. This type of sexual reproduction is not commonly seen in the fungi recovered in the clinical microbiology laboratory; most exhibit asexual reproduction. It is possible that all fungi have a sexual form, but for some species, it has not yet been observed on artificial culture media. **Conidia,** which are produced by most fungi, represent the asexual reproductive cycle. The type of conidia and their morphology and arrangement are important criteria for definitively identifying an organism (Fig. 58.14).

The simplest type of sporulation is the development of a spore directly from the vegetative hyphae. **Arthroconidia** are formed directly from the hyphae by fragmentation through the points of septation (Fig. 58.15). When mature, they appear as square, rectangular, or barrel-shaped thick-walled cells. These result from the simple fragmentation of the hyphae into spores, which are easily dislodged and disseminated into the environment. **Chlamydoconidia** (chlamydospores) are round, thick-walled spores formed directly from the differentiation of hyphae in which there is a concentration of protoplasm and nutrient material (Fig. 58.16). These appear to be resistant resting spores produced by the rounding up and enlargement of the cells of the hyphae. Chlamydoconidia may be **intercalary** (within the hyphae) or **terminal** (on the end of the hyphae).

A variety of other types of spores occur with many species of fungi. Conidia are asexual spores produced singly or in groups by specialized hyphal strands, **conidiophores.** Sometimes the conidia are freed from their point of attachment by pinching off, or **abstriction.** Some conidiophores terminate in a swollen vesicle. From the surface of the vesicle are formed secondary small, **flask-shaped phialides,** which in turn give rise to long chains of conidia. This type of fruiting structure is characteristic of the aspergilli. A single,

simple, slender, tubular conidiophore (**phialide**) that produces a cluster of conidia, held together as a gelatinous mass, is characteristic of certain fungi, including the genus *Acremonium* (Fig. 58.17). In other cases, conidiophores form a branching structure called a **penicillus,** in which each branch terminates in secondary branches (**metulae**) and phialides, from which chains of conidia are borne (Fig. 58.18). Species of *Penicillium* and *Paecilomyces* are representative of this type of sporulation. Some fungi may produce conidia of two sizes: **microconidia,** which are small, unicellular, round, elliptical, or **pyriform** (pear-shaped), or **macroconidia,** which are large, usually multiseptate, and

club- or spindle-shaped (Fig. 58.19). Microconidia may be borne directly on the side of a hyphal strand or at the end of a conidiophore. Macroconidia are usually borne on a short to long conidiophore and may be smooth or rough-walled. Microconidia and macroconidia are seen in some fungal species and are not specific, except as they are used to differentiate a limited number of genera.

The hyphae of the Mucorales are sparsely septate. Sporulation takes place by progressive cleavage during maturation

in the **sporangium,** a saclike structure produced at the tip of a long stalk (**sporangiophore**). Sporangiospores (spores produced in the sporangium) are produced and released by the rupture of the sporangial wall (Fig. 58.20). In rare cases, some isolates may produce zygospores, rough-walled spores produced by the union of two mating types of a Mucorales; this is an example of sexual reproduction.

Clinical Relevance for Fungal Identification

The question of when and how far to go with the identification of fungi recovered from clinical specimens presents an interesting challenge. The current emphasis on cost containment and the ever-increasing number of opportunistic fungi causing infection in compromised patients prompts consideration of whether all fungi recovered from clinical specimens should be thoroughly identified and reported. The extent of identification of yeasts from various specimen sources is discussed in Chapter 62.

When and how far to proceed in the identification of a mold is a difficult question to answer. Except for obvious plate contaminants, all commonly encountered molds should be identified and reported, if recovered from patients at risk for invasive fungal disease. Immunocompromised patients may have serious or even fatal disease caused by fungi that were once thought to be clinically insignificant. Organisms that fail to sporulate after a reasonable time should be reported as present, but identification is not required if the dimorphic fungi have been ruled out or if the clinician believes the organism is not clinically significant. Ideally, all laboratories should identify all fungi recovered from clinical specimens; however, the limits of practicality and economic considerations play a definite role in the decision-making process. The laboratory director, in consultation with the clinicians, must make this decision after considering the patient population, laboratory practice, and economic implications.

An increasing number of fungi may be isolated in the clinical microbiology laboratory. They are considered environmental microbiota but in reality must be regarded as potential pathogens, because infections with a number of these organisms have been reported. The laboratory must identify and report all organisms recovered from clinical specimens so that their clinical significance can be determined. In many instances, the presence of environmental fungi is unimportant; however, that is not always the case.

Laboratory Safety

Although the handling of fungi recovered from clinical specimens poses risks, a common sense approach to the handling of these specimens protects the laboratory from contamination and workers from becoming infected.

Without exception, mold cultures and clinical specimens must be handled in a class II BSC. Some laboratory professionals believe that mold cultures must be handled in an enclosed BSC equipped with gloves; however, this is not necessary if a laminar flow BSC is used. Yeast cultures may be handled on the bench top. An electric incinerator is suitable for decontaminating a loop used to transfer yeast cultures. Cultures of organisms suspected of being pathogens should be sealed with tape to prevent laboratory contamination and should be autoclaved as soon as the definitive identification is made. If common safety precautions are followed, few problems should occur with laboratory contamination or infection acquired by laboratory personnel.

Prevention

Preventing and controlling fungal infections continue to be a challenge to individuals, researchers, laboratorians, and hospitals. Very few formal recommendations are available to prevent exposure to community-associated fungal infections. Good personal hygiene may be the best course for prevention. However, many strategies can be followed to prevent health care–associated infections. Hospital staff members should be aware of the pathogenesis of fungal infections. Fungi are easily spread in ventilation systems, water, and skin-to-skin contact. Hospitals should follow an infection control plan that includes periodic monitoring of air-handling systems and regular testing for environmental spores. Staff members, patients, and visitors should practice good personal hygiene to minimize exposure to potential fungal infections.

The laboratory also plays an important role in fungal prevention and control. Lack of rapid and specific testing continues to be a factor in a timely diagnosis. Early definitive diagnosis ensures that the appropriate therapy is given promptly and prevents mortality.

PROCEDURE 58.1 CALCOFLUOR WHITE–POTASSIUM HYDROXIDE PREPARATION

Method

1. Place a drop of calcofluor white (CW) reagent and a drop of 10% potassium hydroxide (KOH) glycerin in the center of a microscope slide.
2. Add a portion of the clinical specimen to the CW-KOH solution and apply a cover slip.
3. If necessary, dissociate particles by applying gentle pressure to the cover slip with a pencil eraser. Allow to stand for 5 minutes. If particles do not dissociate, repeat this step.
4. Examine the slide for fungal elements using a fluorescent microscope with a 400–500 nm exciter filter and a 500–520 nm barrier filter. Slides are scanned at ×10 magnification for fluorescent fungal elements. The presence and nature of fungal elements are discerned using ×40 magnification.

Reagents

KOH reagent: (10 g KOH, 10 mL glycerin, 80 mL distilled water)

CW reagent: (0.05 g CW, 0.02 g Evans blue, 50 mL distilled water)

Calcofluor white is an industrial textile brightener that nonspecifically binds to chitin and other elements in the fungal cell wall. Calcofluor white fluorescence occurs maximally at an excitation wavelength of 440 nm. Under these conditions, fungal elements fluoresce blue-white. Because CW is a nonspecific stain, an appreciation for fungal element morphology on direct examination is crucial for adequate specimen interpretation. The presence of KOH in the solution dissolves human cellular elements and debris, which allows for easier visualization of fungal elements.

Limitations

Careful interpretation is crucial, because nonspecific fluorescence may be observed with the presence of cotton fibers or certain tissues from patients with tumors.

PROCEDURE 58.2 CELLOPHANE TAPE PREPARATION

Method

1. Touch the adhesive side of a small length of transparent tape to the surface of the colony.
2. Add a drop of lactophenol cotton or aniline blue to the surface of a microscope slide; then, adhere the length of tape to the surface of the slide (Fig. 58.7).
3. Observe microscopically for the characteristic shape and arrangement of the spores.

The transparent adhesive tape preparation allows the laboratorian to observe the organism microscopically approximately the way the fungi sporulates in culture. The relationship of the spores, spore-producing structures (e.g., conidiophores), and the body of the fungus are usually intact, and microscopic identification of an organism can be made easily. If the tape is not pressed firmly enough to the surface of the colony, the sample may consist only of conidia and may not be adequate for identification. When spores are not observed, a wet mount should be made. In some cases, the macroconidia of *Histoplasma capsulatum* may be seen in wet mount preparations when the adhesive tape preparation reveals only hyphal fragments. In other instances, cultures may have sporulated and reveal only the presence of conidia when the adhesive tape preparation is observed. In this type of situation, a second adhesive tape preparation should be made from the periphery of the colony where sporulation is not as prominent.

Some laboratories prefer to use the microslide culture (Evolve Procedure 58.5) for microscopic identification of an organism. This method might appear to be the most suitable, because it allows the examiner to observe microscopically the fungus growing directly underneath the cover slip. Microscopic features should be easily discerned, structures should be intact, and many representative areas of growth are available for observation.

PROCEDURE 58.3 WET MOUNT

Method

1. With a wire bent at a 90-degree angle, cut out a small portion of an isolated colony. The portion should be removed from an intermediate point between the center and the periphery of the colony and should contain a small amount of the supporting agar.
2. Add a drop of lactophenol cotton or aniline blue to a slide and then place the portion on the slide (Fig. 58.8).
3. Place a cover slip in position and apply gentle pressure with a pencil eraser or other suitable object to disperse the growth and the agar. Examine the slide microscopically.

Limitations

The major disadvantage of the wet mount is that the characteristic arrangement of spores is disrupted when pressure is applied to the cover slip. However, this method is suitable in many situations, because characteristic spores are visible, but their arrangement cannot be determined. The wet mount is not always adequate for making a definitive identification.

PROCEDURE 58.4 TEASE MOUNT

Method

1. Place 1 drop of lactophenol cotton or aniline blue stain on a clean microscope slide.
2. With an inoculating needle, gently remove a small portion of a fungal colony. Pick a colony from an area that is neither in the very center nor on the very edge.
3. Place the fungus in the lactophenol cotton or aniline blue stain.
4. With a second needle, tease the fungus apart to form a thin layer.
5. Place a cover slip over the fungus and examine the slide under a microscope.
6. Seal the edges of the cover slip with clear fingernail polish to preserve the mount.

Note: Adding 10% polyvinyl alcohol (PVA) preserves the specimen as a permanent stain for mounting.

PROCEDURE 58.5 MICROSLIDE CULTURE

Method

1. Cut a small block of a suitable agar medium that has been previously poured into a culture dish to a depth of approximately 2 mm. The block may be cut using a sterile scalpel blade or with a sterile test tube that has no lip (which produces a round block).
2. Place a sterile microscope slide on the surface of a culture dish containing sterile 2% agar. Alternatively, place a round piece of filter paper or paper towel in a sterile culture dish, add two applicator sticks, and position the microscope slide on top.
3. Add the agar block to the surface of the sterile microscope slide.
4. With a right-angle wire, inoculate the four quadrants of the agar plug with the organism (Fig. 58.9).
5. Apply a sterile cover slip to the surface of the agar plug.
6. If the filter paper–applicator stick method is used, add a small amount of sterile water to the bottom of the culture dish. Replace the lid of the culture and allow it to incubate at 30°C.
7. After a suitable incubation period (and working inside a biologic safety cabinet), remove the cover slip and place it on a microscope slide containing a drop of lactophenol cotton or aniline blue. Some suggest placing the cover slip near the opening of an incinerator-burner to allow the organism to dry rapidly on the cover slip before adding it to the stain.
8. Observe microscopically for the characteristic shape and arrangement of spores.
9. If the microslide culture is unsatisfactory for microscopic identification, the remaining agar block may be used later if it is allowed to incubate further. The agar plug is then removed and discarded, and a drop of lactophenol cotton or aniline blue is placed on the area of growth and a cover slip is positioned in place. Many laboratorians like to make two cultures on the same slide so that if characteristic microscopic features are not observed on examination of the first culture, the second is available after an additional incubation period.

Limitations

Although this method is ideal for definitive identification of an organism, it is the least practical of all the methods described. It should be reserved for cases in which an identification cannot be made based on an adhesive tape preparation or a wet mount.

Caution: Do not make slide cultures of slow-growing organisms suspected to be dimorphic pathogens (e.g., *Histoplasma capsulatum, Blastomyces* spp., *Coccidioides* spp., *Paracoccidioides brasiliensis, Emmonsia* spp., or *Sporothrix* spp.). Microslide cultures must be observed only after a cover slip has been removed from the agar plug and not while it is in position on top of the agar plug. This method of observation is very dangerous, because it could cause a laboratory-acquired infection.

CASE STUDY 58.1

A 5-year-old male recently adopted from Haiti is seen by a primary care physician. The boy appears to have an infection of the hair and scalp. The physician suspects a dermatophyte and removes infected hairs by plucking them with forceps. The sterile container with the specimen is sent to the laboratory for culture.

Questions

1. What agar and incubation temperature might the laboratorian choose for primary culture?
2. The laboratorian notices that the fungus is a slow grower, taking 12 days to grow. What other details should be noted?
3. The colony appears downy, flat, and spreading. It has a light tan front and red-brown reverse. What is the next step for identifying this fungus?
4. Rare club-shaped microconidia and sterile hyphae are noted with terminal chlamydospores. The laboratorian decides the dermatophyte is a *Microsporum* species. How might *Microsporum canis* be differentiated from *Microsporum audouinii?*

Chapter Review

1. All of the following are medically dimorphic fungi *except:*
   - **a.** *Histoplasma capsulatum*
   - **b.** *Blastomyces dermatitidis*
   - **c.** *Coccidioides* spp.
   - **d.** *Aspergillus niger*
2. Cutaneous mycoses are fungal infections that involve:
   - **a.** Hair
   - **b.** Skin
   - **c.** Nails
   - **d.** All of the above
3. Which fungus is most often acquired by traumatic implantation into the skin?
   - **a.** *Histoplasma capsulatum*
   - **b.** *Sporothrix* spp.
   - **c.** *Coccidioides* spp.
   - **d.** *Talaromyces marneffei*
4. What are the optimal temperature and incubation time before a fungal blood culture is reported as negative?
   - **a.** 37°C; 21 days
   - **b.** 37°C; 7 days
   - **c.** 30°C; 21 days
   - **d.** 30°C; 7 days
5. What is a disadvantage of using the tease mount?
   - **a.** The preparation cannot be preserved.
   - **b.** Lactophenol cotton or aniline blue stains uniformly.
   - **c.** Conidia may be disrupted in the preparation.
   - **d.** Contamination is possible.
6. Which of the following organisms is/are partially or completely inhibited by media containing cycloheximide?
   - **a.** *Cryptococcus* spp.
   - **b.** *Candida krusei*
   - **c.** *Aspergillus niger*
   - **d.** All of the above
7. Which stain uses a bleaching agent for fungal detection?
   - **a.** Gram stain
   - **b.** Lactophenol cotton blue
   - **c.** Calcofluor white
   - **d.** India ink
8. Which criterion applies to the identification of *Histoplasma capsulatum?*
   - **a.** Red pigment on cornmeal agar
   - **b.** Produces yeast form at 25°C and mold form at 36°C
   - **c.** Slow-growing fungus (1–4 weeks)
   - **d.** All of the above
9. **True or False**

   ______ All yeasts should be screened for the presence of *Cryptococcus* spp.

   ______ Rice grain agar is used to differentiate *Microsporum canis* from *Trichosporon rubrum.*

   ______ India ink is used to identify *Aspergillus niger.*

   ______ *Cryptococcus* spp. can be confirmed by antibody testing.

10. **Matching:** *Match each term with the correct description.*

______ saprophytic	a. yeast and filamentous form
______ dermatophytes	b. pigmented hyphae
______ dimorphic	c. asexual spores
______ aerial mycelium	d. saclike structure containing sexual spores
______ melanized	e. living on dead or decayed organic matter
______ hyaline	f. small, round conidia
______ conidia	g. tubular conidiophore
______ ascocarp	h. nonpigmented hyphae
______ phialide	i. fungus that infects the skin
______ microconidia	j. hyphae above the surface

Hyaline Molds, Mucorales, Basidiobolales, Entomophthorales, Dermatophytes, and Opportunistic and Systemic Mycoses

OBJECTIVES

1. Describe where Mucorales, Basidiobolales, and Entomophthorales are found, how they are transmitted to humans, and the diseases they cause.
2. Describe the characteristic colony morphology of the Mucorales, Basidiobolales, and Entomophthorales.
3. Outline the tests needed to diagnose a *Trichophyton* species.
4. List the key features that distinguish *Trichophyton rubrum* and *Trichophyton mentagrophytes*.
5. Compare and contrast the ways *Microsporum audouinii* and *Microsporum canis* are spread and the populations at risk.
6. Define ectothrix and endothrix.
7. Explain why diagnosing an opportunistic fungal infection in an immunocompromised patient is difficult.
8. Differentiate mucormycosis and entomophthoromycosis, including the disease presentation, causative agents, predominant patient populations, and treatment.
9. Compare and contrast *Aspergillus* and *Penicillium* spp., both macroscopically and microscopically.
10. Discuss the dimorphic molds in relation to their endemic areas, disease states, and associated diagnostic methods for identification.

HYALINE MOLDS TO BE CONSIDERED

Current Name

Mucorales

Rhizopus spp.
Mucor spp.
Actinomucor sp.
Apophysomyces spp.
Cokeromyces sp.
Lichtheimia spp.
Rhizomucor sp.
Saksenaea spp.
Syncephalastrum sp.
Cunninghamella spp.

Entomophthorales

Conidiobolus spp.

Basidiobolales

Basidiobolus sp.

Dermatophytes

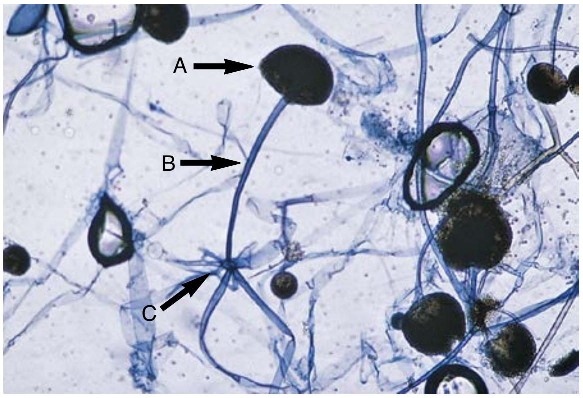
Trichophyton spp.
Microsporum spp.
Epidermophyton sp.

Opportunistic Mycoses

Aspergillus spp.
Fusarium spp.
Geotrichum spp.
Acremonium spp.
Acrophialophora spp.
Arthrographis sp.
Beauveria sp.
Chrysosporium sp.
Coniochaeta spp.
Nannizziopsis sp.
Onychocola sp.
Parengyodontium sp.
Penicillium spp.
Phialemonium spp.
Paecilomyces spp.
Purpureocillium sp.
Rasamsonia spp.
Sarocladium spp. (previously *Acremonium*)
Schizophyllum sp.
Talaromyces spp.
Thermothelomyces sp.

Systemic Mycoses

Blastomyces spp.
Coccidioides spp.
Emergomyces spp.
Emmonsia sp.
Histoplasma capsulatum
Paracoccidioides spp.



• **Fig. 59.1** *Rhizopus* spp. showing sporangium *(A)* on a long sporangiophore *(B)* arising from pauciseptate hyphae. Note the characteristic rhizoids *(C)* at the base of the sporangiophore (×250).

The Mucorales

General Characteristics

The order Mucorales (Zygomycetes) characteristically produce large, ribbonlike hyphae that are irregular in diameter and contain occasional septa. Because the septa may not be apparent in some preparations, this group sometimes has been characterized as aseptate. The specific identification of these organisms is confirmed by observing the characteristic saclike fruiting structures (sporangia), which produce internally spherical, yellow or brown spores (sporangiospores) (Fig. 59.1). Each sporangium is formed at the tip of a supporting structure (sporangiophore). During maturation, the sporangium becomes fractured, and sporangiospores are released into the environment. Sporangiophores are usually connected to one another by occasionally septate hyphae called **stolons,** which attach at contact points where rootlike structures (**rhizoids**) may appear and anchor the organism to the agar surface. Identification of the Mucorales is partly based on the presence or absence of rhizoids and the position of the rhizoids in relation to the sporangiophores.

Epidemiology and Pathogenesis

Although the Mucorales (*Rhizopus, Mucor, Actinomucor, Cokeromyces, Rhizomucor, Saksenaea, Apophysomyces, Lichtheimia [Absidia], Syncephalastrum,* and *Cunninghamella* spp.) are a less common cause of infection than the aspergilli, they are an important cause of morbidity and mortality in immunocompromised patients, particularly patients with diabetes mellitus. The organisms have a worldwide distribution and are commonly found on decaying vegetable matter or old bread (bread mold) or in soil. The organism is generally acquired by inhalation or ingestion of spores or through percutaneous routes, followed by subsequent development of infection. Once established, the infection is rapidly progressive, particularly in patients with diabetes mellitus who have infections that involve the sinuses. Other immunocompromised patients who are susceptible to infection with Mucorales include patients with hematologic malignancies such as acute leukemia and stem cell, kidney, and liver transplant patients. Immunocompetent individuals may acquire skin infections with these fungi after traumatic injection with contaminated material. These organisms are also commonly identified as contaminants in the clinical laboratory but are also a source of nosocomial or health care–associated infections.

Spectrum of Disease

Immunocompromised patients are at greatest risk, particularly those who have uncontrolled diabetes mellitus and transplant patients who are undergoing prolonged corticosteroid, antibiotic, or cytotoxic therapy. The organisms that cause **mucormycosis** (an infection caused by Mucorales) have a marked propensity for vascular invasion and rapidly produce thrombosis and necrosis of tissue. One of the most common presentations is the **rhinocerebral form,** in which the nasal mucosa, palate, sinuses, orbit, face, and brain are involved; each shows massive necrosis with vascular invasion and infarction. Perineural invasion also occurs in mucormycoses and is a potential means of retroorbital spread (i.e., invasion into the brain). Other types of infection involve the lungs and gastrointestinal tract; some patients develop disseminated infection. The Mucorales have also caused localized skin infections in immunocompetent patients with severe burns and infections of subcutaneous tissue in patients who have undergone surgery; infection can also be a result of injury and contamination with spores or soil (Fig. 59.2).

Laboratory Diagnosis

Specimen Collection, Transport, and Processing

Blood cultures are not appropriate for diagnosis of mucormycosis. Specimens from deep lesions or tissues and sterile sites should be collected rapidly and aseptically. Sufficient quantity is essential to improve the identification and recovery of the fungal isolate.

Samples collected for the diagnosis of rhinocerebral forms of infection should include nasal discharge or scrapings, sinus aspirate, or a tissue specimen from a vascularized tissue. Respiratory samples may include sputum and bronchoalveolar lavage fluids. However, if these respiratory specimens result in negative results, a transbronchial or percutaneous computed tomography–guided biopsy of pulmonary lesions may be considered. These procedures pose significant risk to the patient and should be considered carefully.

Separate specimens should be collected for the microbiology laboratory and the histology laboratory. Preservatives used for histologic processes, such as formalin, are inhibitory to fungal growth.

Specimens should be transported in sterile containers. Tissue (biopsy specimens) should be moistened by adding a few drops of sterile saline to the container. Specimens should be transported to the laboratory within 2 hours of collection and processed immediately. Mucorales are extremely sensitive to environmental changes. See General

Gerald Bodey, George Viola, Saud Ahmed, and Mona Shiekh Sroujieh, The University of Texas MD Anderson Cancer Center, Houston, TX.)

Considerations for the Laboratory Diagnosis of Fungal Infections in Chapter 58.

Direct Detection Methods

The diagnosis of mucormycosis is primarily based on direct examination; nucleic acid–based testing; or recovery of the fungus from tissue, body fluids, and exudates.

Stains

A mucormycosis may be diagnosed rapidly by examining tissue specimens or exudate from infected lesions in a calcofluor white and potassium hydroxide preparation. If the sample is too thick, a false negative result may occur because of insufficient dissociation of tissues. It is recommended that the negative slide be maintained overnight and reviewed again the next day. Branching, broad-diameter, predominantly nonseptate hyphae are observed (Fig. 59.3). It is important that the laboratory notify the clinician of these findings, because Mucorales grow rapidly, and vascular invasion occurs at a rapid rate.

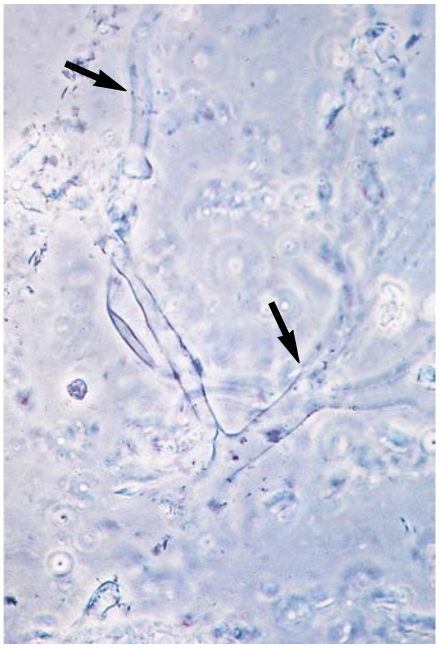
Antigen-Protein

Antigen-protein–based assays are not used for the diagnosis of mucormycosis. In addition, beta-D-glucan testing is not useful for diagnosis.

Nucleic Acid–Based Testing

Nucleic acid testing may be performed on formalin-fixed, paraffin-embedded, fresh or frozen tissue samples. Polymerase chain reaction (PCR) amplification of the internal transcribed spacer, as well as seminested PCR of the 18S ribosomal ribonucleic acid (RNA)/deoxyribonucleic acid (DNA) sequence, has been used to confirm identification in samples that have been identified as histopathology positive. A real-time PCR assay has also been developed that amplifies the cytochrome b gene. Nucleic acid purification from formalin-fixed and paraffin-embedded tissues often results in poor quality of extracted DNA. Therefore, fluorescent *in situ* hybridization that does not require DNA extraction or amplification has the potential to improve the identification of the fungi. The technique uses synthetic oligonucleotides specific to the 5.8S and 18S ribosomal ribonucleic acid (rRNA) of the fungi.

PCR amplification of fungal genes from the serum of high-risk patient populations has demonstrated the potential for early diagnosis of mucormycosis before the demonstration of tissue pathology.



• **Fig. 59.3** Phase-contrast microscopy of a potassium hydroxide preparation of sputum. Note the fragmented portions *(arrows)* of broad, predominantly nonseptate hyphae of *Rhizopus* spp.

Cultivation

Growth media containing high concentrations of carbohydrates inhibits the production of asexual fruiting bodies that are required for the proper identification of the Mucorales species. It is therefore recommended that media such as potato dextrose, 2% malt, and cherry decoction (acidic) agars be used for cultivation. Growth and development of the mycelium in the Mucorales occurs within 24 to 48 hours. Subcultures should be incubated at 27°C to 30°C.

The colonial morphologic features of the Mucorales allow immediate suspicion that an organism belongs to this group. Colonies characteristically produce a fluffy, white to gray or brown hyphal growth that resembles cotton candy and that diffusely covers the surface of the agar within 24 to 96 hours (Fig. 59.4). The hyphae can grow very fast and may lift the lid of the agar plate (also known as a "lid lifter"). The hyphae appear to be coarse. The entire culture dish or tube rapidly fills with loose, grayish hyphae dotted with brown or black sporangia. The different genera and species of Mucorales cannot be differentiated using colonial morphologic features.

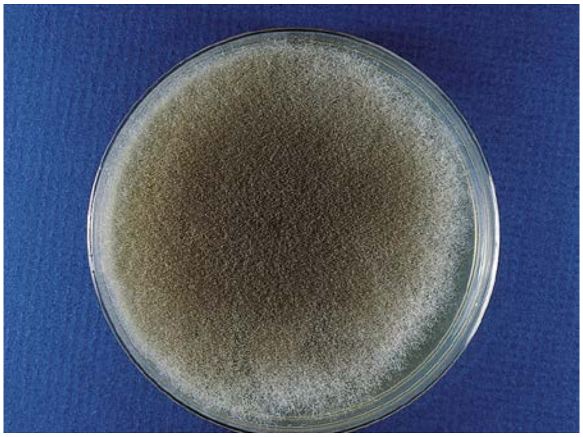
Approach to Identification

Mucorales are characterized by the production of branched, nonseptate, wide mycelia (10 to 20 µm). Sexual reproduction occurs by the formation of a thick walled zygospore; however, morphology of the zygospores is not generally useful for routine identification unless the species is homozygous. Asexual reproduction occurs by the formation of sporangiospores in saclike structures termed sporangiophores. The central axis of the sporangia (multispored structure) is termed the **columella (singular)** and a swelling of the sporangiophore below the columellae (plural) is termed the **apophysis.** Some species also produce rhizoids that hold the sporangiophore within the soil or growth substrate. The rhizoids are then connected to a branching root, or stolon.

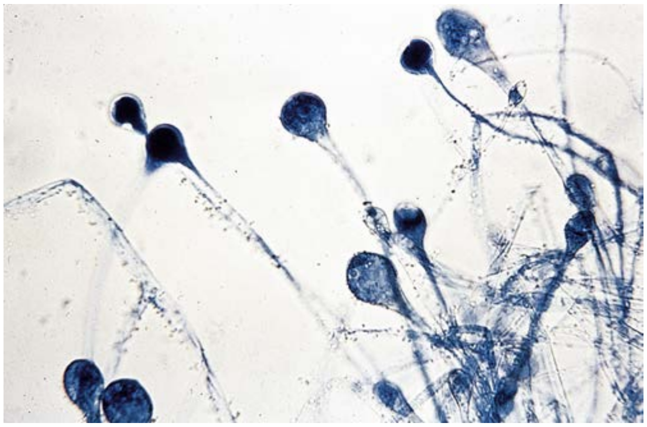
Rhizopus spp. have mostly unbranched sporangiophores with rhizoids that appear opposite the point where the stolon arises, at the base of the sporangiophore (Fig. 59.1). In contrast, *Mucor* spp. are characterized by sporangiophores that are singularly produced or branched and have a round sporangium at the tip filled with sporangiospores. They do not generally have rhizoids or stolons, which distinguishes this genus from the other genera of the Mucorales (Fig. 59.5). *Lichtheimia* spp. are characterized by the presence of rhizoids that originate between branched or whorled sporangiophores (Fig. 59.6) along the stolons between the rhizoids. The sporangia of *Lichtheimia* spp. are pyriform and have a funnel-shaped area (apophysis) at the junction of the sporangium and the sporangiophore. Usually a septum is formed in the sporangiophore just below the sporangium. *Lichtheimia* produce white, fast-growing wooly colonies that become grayish brown. Other genera that are encountered much less commonly in the clinical laboratory are *Rhizomucor, Actinomucor, Cokeromyces, Syncephalastrum, Saksenaea, Cunninghamella,* and *Apophysomyces* spp. and described in Table 59.1.

Serologic Testing

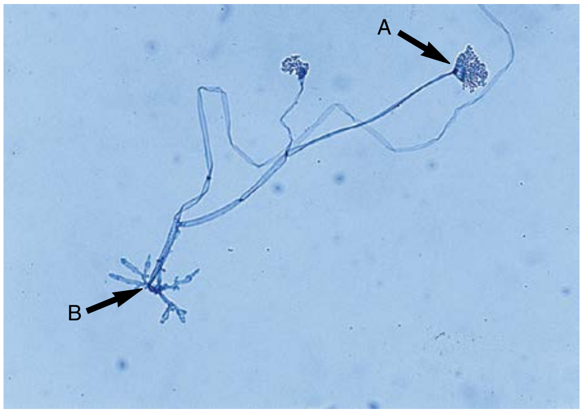
Serology is not useful for diagnosing mucormycosis. Patients with invasive mucormycosis develop Mucorales-specific T cells that may be used to monitor the course of the disease but not for early diagnosis.



• **Fig. 59.4** *Rhizopus* colony.



• **Fig. 59.5** *Mucor* spp. showing numerous sporangia without rhizoids (×430).



• **Fig. 59.6** *Lichtheimia* spp. *(A)* showing sporangia on long sporangiophores arising from pauciseptate hyphae *(B).* Note that rhizoids are produced between sporangiophores and not at their bases (×250).

Matrix-Assisted Laser Desorption Ionization Time-of-Flight Mass Spectrometry

Matrix-assisted laser desorption ionization time-of-flight mass spectrometry (MALDI-TOF MS) has been evaluated for the identification of Mucorales. This technique has

TABLE 59.1 **Morphological Differentiation of the Mucorales, Entomophthorales, and Basidiobolales**

Order/ Genus	Species	Macroscopic Morphology	Microscopic Morphology
Mucorales			
Rhizopus spp.	*R. arrhizus* *R. microsporus* *R. schipperae*	Rapidly produce white cottony colonies that turn brownish to black with the production of sporangiophores. Sporangiophores are unbranched arising singly or in groups, with well-developed rhizoids at the base.	Single or clustered brown sporangiophores. Columellae are ellipsoidal, brown to grey. Sporangiospores are angular and round to ellipsoidal.
Mucor spp.	*M. circinelloides* *M. indicus* *M. irregularis* *M. ramosissimus* *M. velutinosus*	Fast growing white to yellow becoming gray with time. Tall sporangiophores that are simple or branched.	Sporangiospores are hyaline and subspherical to ellipsoidal. *M. circinelloides* rarely produces chlamydospores, and they are absent in *M. ramosissimus.* Columellae are present and some species will demonstrate rhizoids, although it is not typical of the genera.
Actinomucor sp.	*A. elegans*	Growth is slow, colonies appear floccose and white to cream after 7 days becoming brown to beige wooly as they age.	Sporangiophores are hyaline, verticillately branched. Whorls or branches may give rise to secondary branches. Sporangiospores are spherical to ovoidal in a smooth or spiny sporangia, with a subglobose columnella present. Rhizoids and chlamydospores are produced.
Apophysomyces spp.	*A. ossiformis* *A. trapeziformis* *A. variabilis*	Rapid growing white to gray with sporangiophores.	Sporangiophores are smooth-walled, single, unbranched with multispored pyriform sporangia. Columellae are hemispherical, cylindrical, trapezoidal, or ellipsoidal. Apophyses are vase-, bell-, or funnel-shaped.
Cokeromyces sp.	*C. recurvatus*	Slow growing gray to brown.	Long, recurved, twisted stalks arise from terminal vesicles on unbranched sporangiophores. Sporangia are smooth-walled producing spherical sporangiospores. Yeastlike forms are thin- to thick-walled, spherical cells that may produce a ship's wheel appearance similar to *Paracoccidioides brasiliensis* when grown on brain-heart infusion or yeast extract peptone agar.
Lichtheimia spp.	*L. corymbifera* *L. ramosa* *L. ornata*	Fast growing white woolly colonies that become grayish brown with age.	Sporangiophores are highly branched in singles or corymbs from stolons. Rhizoids are present. Sporangia are spherical to pyriform. Columellae are hemispherical to ellipsoidal with a conical apophyses. Sporangiospores are smooth, hyaline, ellipsoidal, cylindrical, or subglobose. Irregular giant cells may be present.
Rhizomucor sp.	*R miehei* *R. pusillus*	Rapidly growing woolly, gray to brown.	Single or branched sporangiophores on aerial mycelium or stolons. Sporangia are multispored with no apophyses. Sporangiospores are round, hyaline, and smooth-walled.
Saksenaea spp.	*S. erythrospora* *S. oblongispora* *S. vasiformis*	White to gray colonies.	Unbranched sporangiophores with dark (melanized) rhizoids. Flask-shaped sporangia.
Syncephalastrum sp.	*S. racemosum*	Rapid growing white to gray, turns darker with age.	Mostly branched sporangiophores bearing globose vesicles. Smooth-walled sporangia with spherical to ovoid merospores arranged in rows. Rhizoids present.
Cunninghamella spp.	*C. bertholletiae* *C. blakesleeana* *C. echinulate* *C. elegans*	White to dark gray.	Laterally branching sporangiophores with a globose vesicle that bears a 1-spored sporangiola. Sporangiola will become a finely echinulate spherical sporangiospore.
Entomophthorales			
Conidiobolus spp.	*C. coronatus* *C. incongruous* *C. lamprauges*	Fast growing hyaline radially folded. Initially appear waxy and become powdery with age.	Primary conidia are spherical with prominent papilla. Villose conidia appear as the colony ages.
Basidiobolales			
Basidiobolus sp.	*B. ranarum*	Colonies appear as yellow, waxy with radial folds.	Primary conidiophores have swollen apices and discharge spherical conidia. Secondary conidia are pyriform with a knob-like tip. Large aseptate mycelia are produced that break into uninucleate hyphal elements.

demonstrated a high correlation with sequencing methods for the identification of fungal isolates (97%), indicating a potential for use as a routine identification method in the clinical laboratory.

The Entomophthorales and Basidiobolales

General Characteristics

The subdivision Entomophthoromycotina contains more than 250 species distributed worldwide. However, only four species have been identified as significant in clinical samples: Order Entomophthorales; *Conidiobolus coronatus, Conidiobolus lamprauges, Conidiobolus incongruus,* and Order Basidiobolales: *Basidiobolus ranarum.*

Epidemiology and Pathogenesis

The organisms are pathogens of arthropods and animals and are primarily present in the soil, decaying vegetable material, and animal feces. Although there is a worldwide distribution, infections are more commonly identified in warm climates. Infections associated with *Conidiobolus* spp. have been identified in Africa, Madagascar, Mayotte, India, China, Japan, and South America. *B. ranarum* has been associated with infections in India, Myanmar, and Africa. Recent gastrointestinal infections with *B. ranarum* have been identified in the United States. Unlike mucormycosis, **entomophthoromycosis** occurs predominantly in immunocompetent individuals.

Spectrum of Disease

Infections from *B. ranarum,* **basidiobolomycosis** are primarily localized to subcutaneous tissue of the arms, legs, buttocks, trunk, perineum, face, or neck. Disseminated infection is rare. The infection presents as a woody, hard, painless nodule. Gastrointestinal infections have been noted. *Conidiobolus* spp. primarily infect the tissue around the nose and on the face. Infection is believed to be through inhalation of the spores in the nasal cavity or inoculation after trauma. After infection, swelling occurs that extends to the nose, cheeks, eyebrows, upper lip, palate, and pharynx. Rare cases of disseminated infection have occurred in immunocompromised patients.

Laboratory Diagnosis

Specimen Collection, Transport, and Processing

See General Considerations for the Laboratory Diagnosis of Fungal Infections in Chapter 58.

Direct Detection Methods

Direct examination methods should be used as previously described for the Mucorales. The **Splendore-Hoeppli phenomenon** (formation of asteroid bodies), the formation of eosinophilic crystals that appear radiate, starlike, asteroid, or club-shaped around a fungal infection, are associated with hyphae in tissue sections stained with hematoxylin-eosin. This is highly indicative of entomophthoromycosis but can also be observed in other bacterial, fungal, and parasitic infections.

Antigen-Protein

No antigen tests are currently available.

Nucleic Acid–Based Testing

A single polymerase chain amplification assay has been developed for the diagnosis of *Basidiobolus* entomophthoromycosis.

Cultivation

Tissue samples should be sliced or minced and cultivated on potato dextrose agar or Sabouraud agar without cycloheximide. Because of the variation in growth temperatures required for the isolation of the different organisms, cultures should be incubated at 37°C (*Conidiobolus* spp.) with a second culture incubated at 25°C to 30°C (*Basidiobolus* sp.).

Approach to Identification

B. ranarum colonies appear slightly yellow pigmented with radial folds. No aerial hyphae are present. After 7 to 10 days of growth, the culture will produce aseptate mycelia with free uninucleated hyphal elements. Sexual reproduction results in thick-walled zygospores with lateral protuberances or beaks. Primary conidiophores have swollen apices with globose spores that are forcibly discharged from the conidiophores, whereas secondary conidia appear pyriform with a knoblike adhesive tip and are passively discharged.

Conidiobolus spp. is a fast-growing fungus that produces hyaline, radially folded colonies that initially appear waxy and become powdery when mycelia begin to develop. The primary conidia are spherical and have prominent **papilla** (small bumps). **Villose** (hairlike spines) conidia appear as the colony ages. *C. coronatus* can be differentiated from the other species based on the absence of zygospores when grown on potato dextrose agar.

Serologic Testing

No serologic tests are available for the diagnosis of entomophthoromycosis.

The Dermatophytes

General Characteristics

The dermatophytes produce infections involving the superficial areas of the body, including the hair, skin, and nails (**dermatomycoses**). The genera *Trichophyton, Microsporum,* and *Epidermophyton* are the principal etiologic agents of the dermatomycoses. There is significant information based on molecular classification of these organisms that is not fully accepted or approved and therefore has not been majorly restructured in this edition. Table 59.2 includes an overview of the current dermatophytic genus, species,

TABLE 59.2 **Dermatophytes**

	Species [Proposed New Name]	Macroscopic Morphology	Microscopic Morphology
Trichophyton spp.	*T. ajelloi [Arthroderma uncinatum]* *T. concentricum* *T. equinum* *T. erinacei* *T. megninii* *T. mentagrophytes* complex *T. rubrum* *T. schoenleinii* *T. simii* *T. soudanense* *T. terrestre complex* *T. tonsurans* *T. vanbreuseghemii [Arthroderma gertleri]* *T. verrucosum* *T. violaceum*	Species vary from powdery to granular and cottony. Coloration is from white to yellow, or pink. Various reverse colors from white to yellow and red to brown.	Species dependent; macroconidia may or may not be present. Macroconidia are generally pencil or club shaped. Microconidia may be tear dropped or round when present.
Microsporum spp.	*M. audouinii* *M. canis* *M. cookei* complex *[Genus Paraphyton]* *M. ferrugineum* *M. gallinae [Lophophyton gallinae]* *M. gypseum* complex *[Genus Nannizzia]* *M. nanum [Nannizzia nana]* *M. persicolor [Nannizzia persicolor]* *M. praecox [Nannizzia praecox]* *M. racemosum* *M. vanbreuseghemii [Lophophyton gallinae]*	Generally powdery pink to buff with reverse yellow to rose or red-brown.	Macroconidia are generally smooth to rough with tapered ends (row-boat appearance). Microconidia are not present. *M. nanum* macroconidia appear egg-shaped or ellipsoidal.
Epidermophyton sp.	*E. floccosum*	Granular, tan to olive brown with reverse tan to yellow.	Macroconidia are club-shaped (beaver tail) with fewer than 6 cells. Chlamydospores may be present. Microconidia are absent.

proposed nomenclature, and general characteristics. Table 59.3 also includes those routinely isolated in the clinical laboratory.

Epidemiology and Pathogenesis

The dermatophytes break down and utilize keratin as a source of nitrogen. They usually are incapable of penetrating the subcutaneous tissue, unless the host is immunocompromised, and even then, penetration into the subcutis is rare. Species of the genus *Trichophyton* are capable of invading the hair, skin, and nails; *Microsporum* spp. involve only the hair and skin; and *Epidermophyton* sp. involves the skin and nails. Common species of dermatophytes recovered from clinical specimens, in order of frequency, are *Trichophyton rubrum, Trichophyton mentagrophytes, Epidermophyton floccosum, Trichophyton tonsurans, Microsporum canis,* and *Trichophyton verrucosum.* The frequency of recovery of these species may differ by geographic locale. Other geographically limited species are described elsewhere.

Spectrum of Disease

Cutaneous mycoses are perhaps the most common fungal infections of humans. They are usually referred to as **tinea** (Latin for "worm" or "ringworm"). The gross appearance of the lesion is an outer ring of the active, progressing infection, with central healing within the ring. These infections may be characterized by another Latin noun to designate the area of the body involved; for example, **tinea corporis** (ringworm of the body); **tinea cruris** (ringworm of the groin, or "jock itch"); **tinea capitis** (ringworm of the scalp and hair); **tinea barbae** (ringworm of the beard); **tinea unguium** (ringworm of the nail); and **tinea pedis** (ringworm of the feet, or "athlete's foot").

Trichophyton spp.

Members of the genus *Trichophyton* are widely distributed and are the most important and common causes of infections of the feet and nails; they may be responsible for tinea corporis, tinea capitis, tinea unguium, and tinea barbae. They are commonly seen in adult infections, which vary

TABLE 59.3 **Characteristics of Dermatophytes Commonly Recovered in the Clinical Laboratory**

Dermatophyte	Colonial Morphology	Growth Rate	Microscopic Identification
Microsporum audouinii[a]	Downy white to salmon-pink colony; reverse tan to salmon-pink.	2 weeks	Sterile hyphae; terminal chlamydoconidia, favic chandeliers, and pectinate bodies; macroconidia rarely seen (bizarre shaped if seen); microconidia rare or absent.
Microsporum canis	Colony usually membranous with feathery periphery; center of colony white to buff over orange-yellow; lemon-yellow or yellow-orange apron and reverse.	1 week	Thick-walled, spindle-shaped, multiseptate, rough-walled macroconidia, some with a curved tip; microconidia rarely seen.
Microsporum cookei complex	Velvety to granular with a wine-red reverse	1week	Thick-walled, rough-walled macroconidia with cellular compartments, no true cross walls; microconidia are teardrop-shaped.
Microsporum gallinae	Flat to velvety with a white surface with pink tinge; red reverse with diffusible pigment	1 week	Smooth to rough-walled macroconidia; thickest cell often at apex; drop-shaped microconidia
Microsporum gypseum	Cinnamon-colored, powdery colony; reverse light tan.	1 week	Thick-walled, rough, elliptical, multiseptate macroconidia; microconidia few or absent.
Epidermophyton floccosum	Center of colony tends to be folded and is khaki green; periphery is yellow; reverse yellowish-brown with observable folds.	1 week	Macroconidia: large, smooth-walled, multiseptate, clavate, and borne singly or in clusters of two or three; microconidia not formed by this species.
Trichophyton mentagrophytes complex	Different colonial types; white, granular, and fluffy varieties; occasional light-yellow periphery in younger cultures; reverse buff to reddish-brown.	7–10 days	Many round to globose microconidia, most commonly borne in grapelike clusters or laterally along the hyphae; spiral hyphae in 30% of isolates; macroconidia are thin-walled, smooth, club-shaped, and multiseptate; numerous or rare, depending on strain.
Trichophyton rubrum	Colonial types vary from white downy to pink granular; rugal folds are common; reverse yellow when colony is young, but wine/red color commonly develops with age.	2 weeks	Microconidia usually teardrop-shaped, most commonly borne along sides of the hyphae; macroconidia usually absent but when present are smooth, thin-walled, and pencil-shaped.
Trichophyton schoenleinii[a]	Irregularly heaped, smooth, white to cream colony with radiating grooves; reverse white.	2–3 weeks	Hyphae usually sterile; many antler-type hyphae seen (favic chandeliers).
Trichophyton tonsurans	White, tan to yellow or rust, suedelike to powdery; wrinkled with heaped or sunken center; reverse yellow to tan to rust red.	7–14 days	Microconidia are teardrop- or club-shaped with flat bottoms; vary in size but usually larger than other dermatophytes; macroconidia rare (balloon forms found when present).
Trichophyton verrucosum	Glabrous to velvety white colonies; rare strains produce yellow-brown color; rugal folds with tendency to skin into agar surface.	2–3 weeks	Microconidia rare, large, and teardrop-shaped when seen; macroconidia extremely rare but form characteristic rat-tail types when seen; many chlamydoconidia seen in chains, particularly when colony is incubated at 37°C.
Trichophyton violaceum[a]	Port wine to deep violet colony, may be heaped or flat with waxy glabrous surface; pigment may be lost on subculture.	2–3 weeks	Branched, tortuous, sterile hyphae; chlamydoconidia commonly aligned in chains.

[a] These organisms are not commonly seen in the United States.

in their clinical manifestations. Most cosmopolitan species are **anthropophilic,** or "human loving"; few are **zoophilic,** primarily infecting animals, and one is geophilic or soil associated. The *T. mentagrophytes* complex includes several zoophilic and anthropophilic species.

Generally, hairs infected with *Trichophyton* organisms do not fluoresce under the ultraviolet (UV) light of a Woods lamp. Fungal elements must be demonstrated inside, surrounding and penetrating the hair shaft or within a skin scraping to diagnose a dermatophyte infection by direct examination. Confirmation requires recovery and identification of the causative organism.

Laboratory Diagnosis

Specimen Collection, Transport, and Processing

See General Considerations for the Laboratory Diagnosis of Fungal Infections in Chapter 58.

Direct Detection Methods

Stains

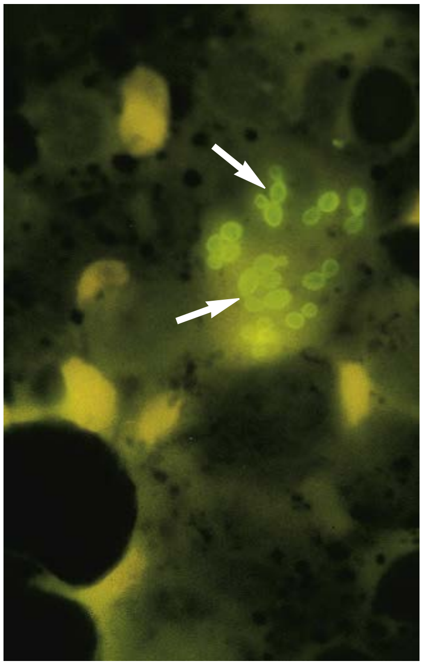
Calcofluor white or potassium hydroxide preparations reveal the presence of hyaline septate hyphae or arthroconidia (Figs. 58.4 and 59.7). Direct microscopic examination of infected hairs may reveal the hair shaft to be filled with masses of large arthroconidia (4 to 7 µm) in chains, characteristic of an **endothrix** type of invasion. In other instances, the hair shows external masses of spores that ensheathe the hair shaft; this is characteristic of the **ectothrix** type of hair invasion. Hairs infected with *Trichophyton schoenleinii* reveal hyphae and air spaces within the shaft. Evolve Procedure 59.1 describes the hair perforation test used for the differentiation of *Trichophyton* spp.

Antigen-Protein

Antigen-protein–based assays are not useful for the detection or identification of dermatophytes.

Nucleic Acid–Based Testing

Nucleic acid amplification assays for dermatophytes are not routine. Current traditional procedures are more cost effective for superficial infections.



• **Fig. 59.7** Calcofluor white stain of sputum showing intracellular yeast cells of *Histoplasma capsulatum (arrows).* The cells are 2 to 5 µm in diameter.

Cultivation

Because the dermatophytes generally present a similar microscopic appearance in infected hair, skin, or nails, final identification typically is made by culture. A summary of the colonial and microscopic morphologic features of these fungi is presented in Table 59.2. Fig. 59.8 presents an identification schema useful to the clinical laboratory for identification of commonly encountered dermatophytes. The schema begins with the microscopic features of the dermatophytes that may be visible in the initial examination of the culture. In many instances, the primary recovery medium fails to function as well as a **sporulation medium**. Often the initial growth must be subcultured onto cornmeal agar or potato dextrose agar to induce sporulation.

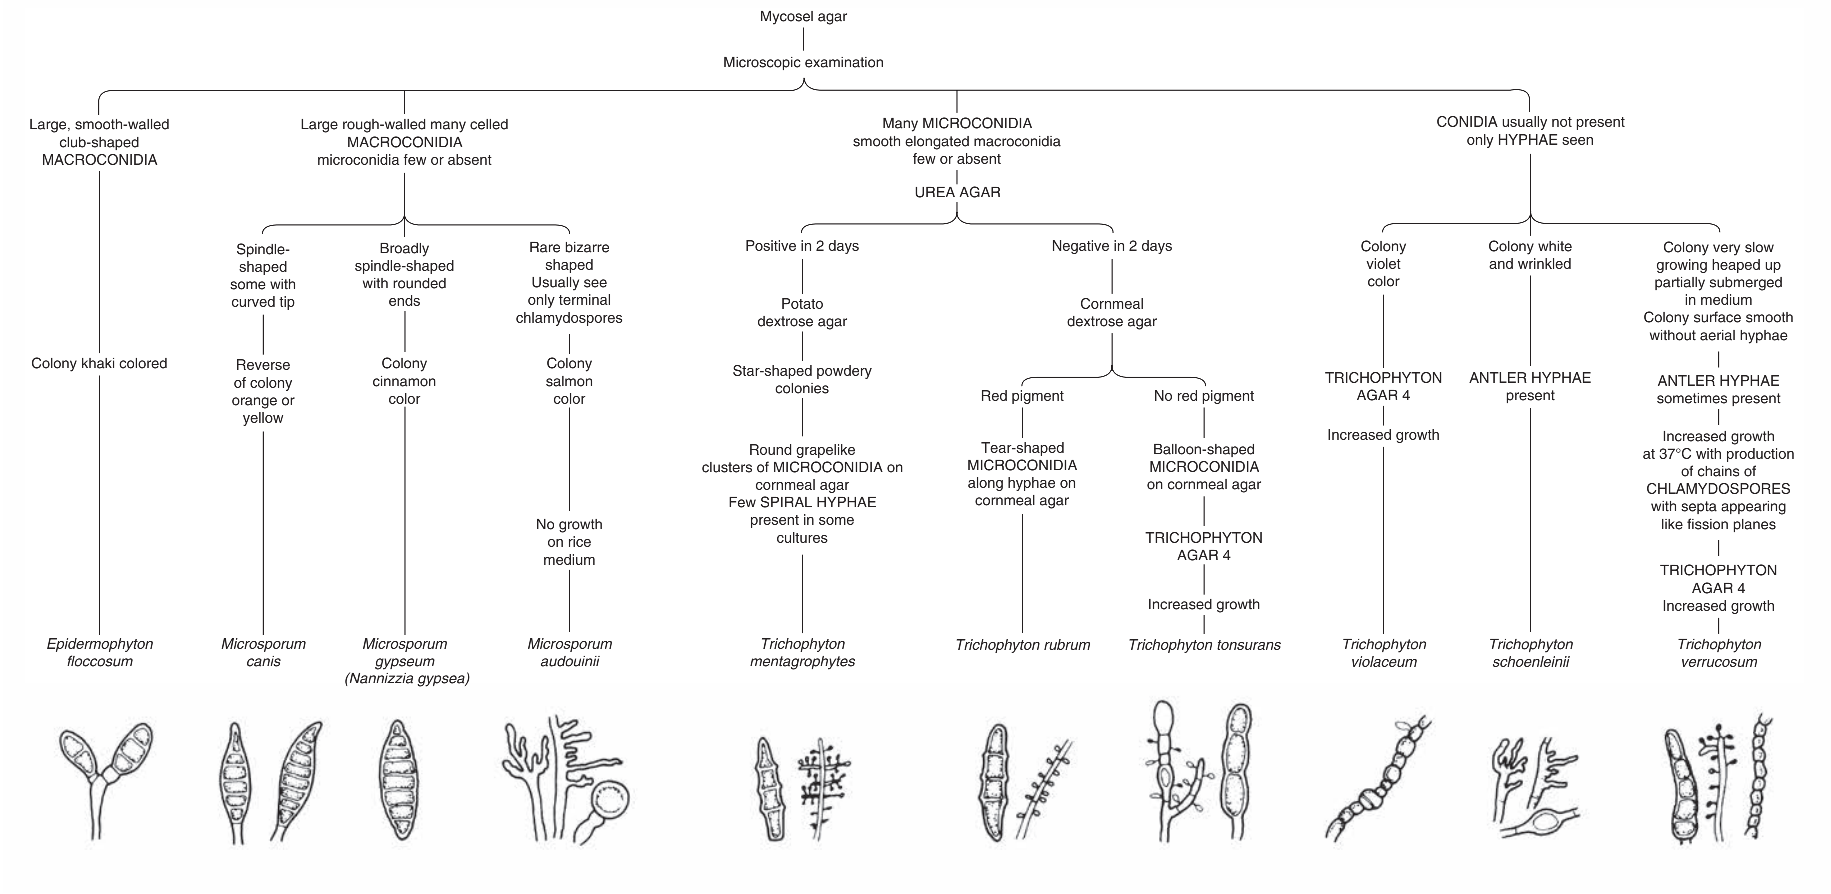
Approach to Identification

Trichophyton spp.

Microscopically, *Trichophyton* organisms are characterized by smooth, club-shaped, thin-walled macroconidia with three to eight septa ranging from 4 × 8 µm to 8 × 15 µm. The macroconidia are borne singly at the terminal ends of hyphae or on short conidiophores; the microconidia (which may be described as "birds on a fence") predominate and are usually spherical, pyriform (teardrop-shaped), or **clavate** (club-shaped) and 2 to 4 µm (Fig. 59.9). Only the common *Trichophyton* species are described here.

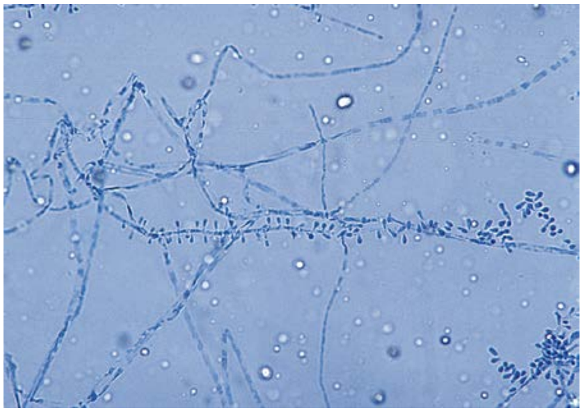
T. rubrum and *T. mentagrophytes* complex are the most common species recovered in the clinical laboratory. *T. rubrum* is a slow-growing organism that produces a flat or heaped-up colony, generally white to reddish, with a cottony or velvety surface. The characteristic cherry-red color is best observed on the reverse side of the colony; however, this is produced only after 3 to 4 weeks of incubation. Occasional strains may lack the deep red pigmentation on primary isolation. Two types of colonies may be produced: fluffy and granular. Microconidia are uncommon in most of the fluffy strains and more common in the granular strains; they occur as small, teardrop-shaped conidia often borne laterally along the sides of the hyphae (Fig. 59.9). Macroconidia are less common, although they are sometimes found in the granular strains, where they appear as thin-walled, smooth-walled, multicelled, cigar-shaped conidia with three to eight septa. *T. rubrum* has no specific nutritional requirements. It does not perforate hair *in vitro* or produce urease.

T. mentagrophytes complex produce two distinct colonial forms: the downy variety recovered from patients with tinea pedis and the granular variety recovered from lesions acquired by contact with animals. The rapidly growing colonies may appear as white to cream-colored or yellow, cottony or downy, and coarsely granular to powdery. They may produce a few spherical microconidia. The granular colonies may show evidence of red pigmentation. The reverse side of the colony is usually rose-brown, occasionally orange to deep red, and may be confused with *T. rubrum.* Granular colonies sporulate freely, with numerous small, spherical



Mycosel agar
Microscopic examination
Large, smooth-walled club-shaped MACROCONIDIA
Colony khaki colored
Epidermophyton floccosum
Large rough-walled many celled MACROCONIDIA microconidia few or absent
Spindle-shaped some with curved tip
Reverse of colony orange or yellow
Microsporum canis
Broadly spindle-shaped with rounded ends
Colony cinnamon color
Microsporum gypseum (Nannizzia gypsea)
Rare bizarre shaped Usually see only terminal chlamydospores
Colony salmon color
No growth on rice medium
Microsporum audouinii
Many MICROCONIDIA smooth elongated macroconidia few or absent
UREA AGAR
Positive in 2 days
Potato dextrose agar
Star-shaped powdery colonies
Round grapelike clusters of MICROCONIDIA on cornmeal agar Few SPIRAL HYPHAE present in some cultures
Trichophyton mentagrophytes
Negative in 2 days
Cornmeal dextrose agar
Red pigment
Tear-shaped MICROCONIDIA along hyphae on cornmeal agar
Trichophyton rubrum
No red pigment
Balloon-shaped MICROCONIDIA on cornmeal agar
TRICHOPHYTON AGAR 4
Increased growth
Trichophyton tonsurans
CONIDIA usually not present only HYPHAE seen
Colony violet color
TRICHOPHYTON AGAR 4
Increased growth
Trichophyton violaceum
Colony white and wrinkled
ANTLER HYPHAE present
Trichophyton schoenleinii
Colony very slow growing heaped up partially submerged in medium Colony surface smooth without aerial hyphae
ANTLER HYPHAE sometimes present
Increased growth at 37°C with production of chains of CHLAMYDOSPORES with septa appearing like fission planes
TRICHOPHYTON AGAR 4 Increased growth
Trichophyton verrucosum

• **Fig. 59.8** Dermatophyte identification schema. (Modified from Koneman EW, Roberts GD. *Practical Laboratory Mycology. 3rd ed.* Baltimore: Williams & Wilkins; 1985.)



• **Fig. 59.9** *Trichophyton rubrum* showing numerous pyriform microconidia borne singly on hyphae (×750).

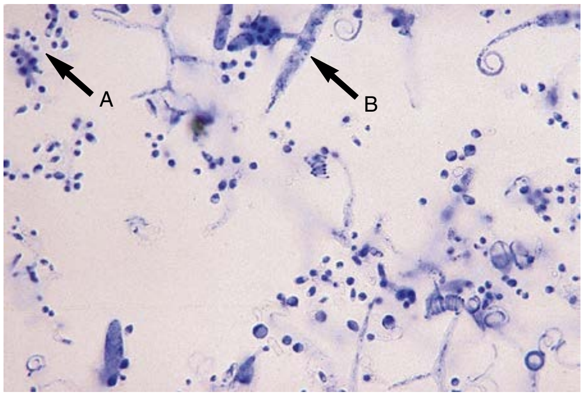
microconidia in grapelike clusters and thin-walled, smooth-walled, cigar-shaped macroconidia measuring 6 × 20 μm to 8 × 50 μm, with two to five septa (Fig. 59.10). Macroconidia characteristically exhibit a definite narrow attachment to their base. Spiral hyphae may be found in one third of the isolates recovered.

T. mentagrophytes complex species produce urease within 2 to 3 days after inoculation onto Christensen's urea agar. Unlike *T. rubrum, T. mentagrophytes* complex perforate hair (Fig. 59.11), a feature that may be used to distinguish between the two fungi when differentiation is difficult.

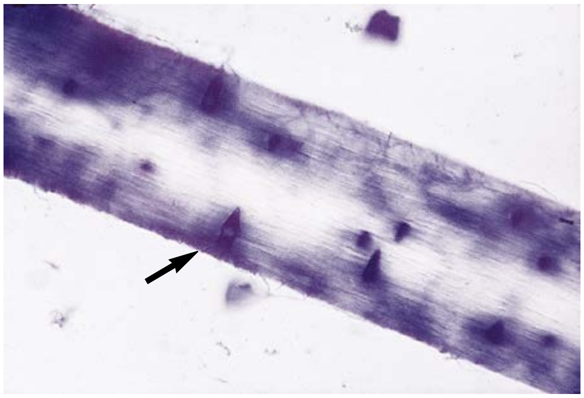
T. tonsurans is responsible for an epidemic form of tinea capitis that commonly occurs in children and occasionally in adults. It has displaced *Microsporum audouinii* as a primary cause of tinea capitis in most of the United States. The fungus causes a low-grade superficial lesion of varying severity and produces circular, scaly patches of **alopecia** (loss of hair). The stubs of hair remain in the epidermis of the scalp after the brittle hairs have broken off, which may give the typical "black dot" ringworm appearance. Because the infected hairs do not fluoresce under a Woods lamp, the physician should carefully search for the embedded stubs, using a bright light.

Cultures of *T. tonsurans* develop slowly and are typically buff to brown, wrinkled, and suedelike in appearance. The colony surface shows radial folds and often develops a craterlike depression in the center with deep fissures. The reverse side of the colony is yellowish- to reddish-brown. Microscopically, numerous microconidia with flat bases are produced on the sides of hyphae. With age, the microconidia tend to become pleomorphic, are swollen to elongated, and are referred to as balloon forms (Fig. 59.12). Chlamydoconidia are abundant in old cultures; swollen and fragmented hyphal cells resembling arthroconidia may be seen. *T. tonsurans* grows poorly on media lacking enrichments (casein agar); however, growth is greatly enhanced by the presence of thiamine or inositol in casein agar.

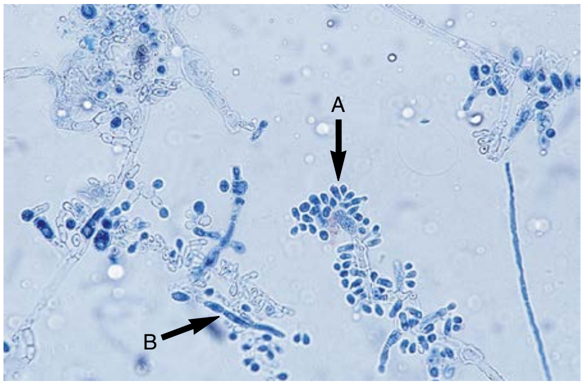
T. verrucosum causes a variety of lesions in cattle and in humans; it is most often seen in farmers, who acquire the infection from cattle. The lesions are found chiefly on the beard, neck, wrist, and back of the hands; they are deep, pustular, and inflammatory. With pressure, short stubs of hair may be recovered from the purulent lesion. Direct examination of the hair shaft reveals sheaths of isolated chains of large spores (5 to 10 μm in diameter) surrounding the hair shaft (ectothrix) and hyphae within the hair (endothrix). Masses of these conidia may also be seen in exudate from the lesions.



• **Fig. 59.10** *A, Trichophyton mentagrophytes* showing numerous microconidia in grapelike clusters. *B,* Several thin-walled macroconidia also are present (×500).



• **Fig. 59.11** Hair perforation by *Trichophyton mentagrophytes.* Wedge-shaped areas *(arrow)* illustrate hair perforation (×100).



• **Fig. 59.12** *Trichophyton tonsurans* showing numerous microconidia *(A)* that are borne singly or in clusters. A single macroconidium *(B)* (rare) is also present (×600).

T. verrucosum grows slowly (14 to 30 days); growth is enhanced at 35°C to 37°C and on media enriched with thiamine and inositol. *T. verrucosum* may be suspected when slowly growing colonies appear to embed themselves into the agar surface.

Kane and Smitka[1] described a medium for the early detection and identification of *T. verrucosum.* The ingredients for this medium are 4% casein and 0.5% yeast extract. The organism is recognized by its early hydrolysis of casein and very slow growth rate. Chains of chlamydoconidia are formed regularly at 37°C. Early detection of hydrolysis, the formation of characteristic chains of chlamydoconidia, and the restrictive slow growth rate of *T. verrucosum* differentiate it from *T. schoenleinii,* another slowly growing organism. Colonies are small, heaped, and folded; occasionally they are flat and disk-shaped. At first, they are glabrous and waxy, with a short aerial mycelium. Colonies range from gray and waxlike to bright yellow. The reverse of the colony most often is nonpigmented but may be yellow.

Microscopically, chlamydoconidia in chains and antler hyphae may be the only structures observed microscopically in cultures of *T. verrucosum* (Fig. 58.10). Chlamydoconidia may be abundant at 35°C to 37°C (Fig. 58.16). Microconidia may be produced by some cultures if the medium is enriched with yeast extract or a vitamin (Fig. 59.13). Conidia, when present, are borne laterally from the hyphae and are large and clavate. Macroconidia are rarely formed, vary considerably in size and shape, and are referred to as "rat tail" or "string bean" in appearance.

T. schoenleinii causes a severe type of infection called **favus.** It is characterized by the formation of yellowish cup-shaped crusts, or **scutulae**, on the scalp; considerable scarring of the scalp; and sometimes permanent alopecia. Infections are common among members of the same family. A distinctive invasion of the infected hair, the favic type, is demonstrated by the presence of large, inverted cones of hyphae and arthroconidia at the base of the hair follicle and branching hyphae throughout the length of the hair shaft. Longitudinal tunnels or empty spaces appear in the hair shaft where the hyphae have disintegrated. In calcofluor white or potassium hydroxide preparations, these tunnels are readily filled with fluid; air bubbles may also be seen in these tunnels.

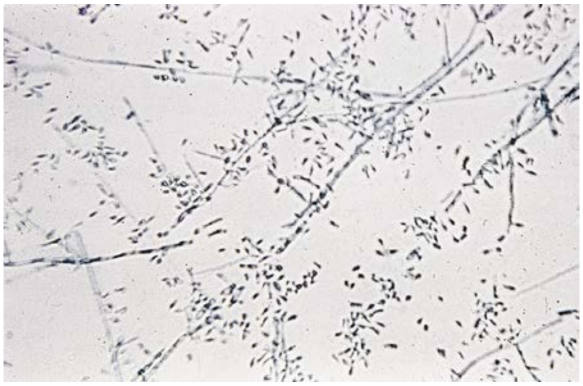
T. schoenleinii is a slowly growing organism (30 days or longer) that produces a white to light-gray colony with a waxy surface. Colonies have an irregular border consisting mostly of submerged hyphae, which tend to crack the agar. The surface of the colony is usually nonpigmented or tan, furrowed, and irregularly folded. The reverse side of the colony is usually tan or nonpigmented. Microscopically, conidia commonly are not formed. The hyphae tend to become knobby and club-shaped at the terminal ends, with the production of many short lateral and terminal branches (Fig. 59.14). Chlamydoconidia are generally numerous. All strains of *T. schoenleinii* may be grown in a vitamin-free medium and grow equally well at room temperature or at 35°C to 37°C.

Trichophyton violaceum causes an infection of the scalp and body and is seen primarily in people living in the Mediterranean region, the Middle and Far East, and Africa. Hair invasion is of the endothrix type; the typical "black dot" type of tinea capitis is observed clinically. Direct microscopic examination of a calcofluor white or potassium hydroxide preparation of the nonfluorescing hairs shows dark, thick hairs filled with masses of arthroconidia arranged in chains, similar to those seen in *T. tonsurans* infections.

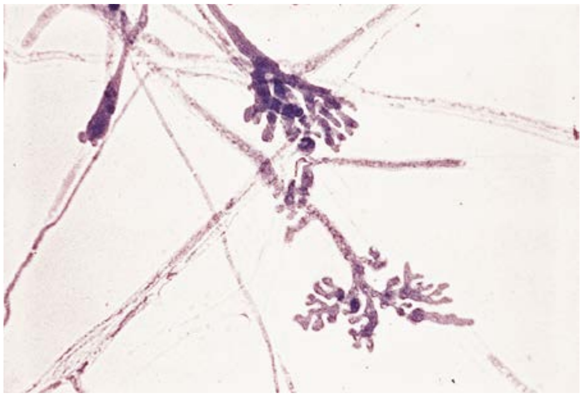
Colonies of *T. violaceum* are very slow growing, beginning as cone-shaped, cream-colored, glabrous colonies. Later these become heaped up, verrucous (warty), violet to purple, and waxy in consistency. Colonies may often be described as "port wine" in color. The reverse side of the colony is purple or nonpigmented. Older cultures may develop a velvety area of mycelium and sometimes lose their pigmentation. Microscopically, microconidia and macroconidia generally are not present; only sterile, distorted hyphae and chlamydoconidia are found. In some instances, however, swollen hyphae containing cytoplasmic granules may be seen. Growth of *T. violaceum* is enhanced on media containing thiamine.

Microsporum spp.

Species of the genus *Microsporum* are immediately recognized by the presence of large (8 to 15 µm × 35 to 150 µm),



• **Fig. 59.13** *Trichophyton verrucosum* showing microconidia, which are rarely seen (×500).



• **Fig. 59.14** *Trichophyton schoenleinii* showing swollen hyphal tips with lateral and terminal branching (favic chandeliers). Microconidia and macroconidia are absent (×500).

spindle-shaped, **echinulate** (covered with small spines), rough-walled macroconidia with thick walls (up to 4 µm) containing four or more septa (Fig. 59.15). The exception is *Microsporum nanum,* which characteristically produces macroconidia with two cells. Microconidia, when present, are small (3 to 7 µm) and club-shaped and are borne on the hyphae, either laterally or on short conidiophores. Cultures of *Microsporum* spp. develop either rapidly or slowly (5 to 14 days) and produce aerial hyphae that may be velvety, powdery, glabrous, or cottony, varying in color from whitish, to buff, to a cinnamon-brown, with varying shades on the reverse side of the colony.

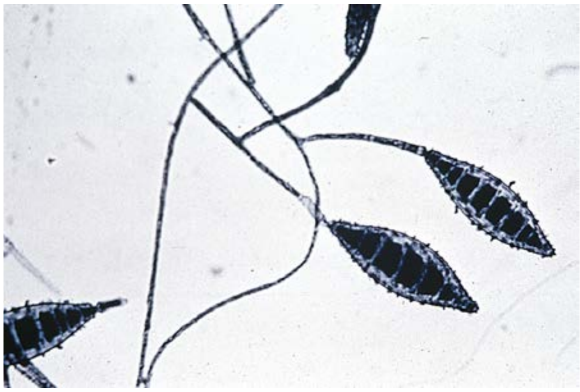
M. audouinii was once the most important cause of epidemic tinea capitis among school children in the United States. This organism is anthropophilic and is spread directly by means of infected hairs on hats, caps, upholstery, combs, or barber clippers. Most infections are chronic; some heal spontaneously, whereas others may persist for several years. Infected hair shafts fluoresce yellow-green under a Woods lamp. Colonies of *M. audouinii* generally grow more slowly than other members of the genus *Microsporum* (10 to 21 days), and they produce a velvety aerial mycelium that is colorless to light gray to tan. The reverse side often appears salmon-pink to reddish-brown. Colonies of *M. audouinii* do not usually sporulate in culture. The addition of yeast extract may stimulate growth and the production of macroconidia in some instances. Most commonly, atypical vegetative forms, such as terminal chlamydoconidia and antler and racquet hyphae, are the only clues to the identification of this organism. *M. audouinii* often is identified as a cause of infection by exclusion of all the other dermatophytes.

M. canis is primarily a pathogen of animals (zoophilic); it is the most common cause of ringworm infection in dogs and cats in the United States. Children and adults acquire the disease through contact with infected animals, particularly puppies and kittens, although human-to-human transfer has been reported. Hairs infected with *M. canis* fluoresce a bright yellow-green under a Woods lamp, which is a useful tool for screening pets as possible sources of human infection. Direct examination of a calcofluor white or potassium hydroxide preparation of infected hairs reveals small spores (2 to 3 µm) outside the hair. Culture must be performed to provide the specific identification.

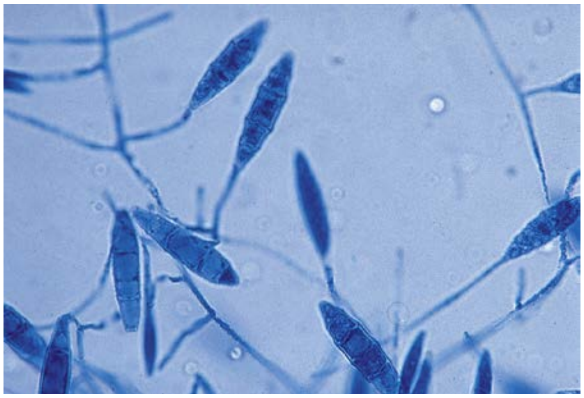
Colonies of *M. canis* grow rapidly, are granular or fluffy with a feathery border, white to buff, and characteristically have a lemon-yellow or yellow-orange fringe at the periphery. On aging, the colony becomes dense and cottony and a deeper brownish-yellow or -orange and frequently shows an area of heavy growth in the center. The reverse side of the colony is bright yellow, becoming orange- or reddish-brown with age. In rare cases, strains are recovered that show no reverse-side pigment. Microscopically, *M. canis* shows an abundance of large (15 to 20 µm × 60 to 125 µm), spindle-shaped, multisegmented (four to eight) macroconidia with curved ends (Fig. 59.15). These are thick-walled with spiny (echinulate) projections on their surfaces. Microconidia are usually few in number, but large numbers occasionally may be seen.

Microsporum gypseum complex are free-living fungi of the soil (**geophilic**) that only rarely causes human or animal infection and occasionally may be seen in the clinical laboratory. Infected hairs generally do not fluoresce under a Woods lamp. However, microscopic examination of the infected hairs shows them to be irregularly covered with clusters of spores (5 to 8 µm), some in chains. These arthroconidia of the ectothrix type are considerably larger than those of other *Microsporum* species.

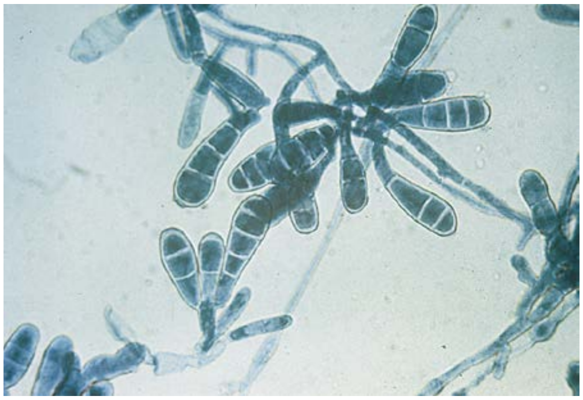
M. gypseum complex species grow rapidly as flat, irregularly fringed colonies with a coarse, powdery surface that appear to be buff or cinnamon colored. The underside of the colony is orange to brownish. Microscopically, macroconidia are seen in large numbers and are characteristically large, are ellipsoidal, have rounded ends, and are multisegmented (three to nine) with echinulated surfaces (Fig. 59.16). Although they are spindle-shaped, these macroconidia are not as pointed at the distal ends as those of *M. canis.* The appearance of the colonial and microscopic morphologic features is sufficient to make the distinction between *M. gypseum* complex and *M. canis.*



• **Fig. 59.15** Large, rough-walled macroconidia of *Microsporum canis* (×430).



• **Fig. 59.16** *Microsporum gypseum* showing ellipsoidal, multicelled macroconidia (×750).



• **Fig. 59.17** *Epidermophyton floccosum* showing numerous smooth, multiseptate, thin-walled macroconidia that appear club-shaped (×1000).

Epidermophyton sp.

E. floccosum, the only member of the genus *Epidermophyton,* is a common cause of tinea cruris and tinea pedis. Because this organism is susceptible to cold, specimens submitted for dermatophyte culture should not be refrigerated before culture, and cultures should not be stored at 4°C. In direct examination of skin scrapings using the calcofluor white or potassium hydroxide preparation, the fungus is seen as fine branching hyphae. *E. floccosum* grows slowly; the growth appears olive-green to khaki, with the periphery surrounded by a dull orange-brown. After several weeks, colonies develop a cottony white aerial mycelium that completely overgrows the colony; the mycelium is sterile and remains so even after subculture. Microscopically, numerous smooth, thin-walled, club-shaped, multiseptate (2 to 4 µm) macroconidia are seen (Fig. 59.17). They are rounded at the tip and are borne singly on a conidiophore or in groups of two or three. Microconidia are absent, spiral hyphae are rare, and chlamydoconidia are usually numerous. The absence of microconidia is useful for differentiating this organism from *Trichophyton* spp.; the morphology of the macroconidia (smooth, thin-walled) is useful for differentiating it from *Microsporum* spp.

Serologic Testing

Serology is not useful for the diagnosis of disease caused by dermatophytes.

The Opportunistic Mycoses

General Characteristics

The tissue-invasive opportunistic mycoses are a group of fungal infections that occur almost exclusively in immunocompromised patients. Opportunistic fungal infections are typically identified in a host compromised by some underlying disease process, such as lymphoma, leukemia, diabetes mellitus, or another defect of the immune system. Many patients, particularly those who undergo some type of transplantation, are placed on treatment with corticosteroids, cytotoxic drugs, or other immunosuppressive agents to control rejection of the transplanted organ. Many fungi previously believed to be nonpathogenic are now recognized as etiologic agents of opportunistic fungal infections. Because most of the organisms known to cause infection in this group of patients are commonly encountered in the clinical laboratory as **saprobes** (saprophytic fungi), it may be impossible for the laboratorian to determine the clinical significance of these isolates recovered from clinical specimens. Laboratories must identify and report completely the presence of all fungi recovered, because each is a potential pathogen. Many of the organisms associated with opportunistic infections are acquired during construction, demolition, or remodeling of buildings or are hospital-acquired. Other information about the specific clinical aspects of the opportunistic fungal infections is discussed with the individual organism.

Epidemiology and Pathogenesis

Aspergillus spp.

Several *Aspergillus* spp. are among the most commonly encountered fungi in the clinical laboratory (Table 59.4); any are potentially pathogenic in an immunocompromised host, but some species are more commonly associated with disease. There are over 350 species of *Aspergillus* widespread in the environment, where they colonize grain, leaves, soil, and living plants. Conidia of the aspergilli are easily dispersed into the environment, and humans become infected by inhaling them. Assessing the significance of *Aspergillus* organisms in a clinical specimen may be difficult. They are commonly found in cultures of respiratory secretions, skin scrapings, and other specimens.

Pathogenesis and Spectrum of Disease

Aspergillus spp.

Aspergillus spp. can cause disease by ingestion of mycotoxins, traumatic inoculation, or inhalation. *Aspergillus* spp. are capable of causing disseminated infection, as is seen in immunocompromised patients, but also of causing a wide variety of other types of infections, including a pulmonary or sinus fungus ball, allergic bronchopulmonary aspergillosis, external **otomycosis** (a fungus ball of the external auditory canal), mycotic keratitis, **onychomycosis** (infection of the nail and nail bed), sinusitis, endocarditis, and central nervous system (CNS) infection. Most often, immunocompromised patients acquire a primary pulmonary infection that becomes rapidly progressive and may disseminate to virtually any organ.

Fusarium spp. and Other Hyaline Septate Opportunistic Molds

Molecular phylogenetic studies have indicated that organisms that were previously considered individual more accurately represent species complexes containing more than 60 different species. The most commonly isolated organisms within this group are within the *Fusarium solani* species complex, including *F. petroliphilum, F. keratoplasticum, F. falciforme,*

TABLE 59.4 Clinically Relevant *Aspergillus* spp.

Species	Macroscopic Morphology	Microscopic Morphology	Seriation
A. fumigatus	Dark blue-green to gray with age; reverse variable	Smooth nonpigmented to green conidiophores short to long with a foot cell at the base; dome shaped vesicle with spherical, rough-walled conidia. Septate hyphae.	Uniseriate; columnar.
A. flavus	Yellow to dark yellow-green	Rough nonpigmented conidiophore; subglobose to globose vesicle; conidia globose (spherical) or ellipsoidal.	Uniseriate and biseriate; loosely radiate or splits into columns with age.
A. nidulans[a]	Dark green, buff to purple-brown; reverse red to purple	Smooth brown conidiophore; hemispherical vesicle; rough, globose conidia; cleistothecia globose and reddish-brown.	Biseriate columnar.
A. niger	Black with white margin, may have yellow surface mycelium; reverse non-pigmented to pale yellow	Smooth nonpigmented to brown conidiophore; globose vesicle; thick-walled brownish-black, rough conidia.	Biseriate radiate that splits into columns with age.
A. terreus	Tan to cinnamon-brown	Smooth, nonpigmented conidiophore; dome-shaped vesicle; smooth subglobose, globose, or elliptical conidia. Single-celled conidia (aleurioconidia) may be present on submerged hyphae.	Biseriate columnar.
A. ustus	Brown-gray or olive-gray; reverse yellow to red or purple	Smooth nonpigmented to brown conidiophore; subglobose to globose vesicle; rough, globose conidia.	Biseriate; radiate to loosely columnar.
A. versicolor	Green to gray or tan with patches of pink or yellow; reverse deep red to variable	Ovate to elliptical vesicle; globose echinulate conidia.	Biseriate; radiate to loosely columnar.

[a]Toxigenic species.

F. solani, F. lichenicola, and *F. neocosmoporiellum.* The second most common group responsible for human disease is the *Fusarium oxysporum* species complex. Additional groups of *Fusarium* spp. that are clinically relevant include the *Fusarium fujikuroi* species complex, *Fusarium incarnatum-Fusarium equiseti* species complex, *Fusarium chlamydosporum* species complex, and the *Fusarium dimerum* species complex.

Infection caused by *Fusarium* spp. and other hyaline septate monomorphic molds is becoming more common, particularly in immunocompromised patients. These organisms are common environmental microbiota and have long been known to cause mycotic keratitis after traumatic implantation into the cornea. Oftentimes infections are associated with the consumption of grains contaminated with trichothecene mycotoxins produced by *F. sporotrichioides* or *F. poae*. Disseminated fusariosis is commonly accompanied by fungemia, which is detected by routine blood culture systems. In contrast, the aspergilli are rarely recovered from blood culture, even in cases of endovascular infection. Necrotic skin lesions are common with disseminated fusariosis. Other types of infection caused by *Fusarium* spp. include sinusitis, wound (burn) infection, allergic fungal sinusitis, and endophthalmitis.

Fusarium spp. are commonly recovered from respiratory tract secretions, skin, and other specimens from patients who show no evidence of infection. Interpretation of culture results rests with the clinician and is often assisted by correlation with histopathology results. *Geotrichum candidum* is an uncommon cause of infection but has been shown to cause wound infections and oral thrush; it is an opportunistic pathogen in immunocompromised hosts. *Acremonium* spp. are also recognized as important pathogens in immunocompromised hosts; these have been associated with disseminated infection, fungemia, subcutaneous lesions, and esophagitis. *Penicillium* spp. includes more than 250 recognized species and are among the most common organisms recovered by the clinical laboratory. In North America, they are rarely associated with invasive fungal disease. However, they may be a cause of allergic bronchopulmonary penicilliosis or chronic allergic sinusitis. *Talaromyces marneffei* is an important and emerging pathogen in Southeast Asia and is discussed further in the section on dimorphic pathogens. Of the *Purpureocillium* species, *Purpureocillium lilacinum* appears to be the most pathogenic species and has been associated with endophthalmitis, cutaneous infections, and arthritis. *Paecilomyces variotii* complex includes five species with *P. variotii* and *P. formosus* being the most important pathogens, causing endocarditis, fungemia, and invasive disease.

A variety of other saprobic fungi are not discussed here in detail and may be encountered in the clinical laboratory but are seen less commonly. Several are included in Table 59.5. Other references are recommended for further information about identification of these organisms.

Laboratory Diagnosis

Specimen Collection, Transport, and Processing

See General Considerations for the Laboratory Diagnosis of Fungal Infections in Chapter 58.

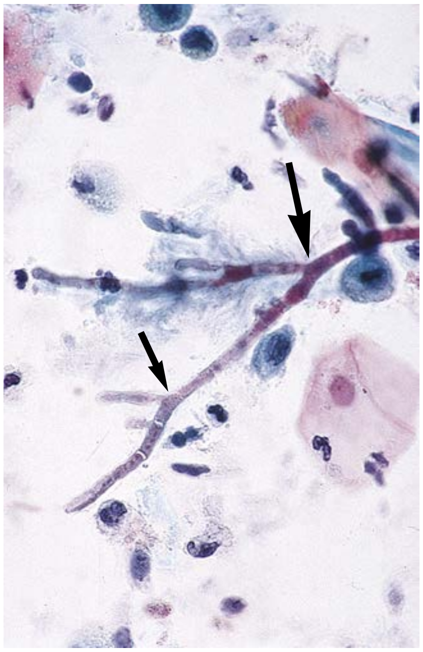
Direct Detection Methods

Stains

Specimens submitted for direct microscopic examination containing organisms in this group demonstrate septate hyphae that usually show evidence of dichotomous branching, often of 45 degrees (Fig. 59.18). In addition, some hyphae may have rounded thick-walled cells. Although often considered to represent an *Aspergillus* species, these

TABLE 59.5 **Other Opportunistic Fungal Organisms**

Genus	Species	Clinical Significance	Macroscopic Morphology	Microscopic Morphology
Acrophialophora spp.	*A. fusispora* *A. levis* *A. seudatica*	Associated with colonization in cystic fibrosis patients; keratitis, pulmonary infections, and brain abscesses.	Pale white and darken centrally to a gray or brown as the colony ages.	Unbranched, brown echinulate conidiophores, anchored by a foot-cell. Conidia are in chains and may have a distinct band.
Arthrographis sp.	*A. kalrae*	Rare opportunist that has been recovered from skin, lung, corneal ulcers, and sinusitis.	White, appear creamy, yeastlike on artificial media. Become hyphal and buff with yellow reverse.	Treelike conidiophores with lateral branches; arthroconidia.
Beauveria sp.	*B. bassiana*	Limited virulence in humans; has been isolated in human cases of keratitis.	Colonies are yellow to white.	Produces solitary conidia sympoidally arranged.
Chrysosporium sp.	*C. zonatum*	Associated with cases of pneumonia and osteomyelitis.	Colonies are yellow to white.	Produces solitary, usually single-celled aleurioconidia that may be smooth to rough.
Coniochaeta spp.	*C. mutabilis* *C. hoffmannii*	Has been isolated in endocarditis and sinusitis in immunocompromised patients.	Colonies are white to salmon, may be moist with darkening black patches.	Phialides are short, stumpy without a basal septum. *C. mutabilis* forms brown chlamydospores.
Nannizziopsis sp.	*N. hominis*		White to yellow.	Produces solitary, usually single-celled aleurioconidia. Arthroconidia may be present.
Onychocola sp.	*O. canadensis*	Associated with onychomycosis.	Raised white to yellow to grayish white.	Two-celled conidia are cylindrical or swollen arthroconidia forming chains.
Parengyodontium sp.	*P. album*	Identified in cases of endocarditis.		Produces solitary conidia sympoidally arranged.
Phialemonium spp.	*P. obovatum*	Associated with endocarditis.		
Rasamsonia spp.	*R. aegroticola* *R. eburnea* *R. piperina*	Emerging pathogen in cystic fibrosis patients.		Cuneiform or ellipsoidal conidia.
Sarocladium spp. (previously *Acremonium*)		Several cases of invasive disease have been reported.		
Schizophyllum sp.	*S. radiatum*	Allergy related sinusitis and pulmonary disease.		
Thermothelomyces sp.	*T. thermophila*	Known to cause fatal aortic vasculitis and associated with cerebral abscess and osteomyelitis following traumatic injection.		Produces solitary, usually single-celled aleurioconidia.



• **Fig. 59.18** Papanicolaou staining of sputum shows the dichotomously branching septate hyphae *(arrows)* of *Aspergillus fumigatus.*

cannot be reliably distinguished from hyphae of *Fusarium* spp., *Pseudallescheria boydii,* or other hyaline molds.

Antigen-Protein

Antigen-protein–based assays are used to monitor patients at high risk for developing invasive fungal infections. One of these assays, the galactomannan (GM) assay, targets GM, a carbohydrate molecule with a mannose backbone that is released from the cell wall of *Aspergillus* spp. *Aspergillus* spp. are the most common source of invasive fungal infections caused by the hyaline septate molds (i.e., **hyalohyphomycosis**). However, the assay may yield false-positive results because of cross-reactivity with other non-*Aspergillus* molds, including *Penicillium, Rhodotorula, Fusarium, Cryptococcus, Blastomyces, Histoplasma capsulatum, Paecilomyces*, and *Alternaria* spp.

The beta-D-glucan assay is designed to detect antigens common to all clinically important fungi. Beta-D-glucan can be detected in the serum of patients infected with systemic aspergillosis. Because the molecule is present in a variety of fungal isolates, the predictive value is not specific to infections with *Aspergillus* spp. It is recommended that the GM and beta-D-glucan assay be used in combination with other diagnostic tests such as nucleic acid amplification for optimal sensitivity and specificity.

Nucleic Acid–Based Tests

Nucleic acid amplification assays are not commonly performed to detect or identify the opportunistic fungi. However, a variety of both broad-range assays (those that detect all fungi) and species-specific assays have been developed and in specialized centers may be used for patient care. These panfungal PCR assays may be used for initial patient diagnosis followed by DNA sequencing for identification. Multiplex amplification and real-time PCR assays have been developed for the detection of systemic aspergillosis in respiratory specimens, blood, tissue, and CSF. These assays vary significantly in their performance from 60% to 100% specificity and 40% to 100% sensitivity.

Matrix-Assisted Laser Desorption Ionization Time-of-Flight Mass Spectrometry

The use of MALDI-TOF MS for the identification of fungal isolates has the potential to provide quick and accurate species identification. Numerous studies have demonstrated the utility of this technique for the identification of *Aspergillus* spp. and other fungal organisms. The performance of MALDI-TOF MS for the identification of *Aspergillus* spp. has been reported for both young and old colonies with a 98.6% correct identification.

Cultivation

Because aspergilli are commonly recovered, it is imperative that the organism be demonstrated in the direct microscopic examination of fresh clinical specimens or that it be recovered repeatedly from patients with a compatible clinical picture to ensure that the organism is clinically significant. Correlation with biopsy results is the best means of establishing the significance of an isolate. Most *Aspergillus* spp. are susceptible to cycloheximide. Specimens submitted for recovery or subculture of these species should be inoculated onto media that lack this ingredient.

Aspergillus fumigatus is the most commonly recovered species from immunocompromised patients; moreover, it is the species most often seen in the clinical laboratory. *Aspergillus flavus* sometimes is recovered from immunocompromised patients and represents a common isolate in the clinical microbiology laboratory. Recovery of *A. fumigatus* or *A. flavus* from surveillance (nasal) cultures has been correlated with subsequent invasive aspergillosis; however, the absence of a positive nasal culture does not preclude infection. *Aspergillus niger* is commonly seen in the clinical laboratory, but its association with clinical disease is somewhat limited; this organism is a cause of fungus ball and otitis externa. *Aspergillus terreus* is a significant cause of infection in immunocompromised patients, but its frequency of recovery is much lower than that of the previously mentioned species. However, correct identification of *A. terreus* is important because it is innately resistant to amphotericin B.

Approach to Identification

Aspergillus spp.

A. fumigatus is a rapidly growing mold (2 to 6 days) that produces a fluffy to granular, white to blue-green colony. Mature sporulating colonies most often have a blue-green, powdery appearance. Microscopically, *A. fumigatus* is characterized by the presence of septate hyphae and short or long conidiophores with a characteristic "foot cell" at their base. The foot cell is T- or L-shaped at the base of the conidiophore, but it is not a separate cell. The tip of the conidiophore expands into a large, dome-shaped vesicle with bottle-shaped phialides covering the upper half or two thirds of its surface. Long chains of small (2 to 3 µm in diameter), spherical, rough-walled, green conidia form a columnar mass on the vesicle (Fig. 59.19). Cultures of *A. fumigatus* are thermotolerant and able to withstand temperatures up to 45°C.

A. flavus is a somewhat more rapidly growing species (1 to 5 days) that produces a yellow-green colony. Microscopically, vesicles are globose, and phialides are produced directly from the vesicle surface **(uniseriate)** or from a primary row of cells called metulae (**biseriate**). The phialides give rise to short chains of yellow-orange elliptical or spherical conidia that become roughened on the surface with age (Fig. 59.20). The conidiophore of *A. flavus* is also coarsely roughened near the vesicle.

A. niger produces darkly pigmented, roughened spores macroscopically, but microscopically its hyphae are hyaline and septate, as are those of other aspergilli (i.e., it is not melanized). *A. niger* produces mature colonies within 2 to 6 days. Growth begins initially as a yellow colony that soon develops a black, dotted surface as conidia are produced. With age, the colony becomes jet black and powdery, but the reverse remains buff or cream colored; this occurs on any culture medium. Microscopically, *A. niger* shows septate hyphae, long conidiophores supporting spherical vesicles giving rise to large metulae, and smaller phialides (biseriate), from which long chains of brown to black, rough-walled conidia are produced (Fig. 59.21). The entire surface of the vesicle is involved in sporulation.

A. terreus is less commonly seen in the clinical laboratory; it produces tan colonies that resemble cinnamon. Vesicles are hemispherical, as seen microscopically, and phialides cover the entire surface and are produced from a primary row of metulae (biseriate). Phialides produce globose to elliptical conidia arranged in chains. This species produces larger cells, **aleurioconidia,** which are found on submerged hyphae (Fig. 59.22).

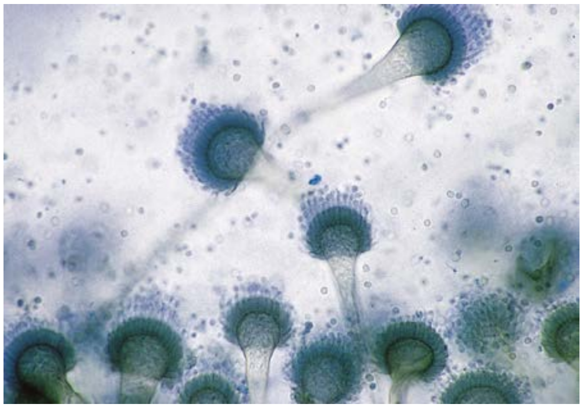
Serologic Testing

The use of serology for *Aspergillus* spp. has been limited to assistance in the diagnosis of chronic or allergic forms of bronchopulmonary aspergillosis and fungus ball.

Serology currently has no value for the diagnosis of disseminated aspergillosis.

Fusarium spp.

Colonies of *Fusarium* spp. grow rapidly, within 2 to 5 days, and are fluffy to cottony and may be pink, purple, yellow, green, or other colors, depending on the species. Microscopically, the hyphae are small and septate



• **Fig. 59.19** *Aspergillus fumigatus* conidiophore and conidia (×400).

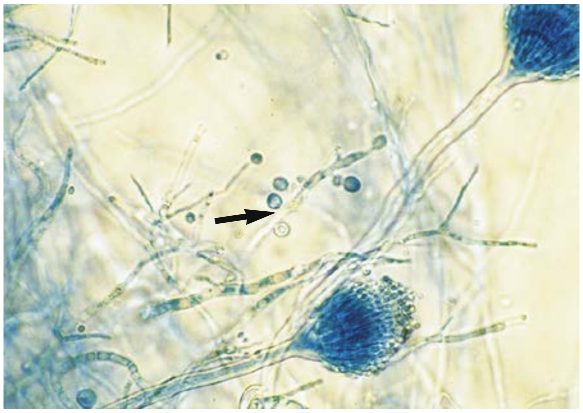
• **Fig. 59.21** *Aspergillus niger* showing a larger spherical vesicle that gives rise to metulae, phialides, and conidia (×750).



• **Fig. 59.22** *Aspergillus terreus* showing typical head of *Aspergillus* and aleurioconidia *(arrow)* found on submerged hyphae of this species (×500).

and give rise to phialides producing either single-celled microconidia, usually borne in gelatinous heads similar to those seen in *Acremonium* spp. (Fig. 58.17) or large, multicelled macroconidia that are sickle- or boat-shaped and contain numerous septations (Fig. 59.23). Some cultures of *Fusarium* spp. commonly produce numerous chlamydoconidia. The most common medium used to induce sporulation is cornmeal agar. The keys to identification of *Fusarium* spp. are based on growth on potato dextrose agar.

Geotrichum candidum

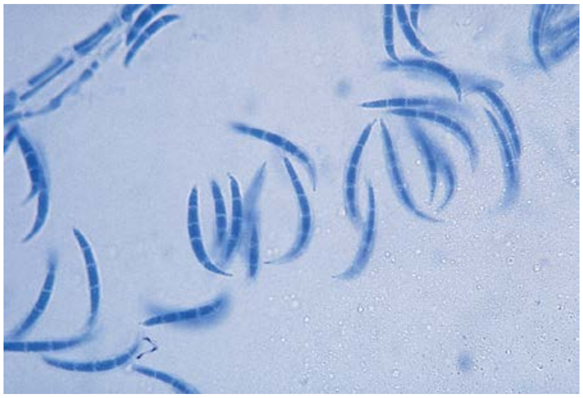
G. candidum often initially appears as a white to cream-colored, yeastlike colony; some isolates may appear as white, powdery molds. Hyphae are septate and produce numerous rectangular to cylindrical to barrel-shaped arthroconidia (Fig. 59.24). Arthroconidia do not alternate but are contiguous, in contrast to *Coccidioides* spp. (Fig. 59.25). Blastoconidia are not produced.

Acremonium spp.

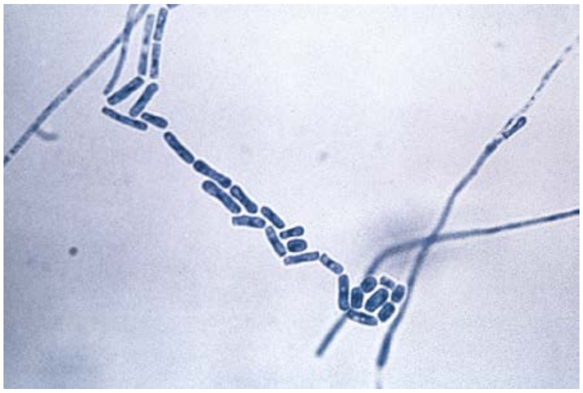
The *Acremonium* spp. are a polyphyletic group that includes approximately 100 species. Molecular analysis is currently underway and will undoubtedly result in some additional restructuring of this group. Colonies of *Acremonium* spp. are rapid growing and may appear yeastlike when initial growth is observed. Mature colonies become white to gray to rose or reddish-orange. Microscopically, small septate hyphae that produce single, unbranched, tubelike phialides are observed. Phialides give rise to clusters of elliptical, single-celled conidia contained in a gelatinous cluster at the tip of the phialide (Fig. 58.17). The most frequently encountered species in the United States are *A. kiliense* and *A. schlerotigenum-A. egyptiacum* group.

Penicillium spp. and *Talaromyces marneffei*

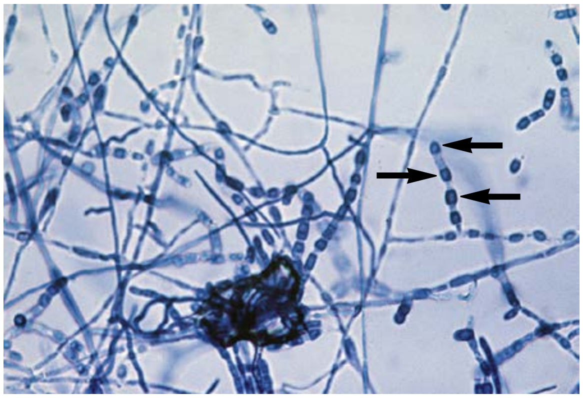
The genus *Penicillium* includes three subgenera: *Aspergilloides, Furcatum*, and *Penicillium*. *Talaromyces* is the only species (formerly *Penicillium* sp.) that is considered a true fungal pathogen and not an opportunist. Colonies of *Penicillium* spp. are most commonly shades of green or blue-green, but pink, white, or other colors may be seen. The surface of the colonies may be velvety to powdery because of the presence of conidia. Microscopically, hyphae are hyaline and septate and produce brushlike conidiophores (i.e., penicilli). Conidiophores produce metulae from which flask-shaped phialides producing chains of conidia arise (Fig. 59.26). *T. marneffei* is discussed in the section on hyaline, septate, dimorphic molds.



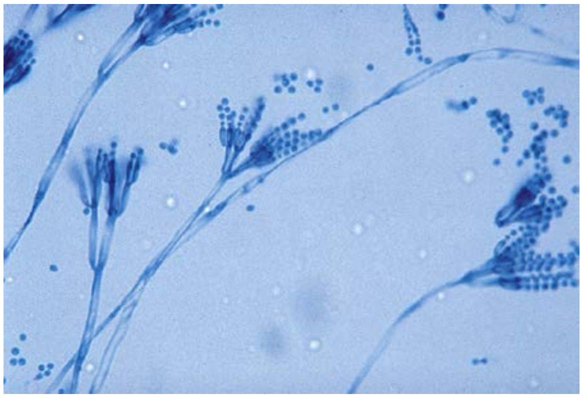
• **Fig. 59.23** *Fusarium* spp. showing characteristic multicelled, sickle-shaped macroconidia (×500).



• **Fig. 59.24** *Geotrichum candidum* showing numerous arthroconidia. (Note that arthroconidia do not alternate with a clear (dysjunctor) cell, as in the case of *Coccidioides* (×430).)



• **Fig. 59.25** Mycelial form of *Coccidioides* spp. showing numerous thick-walled, rectangular, or barrel-shaped *(arrows)* alternate arthroconidia (×500).



• **Fig. 59.26** *Penicillium* spp. showing typical brushlike conidiophores (penicilli) (×430).

Paecilomyces spp.

Colonies of *Paecilomyces* spp. are often velvety, tan to olive-brown, and somewhat powdery. Microscopically, *Paecilomyces* spp. resemble *Penicillium* spp. in that a penicillus is formed. However, the phialides of *Paecilomyces* spp. are long, delicate, and tapering (Fig. 59.27), in contrast to the more blunted phialides of *Penicillium* spp. The penicillus produces numerous chains of small, oval conidia that are easily dislodged. Single phialides producing chains of conidia may also be present.

Purpureocillium spp.

P. lilacinum exhibits colonies that are considered lilac in color exhibiting shades of lavender to pink. Chlamydospores are absent. The genus demonstrates a slower growth rate than *Paecilomyces* spp. Optimal growth temperature is 25°C to 33°C.

Scopulariopsis spp.

Scopulariopsis brevicaulis, S. asperula, and *S. candida* have been associated with onychomycosis, pulmonary infection, fungus ball, and invasive fungal disease in immunocompromised hosts. Colonies of *Scopulariopsis* spp. initially appear white but later become light brown and powdery. Colonies often resemble those of *M. gypseum.* Microscopically, a *Scopulariopsis* resembles a large *Penicillium* at first glance, because a rudimentary penicillus is produced. **Annellophores** produce the flask-shaped **annelides,** which support the lemon-shaped conidia in chains. Conidia are large, have a flat base, and are rough-walled (Fig. 59.28). The *Scopulariopsis* spp. include both hyaline and dematiaceous species. *Scopulariopsis brumptii* has been reported to have caused a brain abscess in a liver transplant patient and invasive infection in bone marrow recipients. *S. candida* and *S. acremonium* have been identified in association with invasive sinusitis.

Serologic Testing

Serology currently has no value for the diagnosis of the opportunistic disseminated fungal infections discussed.

Systemic Mycoses

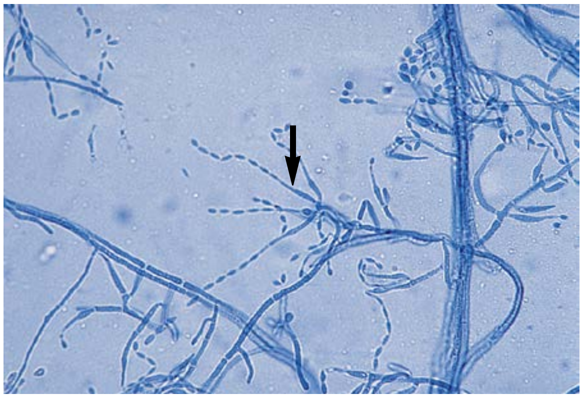
As with many other groups of clinically relevant fungi, significant changes have occurred in the classification and taxonomy of these organisms. *H. capsulatum* is now divided into eight clades (biological taxa claiming a common ancestor), or varieties. Seven of these varieties comprise genetically and geographically distinct populations representing a species; however, the *Histoplasma* var. *duboisii,* the African containing clade, demonstrates the same mitochondrial pattern as the *H. capsulatum* var. *capsulatum* of North and South America. *H. capsulatum* is used throughout this section as the primary isolate of interest.

The genera *Blastomyces* and *Coccidioides* have traditionally been representative of single species, *Blastomyces dermatitidis* and *Coccidioides immitis.* More recent characterization has revealed the existence of a subspecies or separate species in the genus *Blastomyces, Blastomyces gilchristii.* Polyphasic taxonomic analysis has also revealed a correlation between genotypic characteristics of these organisms and clinical phenotypic presentations. Additional species have now been proposed: *B. percursus, B. parvus* (formerly *Emmonsia parva*), *B. helicus* (formerly *Emmonsia helica*), and *B. silverae*. In addition, *Coccidioides* now comprises two species: *C. immitis* that includes all isolates from California and Washington State and *Coccidioides posadasii,* which comprises all other isolates.

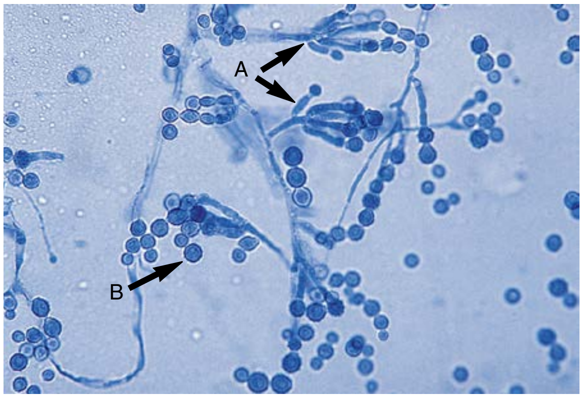
Phylogenetic analysis has indicated that *Paracoccidioides brasiliensis* can be subdivided into at least three distinct species. Several new species are proposed based on geographic regions of endemicity and include *P. lutzii, P. americana, P. restrepiensis*, and *P. venezuelensis.*

The new genus *Emergomyces* contains many of the organisms previously included in the genus *Emmonsia. Emergomyces* includes *Es. pasteurianus* as the type species (previously *Emmonsia pasteuriana*), and four new species: *Es. africanus, Es. orientalis, Es. canadensis*, and *Es. europaeus.* Each species differs in yeast size and geographic distribution.

Emmonsia crescens can be found in the soil and infects humans in North, Central, and South America as well as in Europe, Asia, and Africa. The distribution of disease associated with this fungi is unclear and further analysis is needed.



• **Fig. 59.27** *Paecilomyces* spp. showing long, tapering, delicate phialides *(arrow).*



• **Fig. 59.28** *Scopulariopsis* spp. showing a large penicillus *(A)* with echinulate conidia *(B)* (×430).

General Characteristics

Most of the dimorphic fungi produce systemic fungal infections that may involve any of the internal organs of the body, including lymph nodes, bone, subcutaneous tissue, meninges, and skin. The dimorphic fungal pathogens most commonly encountered in North America are *H. capsulatum, Blastomyces* spp., and *Coccidioides* spp. *Emmonsia* spp., *Paracoccidioides* spp., and *Emergomyces* spp. are geographically distributed throughout Central and South America. Asymptomatic or subclinical infection is common with *H. capsulatum* and *Coccidioides* and may go unrecognized clinically. These infections may be detectable only by serology or after histopathologic review of tissues removed because of lesions found during a **roentgenographic examination.**

Symptomatic infections may present signs of a mild or more severe but self-limited disease, with positive supportive evidence from cultural or immunologic findings. Patients with disseminated or progressive infection have severe symptoms, with spread of the initial disease, often from a pulmonary locus, to several distant organs. However, some cases of disseminated infection may show little in the way of signs or symptoms of disease for long periods, only to undergo exacerbation later. Immunocompromised patients most often present with disseminated infection, particularly those with advanced human immunodeficiency virus (HIV) infection (i.e., acquired immunodeficiency syndrome [AIDS]) or those receiving long-term corticosteroid therapy.

The classic term systemic mycoses, used to refer to the dimorphic fungi, is somewhat misleading, because other fungi, including *Cryptococcus neoformans* complex, *Candida albicans* complex, and *Aspergillus* spp., may also cause disseminated systemic infections.

Epidemiology

Blastomyces spp.

B. dermatitidis is uncommon as an opportunistic pathogen but may cause aggressive disease in immunocompromised individuals, producing a chronic infection that contains a mixture of suppurative and granulomatous inflammation. The disease (**blastomycosis**) is most commonly found in North America and extends southward from Canada to the Mississippi, Ohio, and Missouri river valleys; Mexico; and Central America. Some isolated cases have also been reported from Africa. The largest numbers of cases occur in the Mississippi, Ohio, and Missouri river valley regions. *B. gilchristii* isolates are primarily localized to northwestern Ontario, Wisconsin, and Minnesota. The exact ecologic niche for this organism in nature has not been determined; however, patients with blastomycosis often have a history of exposure to soil or wood, particularly near waterways. Several outbreaks have been reported and have been related to a common exposure. Blastomycosis is more common in males than in females and seems to be associated with outdoor occupations or activities. The disease also occurs in dogs.

Coccidioides spp.

Coccidioides spp. are found primarily in the desert portion of the southwestern United States and in the semiarid regions of Mexico and Central and South America. Although the geographic distribution of the organism is well defined, infection may be seen in any part of the world because of the ease of travel. The infection (**coccidioidomycosis**) is usually acquired by inhalation of the infective arthroconidia. The infection is not contagious; however, person-to-person spread has been reported from contaminated fomites or through an infected organ donor to a recipient.

Emmonsia spp.

Ea. crescens. are rare causes of human infection. The organism produces a self-limited, localized pulmonary infection that may appear asymptomatic. Diagnosis is generally incidental to other underlying conditions. The organism produces adiaspores, which enlarge but do not reproduce in the patient. The clinical presentation depends on the number of adiaspores inhaled. It is unclear at this time whether the organism demonstrates a species-specific geographic distribution.

Emergomyces spp.

The *Emergomyces* spp. appear as beige, slow growing filamentous colonies at room temperature. The conidiophores are short and unbranched, and they form at right angles to hyaline hyphae. At body temperature, they appear as small oval yeast cells. The organism is endemic in South Africa and transmitted by inhalation. *Emergomyces* spp. is rapidly becoming the most commonly diagnosed dimorphic fungal pathogen.

Histoplasma capsulatum

Outbreaks of **histoplasmosis** have been associated with activities that disperse aerosolized conidia or small hyphal fragments. Infection is acquired through inhalation of these infective structures from the environment. The severity of the disease is generally related directly to the inoculum size and the immunologic status of the host. Numerous cases of histoplasmosis have been reported in people who clean out an old chicken coop or barn that has been undisturbed for long periods and in individuals who work in or clean areas that have served as roosting places for starlings and similar birds. Spelunkers (i.e., cave explorers) are commonly exposed to the organism when it is aerosolized from bat guano in caves. An estimated 500,000 people are infected with *H. capsulatum* annually. The history of exposure often is impossible to document, even though histoplasmosis is perhaps one of the most common systemic fungal infections seen in the Midwest and South in the United States, including areas along the Mississippi River, the Ohio River valley, and the Appalachian Mountains.

Paracoccidioides brasiliensis and *P. lutzi*

Infection caused by *Paracoccidioides* spp. is most commonly found in South America, with the highest prevalences in Brazil, Venezuela, and Colombia. It also has been seen in many other areas, including Mexico, Central America, the Caribbean, and Africa. Occasional imported cases are seen in the United States and Europe. The exact mechanism by which **paracoccidioidomycosis** is acquired is unclear; however, some speculate that it has a pulmonary origin and that it is acquired by inhalation of the organism from the environment. Because mucosal lesions are an integral part of the disease process, it also is speculated that the infection may be acquired through trauma to the oropharynx caused by vegetation commonly chewed by some residents of the endemic areas. The specific ecologic niche of the organism in nature is not known.

Talaromyces marneffei

T. marneffei is a dimorphic pathogenic fungus endemic to Southeast Asia, particularly the Guangxi Zhuang Autonomous Region of the People's Republic of China. *T. marneffei* has been associated with the bamboo rat *(Rhizomys pruinosus)* and the Vietnamese bamboo rat *(Rhizomys sinensis).*

Sporothrix spp.

Sporothrix schenckii has been shown to be a complex of numerous species. Those involved in human infection include *S. schenckii, Sporothrix brasiliensis, Sporothrix globosa,* and *Sporothrix luriei. Sporothrix* spp. have a worldwide distribution, and their natural habitat is living or dead vegetation. Humans acquire the infection (**sporotrichosis**) through trauma (thorns, splinters, bites, or scratches), usually to the hand, arm, or leg. The infection is an occupational hazard for farmers, nursery workers, gardeners, florists, and miners; it is commonly known as rose gardener's disease. Infections with *S. brasiliensis* have been transmitted from the bites or scratches of stray cats. Pulmonary sporotrichosis rarely occurs as a result of inhalation of spores.

Pathogenesis and Spectrum of Disease

Traditionally, the systemic mycoses have included only blastomycosis, coccidioidomycosis, histoplasmosis, and paracoccidioidomycosis. Although these fungi are morphologically dissimilar, they have one characteristic in common: dimorphism. Most of these organisms, except for *Coccidioides,* are thermally dimorphic. The dimorphic fungi exist in nature as the mold form, which is distinct from the parasitic or invasive form, sometimes called the tissue form. Distinct morphologic differences may be observed with the dimorphic fungi both *in vivo* and *in vitro,* as discussed later in the chapter.

Blastomyces spp.

Blastomyces spp. commonly produce an acute or chronic suppurative and granulomatous infection. Blastomycosis begins as a respiratory infection and is probably acquired by inhalation of the conidia or hyphal fragments of the organism. The infection may spread and involve secondary sites of infection in the lungs, long bones, soft tissue, and skin.

Coccidioides spp.

Approximately 60% of patients with coccidioidomycosis are asymptomatic and have self-limited respiratory tract infections. However, the infection may become disseminated, with extension to visceral organs, meninges, bone, skin, lymph nodes, and subcutaneous tissue. Fewer than 1% of those who develop coccidioidomycosis ever become seriously ill; dissemination does occur, however, most commonly in individuals of dark-skinned races. Pregnancy also appears to predispose females to disseminated infection. This infection has been known to occur in epidemic proportions. In 1992, an epidemic occurred in northern California, with more than 4000 cases seen in Kern County near Bakersfield. People who visit endemic areas and return to a distant location may present to their local physician; therefore, the endemic mycoses should be considered in the differential diagnosis if the patient has the appropriate travel history. All laboratories should be prepared to deal with the laboratory diagnosis of coccidioidomycosis.

Emergomyces spp.

Es. pasteurianus (previously *Emmonsia*) does not produce **adiaspores** (spores that increase in size inside an animal host) *in vitro* on brain-heart infusion (BHI) agar incubated at 37°C like *Emmonsia* spp. The organism produces cells that resemble budding yeast. Emergomycosis is generally systemic and includes the appearance of widespread cutaneous lesions.

Emmonsia spp.

Nonreplicating *Emmonsia* spp., most notably *Ea. crescens,* produces 25 to 400 μm **adiaspores** *in vitro* on BHI agar incubated at 37°C. In the natural environment the conidia are approximately 2 to 4 μm in diameter but may grow to 500 μm when inhaled into the human lung. The condition associated with inhaled conidia from *Emmonsia* spp. is referred to as **adiaspiromycosis.** The severity of the disease depends on the immunologic status of the patient as well as the inoculum size but may range from asymptomatic to fatal. Symptoms include fever, cough, dyspnea, hemoptysis, weight loss, fatigue, and possible respiratory failure.

Histoplasma capsulatum

H. capsulatum most commonly produces a chronic, granulomatous infection (histoplasmosis) that is primary and begins in the lung and eventually invades the reticuloendothelial system. Approximately 95% of cases are asymptomatic and self-limited, although chronic pulmonary infections occur. The disease can be disseminated throughout the reticuloendothelial system; the primary sites of dissemination are the lymph nodes, liver, spleen, and bone marrow. Infections of the kidneys and meninges are also possible. Resolution of disseminated infection is the rule in immunocompetent hosts, but progressive disease is more common in immunocompromised patients (e.g., patients with AIDS). Ulcerative lesions of the upper respiratory tract may occur in both immunocompetent and immunocompromised hosts.

Paracoccidioides spp.

Paracoccidioides produces a chronic granulomatous infection (paracoccidioidomycosis) that begins as a primary pulmonary infection. It often is asymptomatic and then disseminates to produce ulcerative lesions of the mucous membranes. Ulcerative lesions are commonly present in the nasal and oral mucosa, gingivae, and less commonly the conjunctivae. Lesions occur commonly on the face in association with oral mucous membrane infection. The lesions are characteristically ulcerative, with a serpiginous (snakelike) active border and a crusted surface. Lymph node involvement in the cervical area is common. Pulmonary infection is common, and progressive chronic pulmonary infection is found in approximately 50% of cases. In some patients, dissemination occurs to other anatomic sites, including the lymphatic system, spleen, intestines, liver, brain, meninges, and adrenal glands.

Talaromyces marneffei

T. marneffei commonly infects immunosuppressed individuals. The organism causes either a focal cutaneous or mucocutaneous infection, or it may produce a progressive disseminated and commonly fatal infection. Granulomatous, suppurative, and necrotizing inflammatory responses have been demonstrated. The mode of transmission and the primary source in the environment are unknown, but the bamboo rat has been implicated.

Sporothrix spp.

Sporothrix spp., also dimorphic fungi, are often associated with chronic subcutaneous infections. The primary lesion begins as a small, nonhealing ulcer, often of the index finger or the back of the hand. With time, the infection is characterized by the development of nodular lesions of the skin or subcutaneous tissues at the point of contact and later involves the lymphatic channels and lymph nodes that drain the region. The subcutaneous nodules ulcerate to form an infection that becomes chronic. Only rarely is the disease disseminated. Pulmonary infection may be seen in patients who inhale the spores of *Sporothrix* spp.

Laboratory Diagnosis

Specimen Collection, Transport, and Processing

See General Considerations for the Laboratory Diagnosis of Fungal Infections in Chapter 58.

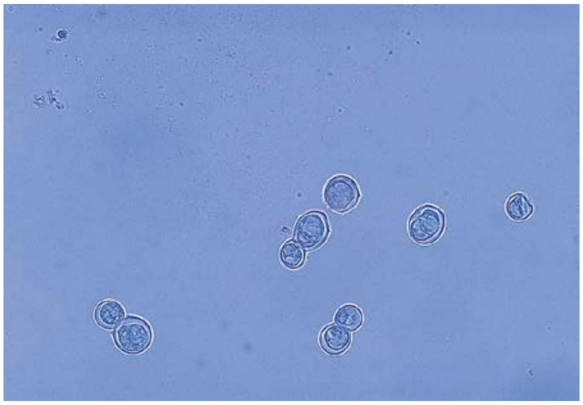
Direct Detection Methods

Stains

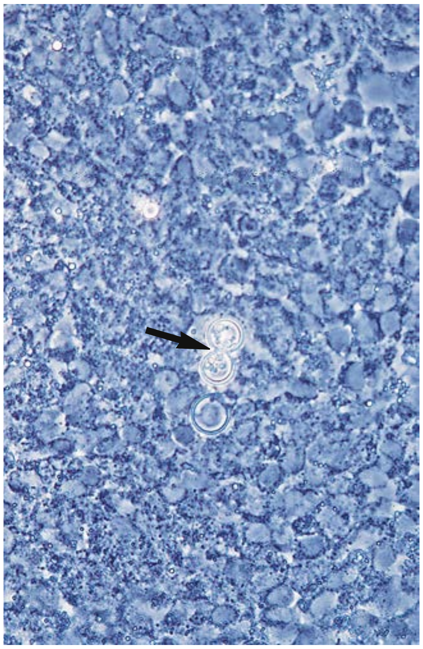
The microscopic morphologic features of the tissue forms, or what has been termed the parasitic forms, of the dimorphic fungi vary with the genus and are described for each.

***Blastomyces* spp.** The diagnosis of blastomycosis may easily be made when a clinical specimen is observed by direct microscopy. *Blastomyces* spp. appear as large, spherical, thick-walled yeast cells 8 to 15 µm in diameter, usually with a single bud that is connected to the parent cell by a broad base (Figs. 59.29 to 59.31). A smaller form (2 to 8 µm) is seen in rare cases.

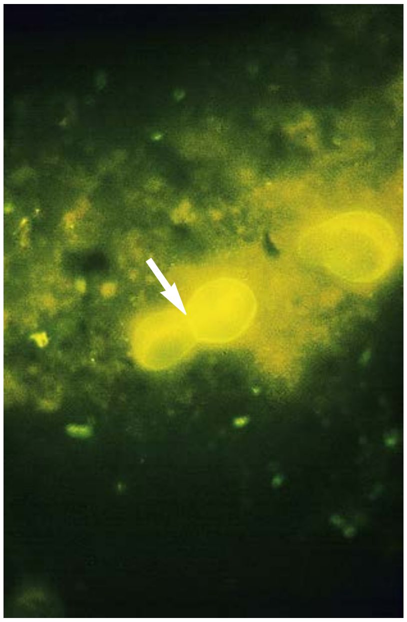
***Coccidioides* spp.** In direct microscopic examinations of sputum or other body fluids, *Coccidioides* spp. appear as a nonbudding, thick-walled spherule, 20 to 200 µm in diameter, that contains either granular material or numerous small (2 to 5 µm in diameter), nonbudding endospores (Figs. 59.32 to 59.35). The endospores are freed by rupture of the spherule wall; therefore, empty and collapsed "ghost" spherules may also be present. Small, immature spherules measuring 5 to 20 µm may be confused with *H. capsulatum* or *Blastomyces* spp. Two endospores or immature spherules lying adjacent to one another may give the appearance that



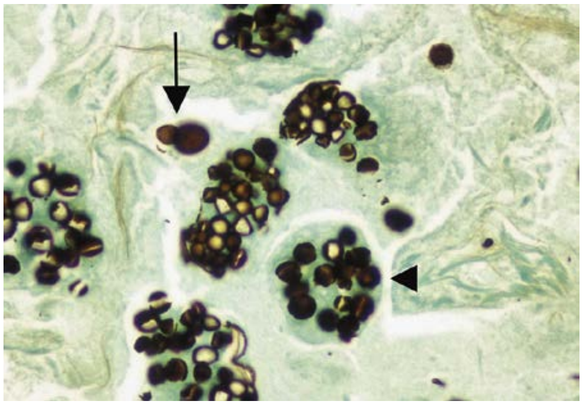
• **Fig. 59.29** *Blastomyces dermatitidis* yeast form showing thick-walled, oval to round, single-budding, yeastlike cells (×500).



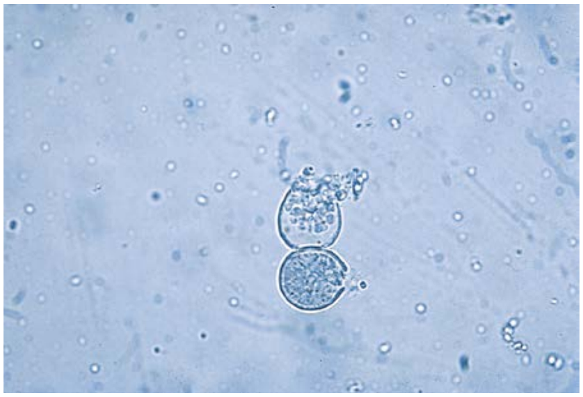
• **Fig. 59.30** Potassium hydroxide preparation of exudate shows a large budding yeast cell with a distinct broad base *(arrow)* between the cells, which is characteristic of *Blastomyces dermatitidis.* (Phase-contrast microscopy.)



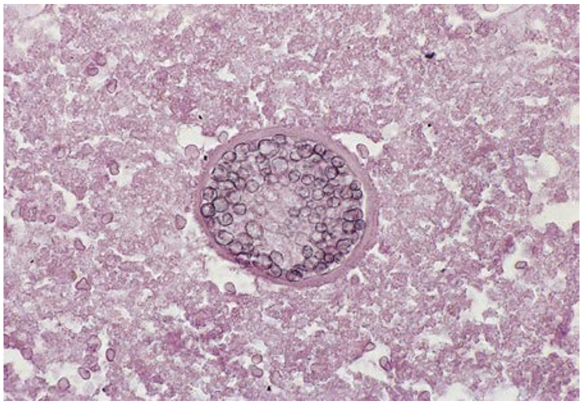
• **Fig. 59.31** Auramine-rhodamine preparation of specimen material from a bone lesion that demonstrates the characteristic broad-based budding yeast *(arrow)* of *Blastomyces dermatitidis.*



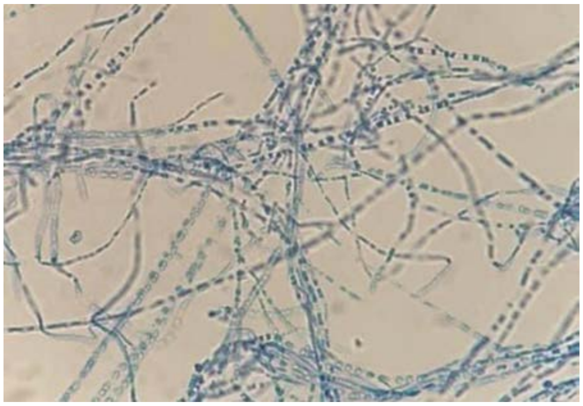
• **Fig. 59.32** Tissue form of *Coccidioides* spp. (i.e., the spherule). The external wall of the spherule does not stain with the silver stain, whereas the internal endospores do stain *(arrowhead).* Also note how the juxtaposed endospores, which have been released from a spherule that has burst, resemble budding yeast *(arrow).* (GMS stain; ×400.)



• **Fig. 59.33** Potassium hydroxide preparation of sputum demonstrates two spherules of *Coccidioides* spp. filled with endospores. When these lie adjacent to each other, they may be mistaken for *Blastomyces dermatitidis.* (Bright-field microscopy.)



• **Fig. 59.34** Histologic section showing a well-developed spherule of *Coccidioides* spp. that is filled with endospores.



• **Fig. 59.35** *Coccidioides* spp. lactophenol cotton blue preparation from Sabouraud agar demonstrating arthroconidia and barrel shaped cells. (Photo courtesy Anna Hartyunyan, MLS (ASCP), Children's Hospital, Los Angeles, CA.)

budding yeast is present. When identification of *Coccidioides* is questionable, a wet preparation of the clinical specimen may be made using sterile saline, and the edges of the cover glass may be sealed with petrolatum and incubated overnight. When spherules are present, the endospores produce multiple hyphal strands.

***Emergomyces* spp.** *Emergomyces* spp. can be differentiated from *Emmonsia* by the presence of budding yeasts and the absence of adiaspores.

***Emmonsia* spp.** *Emmonsia* spp. have not been successfully cultured from human specimens. Therefore, diagnosis is dependent on the histologic appearance of a thick-walled adiaspore granuloma within the lungs. Unlike *Coccidioides* spp., *Emmonsia* spp. adiaspores do not contain endospores and are typically much larger than spherules. A recent report has indicated that PCR and DNA sequencing may be useful in diagnosing adiaspiromycosis.

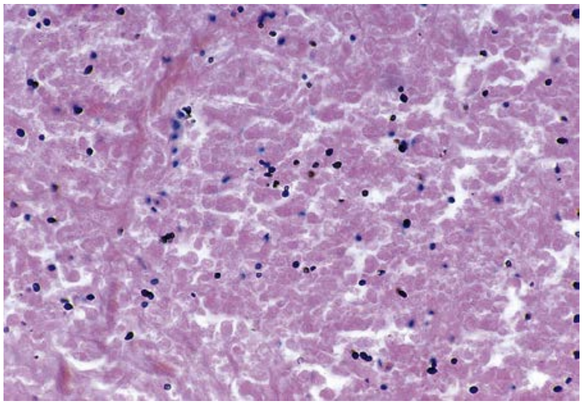
Histoplasma capsulatum. Direct microscopic examination of respiratory tract specimens and other similar specimens often fails to reveal the presence of *H. capsulatum.* However, an astute laboratorian may detect the organism when examining Wright- or Giemsa-stained specimens of bone marrow and, in rare cases, peripheral blood.

H. capsulatum is found intracellularly in mononuclear cells as small, round to oval yeast cells 2 to 5 µm in diameter (Fig. 59.36 and Fig. 59.7).

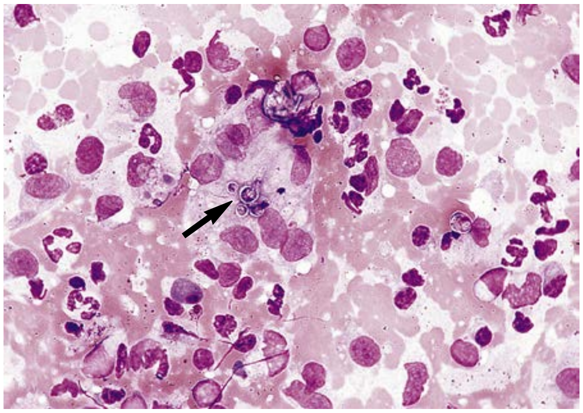
Paracoccidioides brasiliensis. Specimens submitted for direct microscopic examination are important for the diagnosis of paracoccidioidomycosis. Large, round or oval, multiple budding yeast cells (8 to 40 µm in diameter) are usually recognized in sputum, mucosal biopsy specimens, and other exudates. Characteristic multiple budding yeast forms resemble a "mariner's wheel" (Fig. 59.37). The yeast cells surrounding the periphery of the parent cell range from 8 to 15 µm in diameter. Some cells may be as small as 2 to 5 µm but still exhibit multiple buds.

Talaromyces marneffei. Direct examination of infected tissues and exudates reveals that *T. marneffei* produces small, yeastlike cells (2 to 6 µm) that have internal cross-walls; no budding cells are produced (Fig. 59.38). Like *H. capsulatum, T. marneffei* may be detected in peripheral blood smears with disseminated disease.

***Sporothrix* spp.** Exudate aspirated from unopened subcutaneous nodules or from open draining lesions often is submitted for culture and direct microscopic examination. Direct examination of this material usually has little diagnostic value, because demonstrating the rare characteristic yeast forms is difficult. *Sporothrix* usually appear as small (2 to 5 µm in diameter), round to oval to cigar-shaped yeast cells (Fig. 59.39). If stained using the periodic acid-Schiff (PAS) method in histologic section, an amorphous pink material may be seen surrounding the yeast cells (Fig. 59.40).



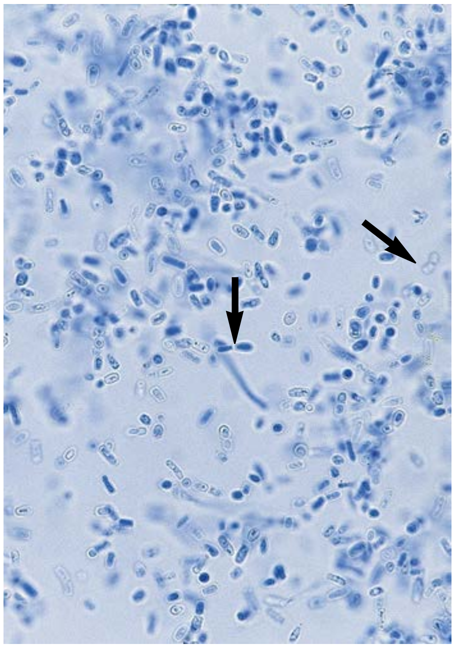
• **Fig. 59.36** These small, oval yeast cells that are relatively uniform in size are characteristic of *Histoplasma capsulatum* (×2000).



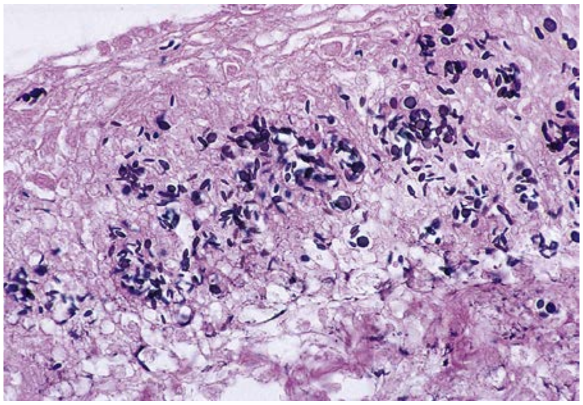
• **Fig. 59.37** *Paracoccidioides brasiliensis* in a bone marrow aspirate shows a yeast cell with multiple buds *(arrow).*

Antigen-Protein

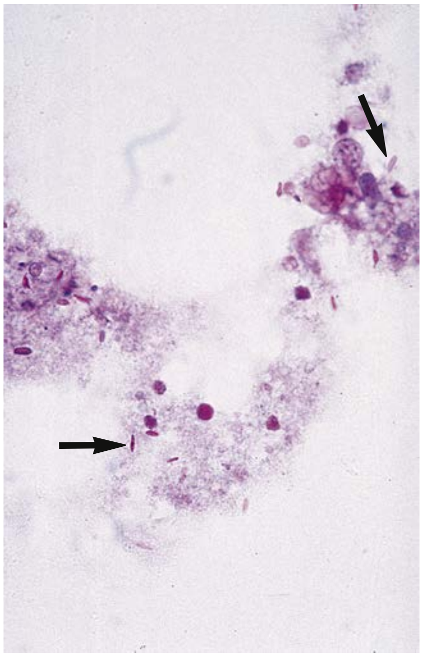
Immunodiffusion methods (the exoantigen test) may be used to identify isolates of these organisms based on precipitation bands of identity between specific antibodies and fungal antigen extracts. However, these assays have been largely replaced by the more rapid nucleic acid hybridization reactions and automated enzyme immunoassays. Antigen testing is available for *H. capsulatum* and *Blastomyces* in a microtiter plate double antibody sandwich EIA that can detect the antigens in urine, serum, or CSF in disseminated infections. A urinary antigen test is also available for the



• **Fig. 59.38** *Talaromyces marneffei* and binary fission *(arrows)* (×500).



• **Fig. 59.39** The deeply staining bodies in this mouse testis are the yeast forms of *Sporothrix* spp.



• **Fig. 59.40** Periodic acid-Schiff (PAS) staining of exudate shows the cigar- to oval-shaped yeast cells *(arrows)* of *Sporothrix* spp.

detection of *Coccidioides* spp. Antigen testing is not currently available for the remaining dimorphic fungal pathogens.

Nucleic Acid Testing

Nucleic acid amplification assays are not routinely performed but are available in some reference laboratories and in research settings. A single FDA-approved assay for the detection of *Coccidioides* is available. Real-time or homogeneous, rapid-cycle PCR assays have been described for *H. capsulatum, Blastomyces, Emmonsia, Paracoccidioides,* and *Coccidioides* species. These assays have proven suitable for isolate identification. Reproducibility and specificity of these assays must be thoroughly evaluated for standardization before implementation in clinical laboratories. No molecular tests are available for *Emergomyces* spp.

Cultivation

The dimorphic fungi are regarded as slow-growing organisms, requiring 7 to 21 days for visible growth to appear at 25°C to 30°C. However, exceptions to this rule occur with some frequency. Occasionally cultures of *Blastomyces* and *H. capsulatum* are recovered in as short a time as 2 to 5 days when many organisms are present in the clinical specimen. In contrast, when a small number of colonies of *Blastomyces* and *H. capsulatum* are present, sometimes 21 to 30 days of incubation are required before they are detected. *Coccidioides* is consistently recovered within 3 to 5 days of incubation, but when many organisms are present, colonies may be detected within 48 hours. Cultures of *P. brasiliensis* are commonly recovered within 5 to 25 days, with a usual incubation period of 10 to 15 days. The growth rate, if slow, might lead the laboratorian to suspect the presence of a dimorphic fungus; however, considerable variation in the time for recovery exists. The exceptions to this slow growth are *Coccidioides* and *T. marneffei,* which may be recovered within 3 to 5 days.

Textbooks present descriptions of the dimorphic fungi that the reader assumes are typical for each particular organism. As is true in other areas of microbiology, variation in the colonial morphologic features also occurs, depending on the strain and the type of medium used. The laboratorian must be aware of this variation and must not rely heavily on colonial morphologic features to identify members of this group of fungi.

The pigmentation of colonies is sometimes helpful but also varies widely; colonies of *Blastomyces* and *H. capsulatum* are described as being fluffy white, with a change in color to tan or buff with age. Some isolates initially appear darkly pigmented, with colors ranging from gray or dark brown to red. On media containing blood enrichment, these organisms may appear heaped, wrinkled, glabrous, neutral in color, and yeastlike; often tufts of aerial hyphae project from the top of the colony. Some colonies may appear pink to red, possibly because of the adsorption of hemoglobin from the blood in the medium. *Coccidioides* is described as fluffy white with scattered areas of hyphae adherent to the agar surface, giving an overall "cobweb" appearance to the colony. However, numerous morphologic forms have been reported, including textures ranging from wooly to powdery and pigmentation ranging from pink-lavender or yellow to brown or buff. The definitive traditional identification method for dimorphic fungus includes observing both the mold and tissue or parasitic forms of the organism. In general, 25°C to 30°C is the optimal temperature for recovery and identification of the dimorphic fungi from clinical specimens. Temperature (35°C to 37°C), certain nutritional factors, and stimulation of growth in tissue independent of temperature are among the factors necessary to initiate the transformation of the mold form to the tissue form. Previously, *Blastomyces* and *H. capsulatum* were identified definitively by the *in vitro* conversion of a mold form to the corresponding yeast form through *in vitro* conversion on a blood-enriched medium incubated at 35°C to 37°C; definitive identification of *Coccidioides* involved conversion to the spherule form by animal inoculation. Except for *Coccidioides,* the conversion of dimorphic molds to the yeast form can be accomplished with some difficulty (Evolve Procedure 59.2). Some reference laboratories may still use the exoantigen test (Evolve Procedure 59.3) to identify the dimorphic pathogens. However, this test requires extended incubation before cultures may be identified.

Blastomyces dermatitidis. *B. dermatitidis* commonly requires incubation for 5 days to 4 weeks or longer at 25°C before growth can be detected. However, it may be detected in as short a time as 2 to 3 days. On enriched culture media, the mold form develops initially as a glabrous or waxy-appearing colony and is off-white to white. With age, the aerial hyphae often turn gray to brown. The waxy, yeastlike appearance is typified on media enriched with blood. Tufts of hyphae often project upward from the colonies, and this has been referred to as the "prickly state" of the organism. However, some isolates appear fluffy on primary recovery and remain so throughout the incubation period. On blood agar at 37°C, colonies are waxy, wrinkled, and yeastlike. Mold-to-yeast conversion usually requires 4 to 5 days.

***Coccidioides* spp.** Cultures of *Coccidioides* are a biohazard to laboratory workers, and strict safety precautions must be followed when cultures are examined. Mature colonies may appear within 2 to 5 days of incubation and may be present on most media, including those used in bacteriology. Laboratory workers are cautioned not to open cultures of fluffy white molds unless they are placed inside a biologic safety cabinet (BSC). Colonies of *Coccidioides* often appear as a delicate, cobweblike growth after 3 to 21 days of incubation. Some portions of the colony exhibit aerial hyphae, whereas in others the hyphae adhere to the agar surface. Most isolates appear fluffy white; however, colonies of varying colors have been reported, ranging from pink to yellow to purple and black. Some colonies exhibit a greenish discoloration on blood agar, and others appear yeastlike, smooth, wrinkled, and tan.

***Emmonsia* and *Emergomyces* spp.** *Emmonsia* spp. produce glabrous, colorless colonies at 25°C that produce yellow to white aerial mycelia over time. Some strains produce orange to gray mycelia. Reverse pigmentation appears gray to grayish-brown. *Emergomyces* spp. appears very similar at 25°C to 30°C and must be differentiated based on the microscopic production of yeastlike cells at 37°C and not adiaspores. Sporulation is enhanced on potato dextrose agar or **Pablum cereal agar.**

The fungi produce conidia from the sides or directly on short stalks that branch from the hyphae. The hyphae may appear swollen and bear peglike structures resulting in the production of secondary conidia in a flowerlike arrangement.

Histoplasma capsulatum. *H. capsulatum* is easily cultured from clinical specimens; however, it may be overgrown by bacteria or rapidly growing molds. A procedure that is useful for recovering *H. capsulatum, B. dermatitidis,* and *Coccidioides* spp. from contaminated specimens (e.g., sputa) uses a yeast extract/phosphate medium and a drop of concentrated ammonium hydroxide (NH_4OH) placed on one side of the inoculated plate of medium. In the past, it was recommended that specimens not be kept at room temperature before culture, because *H. capsulatum* would not survive. The organism survives transit in the mail for as long as 16 days. However, the current recommendation is that specimens be cultured as soon as possible to ensure optimal recovery of *H. capsulatum* and other dimorphic fungi.

H. capsulatum is usually considered a slow-growing mold at 25°C to 30°C and commonly requires 2 to 4 weeks or more for colonies to appear. However, the organism may be recovered in 5 days or less if many yeast cells are present in the clinical specimen. Isolates of *H. capsulatum* have been reported from blood cultures with the Isolator (Alere, Waltham, MA) within a mean time of 8 days. *H. capsulatum* is a white, fluffy mold that turns brown to buff with age. Some isolates ranging from gray to red have also been reported. The organism also may produce wrinkled, moist, heaped, yeastlike colonies that are soft and cream colored, tan, or pink. Tufts of hyphae often project upward from the colonies, as described for *B. dermatitidis* and *H. capsulatum,* and cannot be differentiated using colonial morphologic features.

Paracoccidioides brasiliensis. Colonies of *P. brasiliensis* grow very slowly (21 to 28 days) and are heaped, wrinkled, moist, and yeastlike. With age, colonies may become covered with a short aerial mycelium and turn tan to brown. The surface of colonies often is heaped with crater formations.

Talaromyces marneffei. At 25°C, *T. marneffei* grows rapidly and produces blue-green to yellowish colonies on Sabouraud agar. A soluble, red to maroon pigment that diffuses into the agar and is often best observed by viewing the reverse of the colony is suggestive of *T. marneffei.* Although the growth rate and colonial morphologic features may help the laboratorian recognize the possibility of a dimorphic fungus, they should be considered in combination with the microscopic morphologic features to make the identification. *T. marneffei* cannot be definitively identified by morphologic features alone; thermal conversion studies or nucleic acid–based testing is needed to confirm the identification of this pathogen.

***Sporothrix* spp.** Colonies of *Sporothrix* spp. grow rapidly (3 to 5 days) and initially are usually small, moist, and white to cream-colored. On further incubation, these become membranous, wrinkled, and coarsely matted, with the color becoming irregularly dark brown or black and the colony becoming leathery in consistency. It is not uncommon for the clinical microbiology laboratory to mistake a young culture of *Sporothrix* spp. for a yeast until the microscopic features are observed.

Approach to Identification

Blastomyces dermatitidis–B. gilchristii

Microscopically, hyphae of the mold form of *Blastomyces* spp. are septate and delicate and measure approximately 2 µm in diameter. Commonly, ropelike strands of hyphae are seen; however, these are found with most of the dimorphic fungi. The characteristic microscopic morphologic features are single, circular to pyriform conidia produced on short conidiophores that resemble lollipops (Fig. 59.41); less commonly, the conidiophores may be elongated. The production of conidia in some isolates is minimal or absent, particularly on a medium containing blood enrichment.

When incubated at 37°C, colonies of the yeast form develop within 7 days and appear waxy, wrinkled, and cream to tan. Microscopically, large, thick-walled yeast cells (8 to 15 µm in diameter) with buds attached by a broad base are seen (Fig. 59.29). Some strains may produce yeast cells as small as 2 to 5 µm, called **microforms.** Although these microforms may be present, a thorough search should reveal more typical yeast forms. During conversion, swollen hyphal forms and immature cells with rudimentary buds are also likely to be present. Because the conversion of *Blastomyces* spp. is easily accomplished, this is feasible in the clinical laboratory; however, this is the most appropriate instance in which mold-to-yeast conversion should be attempted. *Blastomyces* may also be identified by the presence of a specific band (i.e., A band) in the exoantigen test or by nucleic acid probe testing. *H. capsulatum, P. boydii,* or *T. rubrum* may occasionally be confused microscopically with *Blastomyces* spp. The site of infection and the relatively slow growth rate of *Blastomyces* spp. and careful examination of the microscopic morphologic features usually differentiate it from these fungi. Identification can also be confirmed using the AccuProbe test (Hologic Inc., San Diego CA) for *Blastomyces.*

Coccidioides spp.

Microscopically, some *Coccidioides* cultures show small, septate hyphae that often exhibit right-angle branches and racquet forms. With age, the hyphae form arthroconidia that are characteristically rectangular to barrel-shaped. The arthroconidia are larger than the hyphae from which they were produced and stain darkly with lactophenol cotton or aniline blue. The arthroconidia are separated by clear or lighter staining, nonviable cells (**dysjunctor cells**). These types of conidia are referred to as **alternate arthroconidia** (Fig. 59.25 and Fig. 59.35). Arthroconidia have been reported to range from 1.5 to 7.5 µm in width and 1.5 to 30 µm in length, whereas most are 3 to 4.5 µm in width and 3 µm in length. Variation has been reported in the shape of arthroconidia, ranging from rounded to square or rectangular to curved; however, most are barrel-shaped. Even if alternate arthroconidia are observed microscopically, definitive identification should be made using nucleic acid probe testing. If a culture is suspected of being *Coccidioides,* it should be sealed with tape to prevent laboratory-acquired infection. Because *Coccidioides* spp. are considered the most infectious of all the fungi, extreme caution should be used in handling cultures of these organisms. Safety precautions include the following:

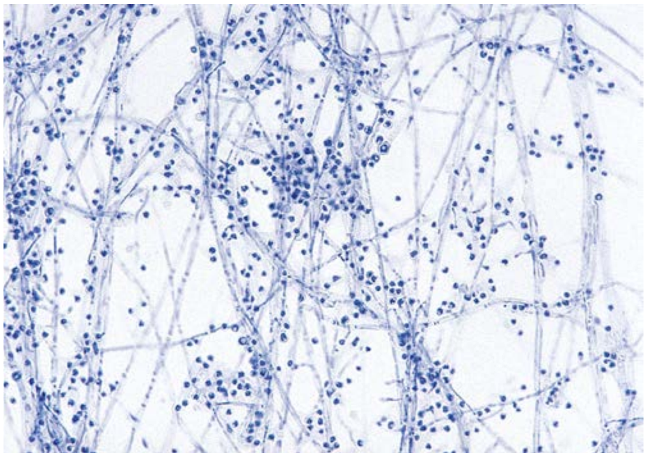
1. If culture dishes are used, they should be handled only in a Level 3 BSC. Cultures should be sealed with tape if the specimen is suspected to contain *Coccidioides* spp.
2. The use of cotton plug test tubes is discouraged, and screw-capped tubes should be used if culture tubes are preferred. All handling of cultures of *Coccidioides* spp. in screw-capped tubes should be performed inside a BSC.
3. All microscopic preparations for examination should be performed in a Level 3 BSC.
4. Cultures should be autoclaved as soon as final identification is made.

Both species of *Coccidioides* were previously classified as select agents in the United States before removal from the list in 2012.

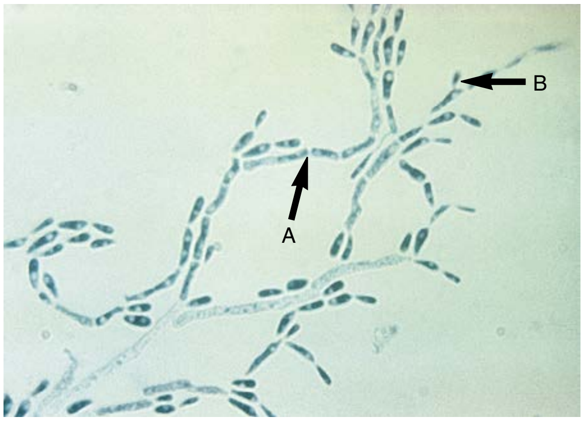
Other, usually nonvirulent fungi that resemble *Coccidioides* microscopically may be found in the environment. Some molds, such as *Malbranchea* spp., also produce alternate arthroconidia, although these tend to be more rectangular; however, such species must be considered when making the identification. *G. candidum* and *Trichosporon* spp. produce hyphae that disassociate into contiguous arthroconidia; these should not be confused with *Coccidioides* (Fig. 59.42 and Fig. 59.24). The colonial morphologic features of older cultures of these fungi may resemble *Coccidioides* spp., but as noted the arthroconidia are not alternate. It is also important to remember that if confusion in identification does arise, or when occasional strains of *Coccidioides* that fail to sporulate are encountered, identification by exoantigen or nucleic acid testing may be performed. Identification can also be confirmed using the AccuProbe test (Hologic Inc., San Diego CA) for *Coccidioides* spp.

Emmonsia spp. and *Emergomyces* spp.

The typical mold phase for *Emmonsia* and *Emergomyces* spp. was previously described in this chapter; however, culture for conversion to the yeast phase should be grown on **phytone yeast extract agar,** BHI, or BHI with blood at 37°C to 40°C. *Es. pasteuriana* produces yeastlike cells on BHI after approximately 10 days of incubation at 37°C. Other species may require up to 14 days of incubation for the yeast phase to be identified. Some of these organisms may be morphologically indistinguishable. Multilocus gene sequencing may be necessary to fully identify clinical isolates included in these genera.



• **Fig. 59.41** The mycelial form of *Blastomyces dermatitidis* shows oval conidia borne laterally on branching hyphae (×1000).



• **Fig. 59.42** *Trichosporon* spp. produce arthroconidia *(A)* and an occasional blastoconidium *(B).*

Histoplasma capsulatum

Microscopically, the hyphae of *H. capsulatum* are small (approximately 2 µm in diameter) and are often intertwined to form ropelike strands. Commonly, large (8 to 14 µm in diameter) spherical or pyriform, smooth-walled macroconidia are seen in young cultures. With age, the macroconidia become roughened or tuberculate and provide enough evidence to make a tentative identification (Fig. 59.43). The macroconidia are produced either on short or long conidiospores. Some isolates produce round to pyriform, smooth microconidia (2 to 4 µm in diameter), in addition to the characteristic tuberculate macroconidia. Some isolates of *H. capsulatum* fail to sporulate despite numerous attempts to induce sporulation.

Conversion of the mold to the yeast form is usually difficult and is not recommended. Microscopically a mixture of swollen hyphae and small budding yeast cells 2 to 5 µm in diameter should be observed. These are similar to the intracellular yeast cells seen in mononuclear cells in infected tissue. The yeast form of *H. capsulatum* cannot be recognized unless the corresponding mold form is present on another culture or unless the yeast is converted directly to the mold form by incubation at 25°C to 30°C after yeast cells have been observed. Nucleic acid testing is recommended as a definitive means of rapidly identifying this organism.

Paracoccidioides spp.

Microscopically, the mold form is similar to that seen with *B. dermatitidis.* Small hyphae (approximately 2 µm in diameter) are seen, along with numerous chlamydoconidia. Small (3 to 4 µm), delicate, globose or pyriform conidia may be seen arising from the sides of the hyphae or on very short conidiophores (Fig. 59.44). Most often cultures reveal only fine septate hyphae and numerous chlamydoconidia.

After temperature-based conversion on a blood-enriched medium, the colonial morphology of the yeast form is characterized by smooth, soft-wrinkled, yeastlike colonies that are cream to tan. Microscopically, the colonies are composed of yeast cells 10 to 40 µm in diameter surrounded by narrow-necked yeast cells around the periphery, as previously described (Fig. 59.37). If *in vitro* conversion to the yeast form is unsuccessful, the exoantigen test (Evolve Procedure 59.3) should be used to make the definitive identification of *P. brasiliensis*. There is no commercial DNA probe test available for the identification of *P. brasiliensis.*

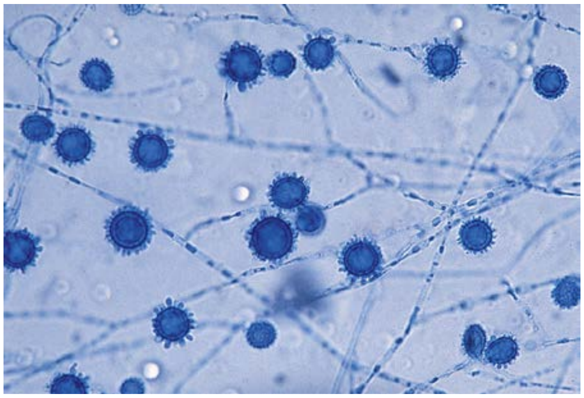
Talaromyces marneffei

At 25°C, *T. marneffei* grows rapidly and produces blue-green to yellowish colonies. A soluble red to maroon pigment, which diffuses into the agar, is highly suggestive of *T. marneffei.* At 37°C, conversion of mycelium to the infective, yeastlike form occurs in approximately 2 weeks. Oval, yeastlike cells (2 to 6 µm in diameter) with septa are seen; abortive, extensively branched, and highly septate hyphae may also be present (Fig. 59.38). A variety of laboratory developed nucleic acid tests have been used to identify this organism from clinical samples.

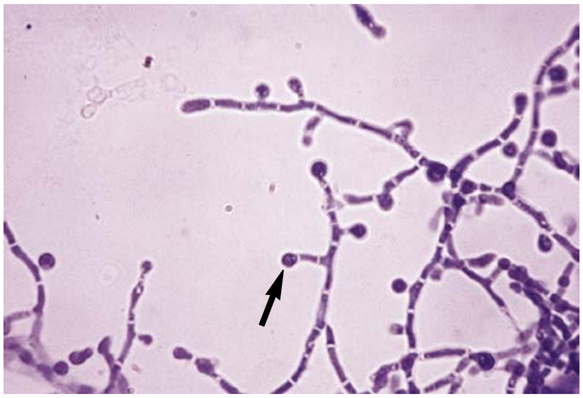
Sporothrix spp.

Microscopically, hyphae are delicate (approximately 2 µm in diameter), septate, and branching. Single-celled conidia 2 to 5 µm in diameter are borne in clusters from the tips of single conidiophores (flowerette arrangement). Each conidium is attached to the conidiophore by an individual, delicate, threadlike structure (**denticle**) that may require examination under oil immersion to be visible. As the culture ages, single-celled, thick-walled, black-pigmented conidia may also be produced along the sides of the hyphae, simulating the arrangement of microconidia produced by *T. rubrum* (sleeve arrangement) (Fig. 59.45).

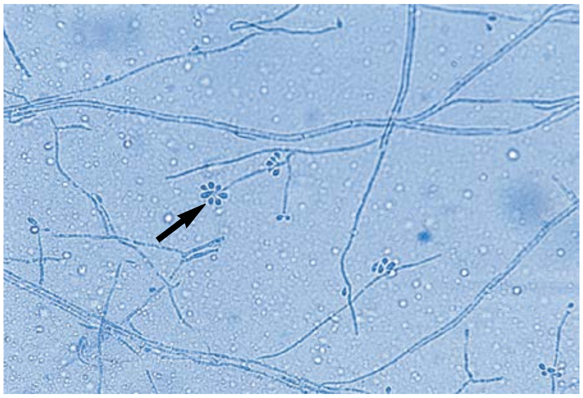
Because of similar morphologic features, saprophytic species of the genus *Sporotrichum* may be confused with *Sporothrix* spp., and they must be differentiated. During incubation of a culture at 37°C, colonies of *Sporothrix* spp. transform to a soft, cream-colored to white, yeastlike appearance. Microscopically, singly or multiply budding, spherical, oval, or elongate, cigar-shaped yeast cells are observed without difficulty (Fig. 59.46). Conversion from the mold form to the yeast form is easily accomplished and usually occurs within 1 to 5 days after transfer of the culture to a medium containing blood enrichment; most isolates of *Sporothrix* spp. are converted to the yeast form within 12 to 48 hours at 37°C.



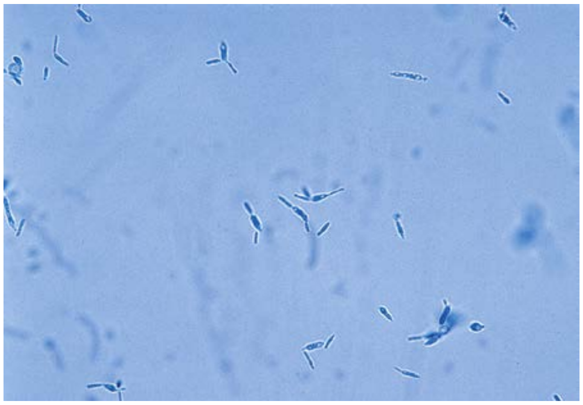
• **Fig. 59.43** The mycelial form of *Histoplasma capsulatum* produces characteristic tuberculate macroconidia (×1000).



• **Fig. 59.44** Mycelial form of *Paracoccidioides brasiliensis* shows septate hyphae and pyriform conidia singly borne *(arrow)* (×430).



• **Fig. 59.45** The mycelial form of *Sporothrix* spp. demonstrating pyriform to ovoid microconidia in a flowerette morphology at the tip of the conidiophore *(arrow)* (×750).



• **Fig. 59.46** The yeast form of *Sporothrix* spp. consists of cigar-shaped and oval budding cells (×500).

Sporotrichum spp. do not produce a yeast form. Molecular sequencing of the 18S rRNA or 28S rRNA along with the calmodulin gene may be required for species identification.

Serologic Testing

Fungal serology includes rapid and useful tests that may aid the diagnosis of systemic fungal infections caused by *H. capsulatum, Paracoccidioides,* and *Coccidioides* species. These tests have also been useful to study the epidemiology of these fungal infections, because even individuals with historically distant, asymptomatic, or subclinical infections often have developed an antibody response to the infecting pathogen. Unfortunately, these tests require detailed preparation and technical expertise. False-negative reactions may occur if serology specimens are drawn in immunocompromised individuals who are unable to produce an antibody response. False-positive reactions may occur because of cross reactivity with other fungi. For example, because the antigens of *H. capsulatum* are similar to those of *B. dermatitidis,* occasionally a specimen from a patient with histoplasmosis demonstrates a positive reaction for *B. dermatitidis* in serologic tests. Serology does not appear to be useful for the diagnosis of blastomycosis, and no tests have been developed for the diagnosis of adiaspiromycosis or emergomycosis.

Two assays, complement fixation and immunodiffusion, have been used together to detect antibodies directed toward *H. capsulatum* and *Coccidioides* spp. In the complement fixation assay, titers of 1:32 or greater indicate active infection with *H. capsulatum.* Titers as low as 1:2 to 1:4 have been identified in patients with coccidioidomycosis. Titers greater than 1:16 usually indicate active disease. Bands of identity form in the immunodiffusion test between known antisera, known fungal antigen, and the antibodies present in the patient's serum. Specific bands of identity are used for serologic detection of particular fungi, whereas nonspecific bands suggest the possibility of an infection by another fungal pathogen. One or two bands of identity, the H protein and M protein bands may occur in patients with histoplasmosis. The presence of both bands indicates active infection. The presence of an M protein band may indicate early or chronic infection. Newer enzyme immunosorbent assays have been developed and demonstrate improved sensitivity and specificity for the identification of histoplasmosis and coccidioidomycosis. A latex agglutination assay has been developed for the presumptive identification of *Coccidioides* infections. However, the test demonstrates a high false positive rate and is not recommended for use with CSF specimens.

Visit the Evolve site for a complete list of procedures, review questions, and case studies.

PROCEDURE 59.1

Hair Perforation Test

Method

1. Place a filter paper disk in the bottom of a sterile culture dish.
2. Cover the surface of the paper disk with sterile distilled water.
3. Add a small portion of sterilized hair(s) to the water.
4. Inoculate a portion of the colony directly onto the hair.
5. Incubate at 25°C for 10–14 days.
6. Observe the hairs regularly by placing them in a drop of water on a microscope slide. Position a coverslip and examine microscopically for conical perforations of the hair shaft (Fig. 59.11).

PROCEDURE 59.2

In Vitro Conversion of Dimorphic Molds

Principle

Dimorphic molds exist in the yeast or spherule form in infected tissue. Proof that a mold is one of the systemic dimorphic fungi can be obtained by simulating the host environment and converting the mold to the yeast form. This method is recommended for identifying *Blastomyces* spp., *Talaromyces marneffei,* and *Sporothrix* spp. Conversion of *Coccidioides* spp. to its spherule form requires special media or animal inoculation and is not recommended for clinical laboratories. *Histoplasma capsulatum* most often does not convert from the mold to the yeast form *in vitro* or does so only after extended incubation at 35°C–37°C.

Method

1. Transfer a large inoculum of the mold form of the culture onto the surface of a fresh, moist slant of brain-heart infusion agar containing 5%–10% sheep blood. If *Blastomyces* spp. are suspected, a tube of cottonseed conversion medium should be inoculated.
2. Add a few drops of sterile distilled water to provide moisture if the surface of the culture medium appears dry.
3. Leave the cap of the screw-capped tube slightly loose to allow the culture to have adequate oxygen exchange.
4. Incubate cultures at 35°C–37°C for several days; observe for the appearance of yeastlike portions of the colony. Several subcultures of any growth that appears may need to be made, because several transfers are often required to accomplish the conversion of many isolates. Cultures of *Blastomyces* spp., however, are usually easily converted and require 24–48 hours on cottonseed agar medium. *Coccidioides* spp. may be converted *in vitro* to the spherule form using a Converse liquid medium; however, this method is of little use to the clinical laboratory and should not be attempted. Genetic probe hybridization, DNA sequencing, species-specific polymerase chain reaction (PCR), and exoantigen detection are recommended methods of definitively identifying isolates suspected to be *Coccidioides* spp. *Ea. crescens* produces adiaspores when cultivated on Phytone Yeast Extract Agar, BHI, or BHIB at 37°C–40°C*. Es. pasteurianus* must be cultivated for approximately 10 days at 37°C on BHI before the production of yeastlike cells is apparent.

Quality Control

Because of the hazardous nature of stock cultures, it is not recommended that they be tested routinely. An extract of control strains can be used as a positive control. Because conversion of the dimorphic molds to the corresponding yeast or spherule forms is technically cumbersome and often involves long delays, attempts to convert the dimorphic fungi are not recommended in the routine mycology laboratory.

PROCEDURE 59.3

Exoantigen Test

Principle

Specific antibodies developed against particular mycelial antigens react in a gel immunodiffusion precipitin test. The mold forms of the dimorphic fungi can be identified definitively by an antigen-antibody reaction, eliminating the need for conversion to the yeast form.

Method

1. Cover a mature fungus culture on a Sabouraud dextrose agar slant with an aqueous solution of merthiolate (1:5000 final concentration), which is allowed to remain in contact with the culture for 24 h at 25°C. The entire surface of the colony must be covered so that effective killing of the organism is ensured and solubilization of the exoantigen is maximized.
2. Filter the aqueous solution that overlays the culture through a 0.45-μm membrane filter. This should be done inside a biologic safety cabinet (BSC).
3. Concentrate 5 mL of this solution using a Minicon Macrosolute B-15 Concentrator (Millipore, Billerica, MA). The solution is concentrated 50× when testing with *Histoplasma capsulatum* and *Blastomyces* antiserum and 5× and 25× for reaction with *Coccidioides* antiserum.
4. Use the concentrated supernatant in the microdiffusion test. Place the supernatant in wells punched into a plate of buffered, phenolized agar adjacent to the control antigen well and test it against positive control antiserum obtained from commercial sources.
5. Allow the immunodiffusion test to react for 24 hours at 25°C. Then, observe the plate for precipitin bands of identity with the reference reagents. The sensitivity of the exoantigen test may be improved in the identification of *Blastomyces* by incubating the immunodiffusion plates at 37°C for 48 h; however, bands appear sharper at 25°C after 24 h. Any culture suspected of being *Blastomyces* should be incubated at both temperatures.
6. *Coccidioides* may be identified by the presence of the CF, TP, or HL antigens; *H. capsulatum* may be identified by the presence of H protein or M protein bands (or both); and *Blastomyces* may be identified by the A protein band. Detailed instructions for performing and interpreting the tests are included with the manufacturers' package inserts.

Quality Control

Extracts from known fungi are tested each time the test is performed. Lines of identity with the unknown strain are necessary for identification.

Data from Murray CK, Beckius ML, Green JA, et al. Use of chromogenic medium in the isolation of yeasts from clinical specimens. *J Med Microbiol.* 2005;54:981; and Tan GL, Peterson EM. Chromagar *Candida* medium for direct susceptibility testing of yeast from blood cultures. *J Clin Microbiol.* 2005;43:1727.

CASE STUDY 59.1

An elderly female with diabetes visits her clinician because she has a brown, dull, discolored toenail. The clinician takes nail clippings for culture. The laboratory places the clippings on media with no cycloheximide. SAB agar reveals a rapid-growing colony that is mature in 5 days. The colonies are initially white, become tan with age, and are velvety and powdery. The reverse is tan with a brown center. Microscopic examination reveals septate hyaline hyphae with annelides. Annelides are both solitary and in clusters that resemble a penicillus.

Questions

1. Why did the laboratory use agar without cycloheximide?
2. How would you distinguish between *Talaromyces* and *Scopulariopsis* spp.?
3. One-celled conidia are rough-walled, and spiny conidia in chains are seen. What organism is identified?

Chapter Review

1. Which test can be used to differentiate *T. mentagrophytes* from *T. rubrum?*
   a. Fluorescence using a Woods lamp
   b. *In vitro* hair perforation
   c. Red color on reverse side of colony
   d. Pyriform microconidia

2. Tinea capitis is caused by which dermatophyte?
   a. *T. tonsurans*
   b. *M. audouinii*
   c. *M. canis*
   d. All of the above

3. *Microsporum* infection involves:
   a. Hair, skin, and nails
   b. Hair and skin
   c. Skin and nails
   d. None of the above

4. A Woods lamp is used to detect fluorescing hairs in which dermatophyte?
   a. *M. audouinii*
   b. *M. canis*
   c. M. *gypseum*
   d. A and B

5. Sickle- or boat-shaped macroconidia on cornmeal agar are characteristic of:
   a. *Alternaria* spp.
   b. *Aspergillus* spp.
   c. *Penicillium* spp.
   d. *Fusarium* spp.

6. Which of the following produces rhizoids?
   a. *Mucor* spp.
   b. *Rhizopus* spp.
   c. *Trichophyton* spp.
   d. *Microsporum* spp.

7. Which dimorphic fungus is found in the Missouri River valley?
   a. *B. dermatitidis*
   b. *H. capsulatum*
   c. *Coccidioides* spp.
   d. *P. brasiliensis*

8. Which dimorphic fungus may be contracted by people who clean chicken coops?
   a. *B. dermatitidis*
   b. *H. capsulatum*
   c. *Coccidioides* spp.
   d. *P. brasiliensis*

9. Which organism is capable of producing an unusually large spore when inhaled into the human respiratory tract?
   a. *B. dermatitidis*
   b. *H. capsulatum*
   c. *Coccidioides* spp.
   d. *Ea. crescens*

10. **Matching:** *Match each term with the correct description.*

_____ rhizoid	a. inside the hair shaft
_____ ectothrix	b. ringworm of the body
_____ endothrix	c. rose-gardener's disease
_____ sporangia	d. rootlike hypha
_____ tinea corporis	e. infects animals
_____ tinea cruris	f. infects humans
_____ *Sporothrix schenckii*	g. athlete's foot
_____ *Trichosporon mentagrophytes*	h. outside the hair shaft
_____ anthropophilic	i. jock itch
_____ zoophilic	j. fruiting structures

60

Dematiaceous (Melanized) Molds

OBJECTIVES

1. Describe the melanized fungi, including natural habitat, transmission, and diseases with signs and symptoms.
2. Identify the site where mycetomas are commonly located and the population or populations at risk of infection.
3. Compare and contrast *Exophiala jeanselmei* and *Exophiala dermatitidis,* including test methods to distinguish between the two.
4. Describe the microscopic and morphologic features of *Pseudallescheria boydii,* including its sexual and asexual forms.
5. Differentiate the diagnostic microscopic features of the molds included in this chapter.

SEPTATE DEMATIACEOUS MOLDS TO BE CONSIDERED

Superficial Infections

Alternaria alternata
Aureobasidium melanogenum
Cladophialophora boppii
Cyphellophora europaea
Cyphellophora laciniata
Cyphellophora pluriseptata
Curvularia spp.
Hortaea werneckii
Neoscytalidium dimidiatum
Piedraia hortae
Scopulariopsis brevicaulis
Triadelphia pulvinata

Cutaneous and Corneal

Alternaria alternata
Alternaria infectoria
Bipolaris oryzae
Cladophialophora boppii
Cladophialophora emmonsii
Cladophialophora saturnica
Cladorrhinum bulbillosum
Cladosporium cladosporioides
Cladosporium oxysporum
Curvularia lunata
Curvularia senegalensis
Curvularia spicifera
Diaporthe longicolla
Diaporthe phaseolorum
Diaporthe phoenicicola
Exophiala bergeri
Exophiala dermatitidis
Exophiala jeanselmei
Exophiala oligosperma
Exophiala xenobiotica
Exserohilum rostratum
Knufia epidermidis
Lasiodiplodia theobromae
Macrophomina phaseolina
Neoscytalidium dimidiatum
Sporothrix pallida

Subcutaneous (Includes Mycetomas)

Alternaria spp.
Cyphellophora suttonii
Cladophialophora bantiana
Curvularia spp.
Diaphorthe bougainvilleicola
Diaphorthe phaseolorum
Exserohilum spp.
Exophiala spp.
Hongkongmyces pedis
Knoxdaviesia dimorphospora
Lasiodiplodia theobromae
Lomentospora prolificans
Madurella spp.
Neoscytalidium dimidiatum
Ochroconis mirabilis
Phaeoacremonium spp.
Pleurostoma richardsiae
Scedosporium spp.
Scopulariopsis spp.
Trematosphaeria grisea
Veronaea botryose

Systemic Phaeohyphomycosis

Arthrocladium fulminans
Aureobasium pullulans
Cladophialophora bantiana
Cladophialophora modesta
Curvularia spp.
Exserohilum rostratum
Exophiala dermatitidis
Exophiala phaeomuriformis
Exophiala spinifera
Fonsecaea monophora
Fonsecaea pedrosoi
Hormonema dematioides
Lasiodiplodia theobromae
Lomentospora prolificans
Neoscytalidium dimidiatum

SEPTATE DEMATIACEOUS MOLDS TO BE CONSIDERED

Ophiostoma piceae
Phaeoacremonium parasiticum
Phialophora verrucosa
Rhinocladiella mackenziei
Scedosporium spp.
Triadelphia disseminata
Verruconis gallopava

Chromoblastomycosis

Cladophialophora carrionii
Cladophialophora boppii
Cladophialophora samoënsis
Cyphellophora ludoviensis
Phialophora verrucosa
Fonsecaea monophora
Fonsecaea pedrosoi
Fonsecaea pugnacius
Rhinocladiella tropicalis
Rhinocladiella aquaspersa

General Characteristics

The dematiaceous fungi were once only characterized by the dark coloration because of their ability to produce melanin. More recently, organisms, including medically important fungi, have been classified using molecular techniques (Table 60.1). Many of the agents in this chapter cause phaeohyphomycosis or chromoblastomycosis and are known agents of superficial and subcutaneous mycoses that involve the skin and subcutaneous tissues and, less commonly, deeply invasive or disseminated disease. These organisms are ubiquitous in nature and exist as saprophytes and plant pathogens. Humans and animals serve as accidental hosts after traumatic inoculation of the organism into cutaneous and subcutaneous tissues.

In the mycology laboratory, these fungal species often are initially separated by growth rate into the **slow-growing dematiaceous molds,** which may require 7 to 10 days to grow, and the **rapid-growing dematiaceous molds,** which usually grow in less than 7 days. It has been recommended that in medical mycology the term dematiaceous only be applied to rapidly growing members of the Ploesoporales (*Alternaria, Bipolaris, Curvularia, Exoserohilum,* and *Hongkongmyces*). This has not been widely implemented and will take time for all of the changes to be apparent in clinical mycology. When nonsterile body sites are cultured, determining the significance of these organisms is very difficult. If colonies of common saprophytic molds occur near the edge of the plate and are clearly away from the inoculum, they should be considered contaminants unless additional evidence of infection is present.

Epidemiology and Pathogenesis

Superficial Infections

Tinea nigra is a superficial skin infection caused by *Hortaea werneckii,* a halophilic species. It is manifested by blackish brown, macular patches on the palm of the hand or the sole of the foot. Lesions have been compared with silver nitrate staining of the skin. **Black piedra** is a fungal infection of the hair, scalp, and occasionally the axillary and pubic hair caused by the dematiaceous fungus *Piedraia hortae. Neoscytalidium dimidiatum,* a common plant pathogen, causes infections of the skin and nails that may lead to **hyperkeratosis** (thickening of the epidermis). These diseases occur primarily in tropical areas of the world, with cases reported from Africa, Asia, and Latin America. *Phialophora* spp. and *Cyphellophora* spp. have also been known to be the causative agents of mild skin infections and onychomycoses (M & M, Chowdhary 2015).

Several species in the order Chaetothyriales are capable of causing superficial infections in humans including *Cyphellophora* spp., *Phialophora europaea,* and *Knufia epidermidis.* The fungi are typically associated with mild cutaneous skin infections or nail infections.

Mycetoma

A **mycetoma** is a chronic granulomatous infection that usually involves the lower extremities but may occur in any part of the body. The infection is characterized by swelling, purplish discoloration, tumorlike deformities of the subcutaneous tissue, and multiple sinus tracts that drain purulent material containing yellow, white, red, or black granules called grains. The color of the granules is partly dependent on the type of infecting organism. The infection gradually progresses to involve the bone, muscle, or other contiguous tissue and ultimately requires amputation in most progressive cases. Dissemination of the organism may occur but is uncommon. Mycetomas usually are seen among people living in tropical and subtropical regions of the world whose outdoor occupations and failure to wear protective clothing predispose them to trauma.

Two types of mycetomas have been described. Actinomycotic (bacterial) mycetomas are caused by the aerobic actinomycetes, including *Nocardia, Actinomadura,* and *Streptomyces* spp. (The aerobic *Actinomycetes* are described in detail in Chapter 18.) Eumycotic (fungal) mycetomas are caused by a heterogeneous group of fungi that have septate hyphae. Eumycotic mycetomas are subcategorized as white grain mycetomas or black grain mycetomas, a distinction determined by the pigmentation of the infecting agent's hyphae.

Some hyaline septate molds can cause mycetomas; however, the disease is covered in this section because many of the etiologic agents are dematiaceous fungi. Etiologic agents of eumycotic mycetoma to be discussed include *Scedosporium* spp. and *Acremonium* spp., causative agents of white grain mycetomas, and *Exophiala jeanselmei, Curvularia* spp., *Cladophialophora bantiana, Trematosphaeria grisea*, and *Madurella* spp., causative agents of black grain mycetomas.

TABLE 60.1 Classification and Taxonomy of the Clinically Relevant Melanized Fungi

Order	Genera	Species	Characteristics
Botryosphaeria	*Lasiodiplodia*	*L. theobroma*	Initially spherical, thick-walled hyaline conidia that brown with age and develop a median septum.
	Macrophomina	*M. phaseolina*	Dark sclerotic bodies and melanized mycelium.
	Neoscytalidium	*N. dimidiatum*	Produces arthroconidia in culture.
Calosphaeriales	*Pleurostoma*	*P. ochracea* *P. repens* *P. richardsiae*	Dark hyphae with pale, tapering phialides that may be single or aggregated in dense brushes; hyaline conidia.
Capnodiales	*Cladosporium*	*C. cladosporioides* *C. oxysporum* *C. sphaerospermum*	Branching chains of single-celled or septate conidia.
	Hortea	*H. werneckii*	Yeastlike, aseptate or septate elements.
Chaetothyriales	*Anthopsis*	*Anthopsis* sp.	Ampulliform phialides that appear inverted with collarettes.
	Arthrocladium	*A. fulminans*	Moniliform hyphae and chlamydospore-like structures.
	Cladophialophora	*C. bantiana* *C. carrionii*	Long, branched conidial chains and grows at 40°C. Small conidia in branched chains.
	Cyphellophora	*C. europaea* *C. laciniata* *C. ludoviensis* *C. pluriseptica* *C. reptans* *C. suttonii*	Slender, curved, transversely septate conidia.
	Exophiala	*E. bergeri* *E. dermatitidis* *E. jeanselmei* *E. oligosperma* *E. phaeomuriformis* *E. spinifera* *E. xenobiotica*	Conidia in chains or compacted phialides. *E. dermatitis* is recognized by phialides without collarettes with short annellated zones.
	Fonsecaea	*F. compacta* *F. monophora* *F. nubica* *F. pedrosoi* *F. pugnacius*	*Phialophora*-like phialides with collarettes and *Rhinocladiella*-like sympodial conidiophores.
	Knufia	*K. epidermidis*	Produce phialides, arthroconidia, holoblastic conidia, endoconidia, and yeastlike budding cells in culture.
	Phialophora	*P. verrucosa*	Darkened funnel-shaped collarettes.
	Rhinocladiella	*R. aquaspersa* *R. atrovirens* *R. basitona* *R. mackenziei* *R. similis* *R. tropicalis*	Sympoidial conidiophores with one-celled conidia on denticles.
	Veronaea	*V. botryose*	Sympodial rachis with denticles, single-septate conidia.
Diaporthales	*Diaporthe*	*D. bougainvilleicola* *D. longicolla* *D. phaseolorum* *D. phoenicicola*	Oval to fusoid conidia or thin, curved, or bent elongated conidia.

Continued

TABLE 60.1 **Classification and Taxonomy of the Clinically Relevant Melanized Fungi—cont'd**

Order	Genera	Species	Characteristics
Dothideales	*Aureobasidium*	*A. melanogenum* *A. pullulans*	Budding yeastlike, hyaline and melanized thick-walled hyphae that produce dark brown chlamydospores with age.
	Hormonema	*H. dematioides*	Produce conidia in a basipetal succession.
Microascales	*Knoxdaviesia*	*K. dimorphospora*	Lateral undifferentiated hyphae, epllipsoid, pale brown conidia.
	Lomentospora	*L. prolificans*	Elongated, annellidic conidiogenous cells and obovoid conidia.
	Microascus	*M. brunneosporus* *M. cinereus* *M. gracilis*	Dark brown to black, globose to ampulliform ascomata, with papilla. Ascospores are ellipsoid or quadrangular. Single or penicillate conidiophores with conidia in basipetal chains.
	Scopulariopsis	*S. asperula* *S. brevicaulis* *S. candida*	Globose or pyriform, black ascomata. Annellides arranged penicillately on conidiophore being single or small groups of stalks, smooth or rough walled conidia in basipetal chains.
	Scedosporium	*S. apiospermum* *S. aurantiacum* *S. boydii* *S. dehoogii*	Conidiophores with annelides. Conidia are obovoid and become brown with age. Produces laterally on hyphae or short pedicels.
	Triadelphia	*T. disseminate* *T. pulvinata*	
Ophiostomatales	*Ophiostoma*	*O. piceae*	Subglobose, dark perithecia asci with long necks; yeastlike cells and septate hyphae.
	Sporothrix	*S. brasiliensis* *S. chilensis* *S. globose* *S. luriei* *S. pallida* *S. schenckii*	Conidiophore bear clusters of thin denticles with hyaline, tear-shaped conidia. Subglobose or elongated conidia may also be present.
Pleosporales	*Alternaria*	*A. alternate* *A. infectoria*	Conidia in chains with alternating septa. *A. infectoria* produces conidia with long apical beaks.
	Bipolaris	*B. australiensis* *B. hawaiiensis* *B. oryzae* *B. spicifera*	Large ellipsoid to subcylindrical, straight conidia with a distosepta and a dark, flat basal scar.
	Curvularia	*C. aeria* *C. americana* *C. geniculate* *C. hominis* *C. muehlenbeckiae* *C. lunata* *C. senegalensis*	Elongated conidia that are distoseptate with an asymmetrical swollen middle cell resulting in a curved appearance.
	Exserohilum	*E. longirostratum* *E. mcginnisii* *E. rostratum*	Long, distoseptate conidia with a protruding basal hilum.
	Hongkongmyces	*H. pedis*	
Sordariales	*Madurella*	*M. mycetomatis*	
	Cladorrhinum	*C. bulbillosum*	Aseptate conidia with intercalary conidiogenous cells with lateral phialide openings.

TABLE 60.1 **Classification and Taxonomy of the Clinically Relevant Melanized Fungi—cont'd**

Order	Genera	Species	Characteristics
Togniniales	*Phaeoacremonium*	*P. parasiticum* *Phaeoacremonium* spp. (10 additional species)	Warted mycelium and slender, tubular, tapering brown phialides.
Venturiales	*Ochroconis*	*O. mirabilis*	Rust to brown olivaceous colonies that produce 1–3 septate conidia from small, open denticles on sympodial cells.
	Verruconis	*V. gallopava*	Same as *Ochroconis* sp.

Madurella mycetomatis is the most common fungal agent associated with mycetoma. However, nucleic acid–based sequencing of several genes has indicated that multiple additional species exist and are associated with mycetoma. These species have likely been misidentified as *M. mycetomatis* in previous cases and include *Madurella pseudomycetomatis, Madurella tropicana,* and *Madurella fahalii.*

Most patients with mycetomas live in tropical regions, but infections can occur in temperate zones. The most common etiologic agent of white grain mycetoma in the United States is caused by *Scedosporium* spp. The organisms associated with mycetoma are saprophytic and commonly found in soil, standing water, and sewage; humans acquire infections through traumatic implantation of the organism into the skin and subcutaneous tissues.

Chromoblastomycosis

Chromoblastomycosis is a chronic fungal infection acquired through traumatic inoculation of an organism, primarily into the skin and subcutaneous tissue. The infection is characterized by the development of a papule at the site of the traumatic insult that slowly enlarges to form warty or tumorlike lesions characterized as resembling cauliflower capable of spreading through the lymphatic system. Secondary infection and ulceration may occur. The lesions usually are confined to the feet and legs but may involve the head, face, neck, and other body surfaces.

Histologic examination of the lesion reveals characteristic **sclerotic bodies,** which are copper-colored, septate cells that appear to be dividing by binary fission and resemble copper pennies. These infections cause hyperplasia of the epidermal layer of the skin, which may be mistaken for squamous cell carcinoma. Fungal brain abscess, known as cerebral chromoblastomycosis, may be caused by the dematiaceous fungi; however, it is more appropriately considered a type of phaeohyphomycosis and is discussed with that disease. Chromoblastomycosis is widely distributed, but most cases occur in tropical and subtropical areas of the world. Occasional cases are reported from temperate zones, including the United States. The infection is seen most often in areas in which agricultural workers do not wear protective clothing and suffer thorn or splinter puncture wounds. The fungi most often associated with chromoblastomycosis include *Cladophialophora carrionii, Fonsecaea monophora* and *pedrosoi,* and *Phialophora verrucosa.* Additional species of *Cladophialophora* have also been reported as the cause of chromoblastomycosis.

Phaeohyphomycosis

Phaeohyphomycosis is a general term used to describe any infection caused by a dematiaceous organism; it includes molds; brownish, yeastlike cells; pseudohyphae; and hyphae, except those described previously. These infections may be subcutaneous, localized, or systemic, and they may be caused by a number of dematiaceous fungi. They include phaeohyphomycotic cysts, progressive soft tissue infection, brain abscess, sinusitis, endocarditis, mycotic keratitis, pulmonary infection, and systemic infection. Symptoms often include headache, neurologic manifestations, and seizures. The most common fungal isolates associated with neurologic manifestations include *C. bantiana, Rhinocladiella mackenziei, Verruconis gallopava,* and *Exophiala dermatitidis. Alternaria, Exserohilum, Bipolaris, E. jeanselmei, Exophiala spinifera,* and *Curvularia* spp. are also commonly associated with phaeophyomycosis.

Pathogenesis and Spectrum of Disease

The spectrum of disease caused by the dematiaceous fungi ranges from superficial infections (e.g., skin and hair) to emergent, rapidly progressive, and often fatal disease (e.g., brain abscess). The following list, which is not comprehensive, provides the common etiologic agents of diseases that may be caused by dematiaceous fungi (Table 60.2).

- Mycetoma
  - Bacterial: *Nocardia, Actinomadura,* and *Streptomyces* spp.
  - White grain mycetoma: *S. apiospermum* complex and *Acremonium* and *Fusarium* spp.
  - Black grain mycetoma: *Madurella* spp., *E. jeanselmei,* and *Curvularia* spp.
- Chromoblastomycosis: *Cladophialophora, Phialophora,* and *Fonsecaea* spp.
- Phaeohyphomycosis: *E. jeanselmei; E. dermatitidis;* and *Curvularia, Bipolaris, Alternaria,* and *Exserohilum* spp.

- Sinusitis: *Alternaria, Bipolaris, Exserohilum,* and *Curvularia* spp.
- Mycotic keratitis and endophthalmitis: *E. dermatitidis, Bipolaris,* and *Curvularia* spp.
- Brain abscess: *C. bantiana, E. dermatitidis,* and *Bipolaris* spp.

Laboratory Diagnosis

Specimen Collection, Transport, and Processing

See General Considerations for the Laboratory Diagnosis of Fungal Infections in Chapter 58.

TABLE 60.2 **Common Isolated Dematiaceous Fungi**

Organism	Disease	Site	Tissue Form
Slow-Growing Species			
Cladophialophora spp.	Chromoblastomycosis	Subcutaneous	Sclerotic bodies
	Phaeohyphomycosis	Brain, subcutaneous	Septate hyphae
Verruconis gallopava	Phaeohyphomycosis	Brain, subcutaneous, lungs	Septate hyphae
Exophiala dermatitidis	Phaeohyphomycosis	Brain, eye, subcutaneous, and dissemination	Hyphal fragments and budding yeast
	Pneumonial	Lungs	
Hortaea jeanselmei	Mycetoma phaeomycotic cyst	Subcutaneous	Hyphal fragments and budding yeasts
Hortaea werneckii	Tinea nigra	Skin	Hyphal fragments and budding yeast
Fonsecaea spp.	Chromoblastomycosis	Subcutaneous	Sclerotic bodies
	Phaeohyphomycosis	Brain	Septate hyphae
	Cavitary lung disease	Lungs	Septate hyphae
Phialophora spp.	Chromoblastomycosis	Subcutaneous	Sclerotic bodies
	Phaeohyphomycosis	Subcutaneous	Septate hyphae
	Septic arthritis	Joints	Septate hyphae
Piedraia hortae	Black piedra	Hair	Asci-containing nodules cemented to hair shafts
Madurella spp.	Mycetoma	Subcutaneous	Hyphal fragments
Rapid-Growing Species			
Alternaria spp.	Phaeohyphomycosis	Subcutaneous	Septate hyphae
	Sinusitis	Sinuses	Septate hyphae, possibly fungus ball
	Nasal septal erosion	Nasal septum	Septate hyphae
	Ulcers and onychomycosis	Skin, nails	Septate hyphae
Bipolaris spp.	Phaeohyphomycosis	Subcutaneous, brain, eye, bones	Septate hyphae
	Sinusitis, fungus ball	Sinuses	Septate hyphae; possibly fungus ball
Curvularia spp.	Sinusitis	Sinuses	Septate hyphae; possibly fungus ball
	Phaeohyphomycosis	Subcutaneous, heart valves, eye, and lungs	Septate hyphae
Exserohilum spp.	Phaeohyphomycosis	Subcutaneous	Septate hyphae
Scedosporium spp. (*Scedosporium apiospermum* complex)	Mycetoma	Subcutaneous	Granules of hyaline hyphae
	Phaeohyphomycosis	Subcutaneous, skin, joints, bones, brain, lungs	Septate, hyaline hyphae

Direct Detection Method

Stains

In general, dematiaceous fungal hyphae are seen in clinical specimens by direct microscopic examination or by histopathologic examination of tissue obtained during surgery or autopsy. The dematiaceous character of the hyphae may not be appreciated if the examination is performed using calcofluor white or fluorescent microscopy alone, without observing the hyphae using traditional transmitted light microscopy. The **Fontana-Masson stain,** 10% silver nitrate and ammonium hydroxide, stains fungal elements brown to black in a red background. This technique improves the detection of melanin granules. The Fontana-Masson stain is useful to detect melanization that may appear as hyaline molds using light microscopy.

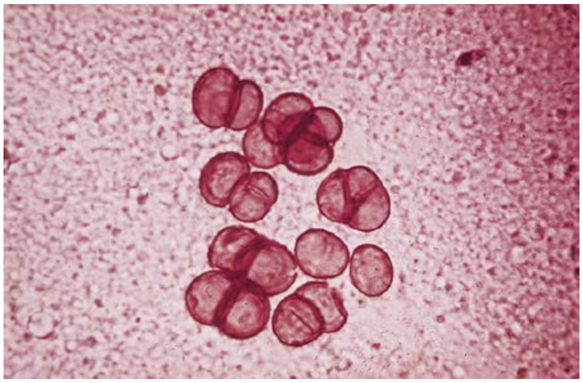
Superficial Infections

Direct microscopic examination of a clinical specimen from a patient with tinea nigra may show dematiaceous hyphae and small budding yeast cells and/or hyphal fragments. Portions of hairs from a patient with black piedra are examined in wet mounts using potassium hydroxide (KOH) that is gently heated for nodules composed of cemented mycelium. Crushing the mature nodules reveals oval asci, containing two to eight aseptate ascospores, 19 to 55 µm long by 4 to 8 µm in diameter. The asci are spindle shaped and have a filament at each pole.

Sinusitis associated with fungal infections typically reveal dense masses of pigmented, branched and septate hyphae. The hyphal elements appear as amorphous fungal balls that block the sinus cavities but are not invading the mucosal lining.

Chromoblastomycosis

The laboratory diagnosis of chromoblastomycosis is made easily. Scrapings from crusted lesions added to 10% KOH show **muriform cells** (aggregation of dark brown cells that resemble stones in a stonewall) or sclerotic bodies, which are rounded, brown, 4 to 10 µm in diameter, and have fission planes. They resemble copper pennies (Fig. 60.1).



• Fig. 60.1 Sclerotic bodies from the tissue of a patient with chromoblastomycosis (×400). (From Velasques LF, Restrepo A. Chromomycosis in the toad (*Bufo marinus*) and a comparison of the etiologic agent with fungi causing human chromomycosis. *Sabouraudia* 1975;13:1.)

Mycetoma and Phaeohyphomycosis

Direct examination of clinical specimens from patients with a eumycotic mycetoma or phaeohyphomycosis demonstrates yellowish brown, septate to **moniliform hyphae** (string of beads), with or without budding yeast cells present. The presence of dematiaceous yeasts depends on the fungus. Dematiaceous yeasts are commonly seen in the direct examination of clinical specimens from patients with infections caused by *Exophiala* spp. Macroscopic examination of granules from mycetoma lesions caused by *S. apiospermum* complex reveal them to be white to yellow and 0.2 to 2 mm in diameter. Microscopically, the granules of *S. apiospermum* complex consist of loosely arranged, intertwined septate hyaline hyphae cemented together.

Observation of pigmented hyphae in hematoxylin-eosin or unstained histopathologic sections is presumptive for a diagnosis of dematiaceous fungal disease. The methenamine silver stain used to detect fungal elements in tissues stains fungi black, which makes determining whether they are hyaline septate or dematiaceous septate molds impossible. Fontana-Masson stain, which stains the melanin and melanin-like pigments in the cell walls of these organisms, may be used to confirm the presence of pigmented hyphae in histologic sections. Culture of the specific etiologic agent is necessary for final confirmation.

Serologic Testing

Some serologic and skin tests may be useful for the diagnosis of allergy to dematiaceous fungi. However, serology is not useful for the diagnosis of invasive dematiaceous fungal disease.

Nucleic Acid–Based Tests

Nucleic acid amplification assays can be used for detection or identification of these fungi. Polymerase chain reaction (PCR) tests have been developed for *S. apiospermum* complex, and direct DNA testing is available for *Madurella* spp. from the actual grains. Amplification tests have been developed to detect fungal DNA in normally sterile body fluids such as cerebrospinal fluid and brain tissue in patients with suspected fungal meningitis.

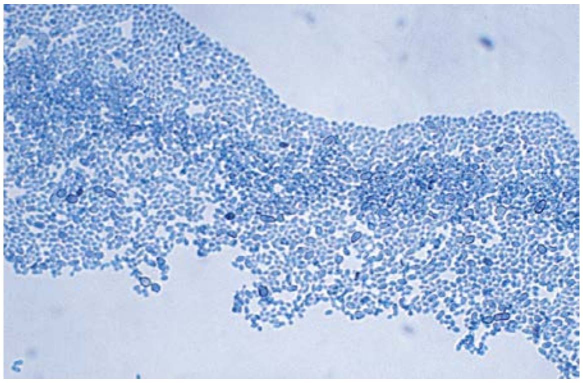
Nucleic acid–based sequencing of ribosomal genes may be used for the identification of fungal isolates. However, sequences should be evaluated carefully by comparison with type strains. In addition, a variety of high-resolution multigene typing systems have been used in recent years primarily for epidemiologic purposes.

Matrix-Assisted Laser Desorption Ionization Time-of-Flight Mass Spectrometry

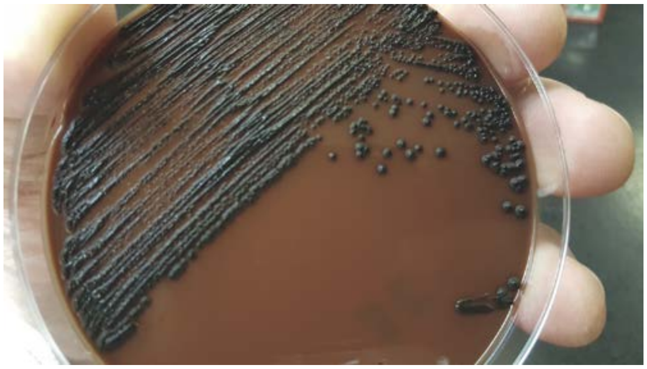
Matrix-assisted laser desorption ionization time-of-flight mass spectrometry (MALDI-TOF MS) has been successfully used to identify clinically relevant fungal isolates including yeasts and molds. As more application of this technique becomes available in the clinical laboratory, rapid diagnosis of fungal infections will undoubtedly become more accurate, resulting in improved patient prognosis and treatment.

Cultivation

Although dematiaceous molds recovered in the clinical mycology laboratory may represent true pathogens, more often they represent transient microbiota, inhaled spores, or contaminants. Cultures from sterile body sites, if aseptically obtained, should not contain these molds. Cultures should be interpreted in conjunction with the results of the direct examination for fungal elements, corresponding histopathology, and discussion with the clinician to most effectively establish the diagnosis of mycotic infection caused by these organisms.



• **Fig. 60.2** Yeast forms of *Hortaea werneckii.*



• **Fig. 60.3** *Exophiala jeanselmei* on chocolate agar. (Photo courtesy Brooks Kyle Murillo-Kennedy, Houston, TX.)

Superficial Infections

H. werneckii, the causative agent of tinea nigra, may be recovered on common fungal media but grows very slowly. Initial colonies of *H. werneckii* may be olive to black, shiny, and yeastlike (Fig. 60.2) and usually grow within 2 to 3 weeks. As the cultures age, colonies become filamentous, with velvety gray aerial hyphae. *P. hortae,* the causative agent of black piedra, is easily cultured on any fungal culture medium lacking cycloheximide. Colonies of this organism are also very slow growing, appear dark brown to black, and produce aerial mycelium. Some isolates may produce a red to brown diffusible pigment.

Cyphellophora produce slender, curved, one- to three-septate conidia. The conidia are produced on **collarettes.** Cultures are typically melanized without budding cells. *Exophilia,* which is considered a black yeast, demonstrates a high degree of morphologic variability. Colonies initially appear moist and then become wooly or velvety. The conidia are produced from narrow scars or extensions referred to as annelidic. The *Exophilia* are also capable of growth at 40°C and fail to assimilate nitrate. *Phialophora* produce phialides (flask shaped) and have no budding cells.

N. dimidiatum produces a rapidly growing black arthroconidia in culture.

Mycetoma

White Grain Mycetoma. *Scedosporium* spp. grow rapidly (5 to 10 days) on common laboratory media. Initial growth begins as a white, fluffy colony that changes in several weeks to a brownish gray (the so-called mousy gray) colony; the reverse of the colony progresses from tan to dark brown. *Acremonium* spp. that cause mycetomas, such as *Acremonium falciforme,* grow slowly and produce gray colonies.

Black Grain Mycetoma. Colonies of *Madurella* spp. and *E. jeanselmei* (Fig. 60.3) are slow growing, unlike colonies of *Curvularia* spp. Colonies of *Madurella* spp. vary from white (during the early phases of growth) to olive-brown; a brown diffusible pigment is characteristic of this fungus. Colonies of *E. jeanselmei* appear yeastlike and darkly pigmented (olive to black) but in time develop a velvety appearance with the production of aerial hyphae. *Curvularia* spp. produce a fluffy or downy, olive-gray to black colony, and growth is rapid. *T. grisea* forms slow-growing, velvety colonies that appear smooth or radially furrowed and dark gray or olive-brown to black. The reverse side of the colonies appears black. The hyphae are septate and nonsporulating.

Chromoblastomycosis

The fungi known to cause chromoblastomycosis, *Cladophialophora, Phialophora* spp., and *Fonsecaea* spp., are all dematiaceous. These fungi are slow growing and produce heaped-up, slightly folded, darkly pigmented colonies with a gray to olive to black and velvety or suedelike appearance. The reverse side of the colonies is jet black. Microscopic examination is necessary to identify the pathogenic agent definitively.

Phaeohyphomycosis

The colonies of many of the rapidly growing dematiaceous molds are similar; identification relies on microscopic examination. The colonies of *Alternaria* spp. are rapidly growing, fluffy, and gray to gray-brown or gray-green. *Curvularia* spp. produce rapidly growing colonies that resemble those of *Alternaria* spp. *Bipolaris* spp. produce colonies that are gray-green to dark brown and slightly powdery, as do *Exserohilum* spp.

The colonies of many of the slow-growing dematiaceous molds are also similar to one another and require identification based on microscopic morphology. *E. jeanselmei* and *E. dermatitidis* grow slowly (7 to 21 days) and initially produce shiny, black, yeastlike colonies. *E. dermatitidis* often is mucoid and may be brown, compared with *E. jeanselmei,* but the two organisms are very similar in appearance. Colonies become filamentous and velvety with age because of the production of mycelium. *E. spinifera* produces large, stiff conidiophores. *C. bantiana* produces long, poorly branched conidial chains. The fungus is also capable of growth at 40°C. *R. mackenziei* produces pale brown conidiophores with elongated conidia on denticles (projection or peg) and may produce exophiala-like budding cells in culture. *V. gallopava* produces a rusty-brown to olive colony with one- to three-septate condia on small denticles. The colonial morphology of other slowly growing dematiaceous fungi (e.g., *Fonsecaea* spp.) was described in the previous section.

Approach to Identification

Superficial Infections

H. werneckii is a dematiaceous fungus that produces yeastlike cells that may be one or two celled. Conidia produced by this organism are produced by annellophores (conidia-forming cells that produce conidia-containing transverse rings), which bear successive rings (annelides) that are difficult to see microscopically. The biophysical profile is used to differentiate this fungus from other *Exophiala* spp. In contrast, *P. hortae* usually does not sporulate on routine mycologic media but demonstrates highly septate, dematiaceous hyphae and swollen intercalary cells.

Mycetoma

The specific etiologic agent of a eumycotic mycetoma cannot be determined without culturing the organism. Culture media containing antibiotics should not be used as the sole medium for culturing clinical specimens from a mycetoma, because species of the aerobic actinomycetes are susceptible to antibacterial antibiotics and may be inhibited by these agents.

White Grain Mycetoma: *Scedosporium apiospermum* complex and *Acremonium* spp.

As previously mentioned, white grain mycetoma are hyaline molds that produce septate hyphae. The features described here are useful for identification regardless of the disease process (i.e., mycetoma or hyalohyphomycosis). *S. apiospermum* complex is also involved in causing a variety of infections elsewhere in the body. These include infections of the nasal sinuses and septum, meningitis, arthritis, endocarditis, mycotic keratitis, external otomycosis, brain abscess, and disseminated invasive infection. Most of these more serious infections occur primarily in immunocompromised patients.

S. apiospermum is the former asexual phase of *Pseudoallescheria boydii.* A nomenclature transition is currently in progress that would result in a single genus and species name for fungi that demonstrate multiple morphologic forms. The asexually produced conidia of *S. apiospermum* complex are golden brown, elliptical to pyriform and single-celled and are borne singly from the tips of long or short conidiophores (annellophores) (Fig. 58.2). This anamorph (a fungus that disseminates reproductive structures without meiosis) predominates in cultures from clinical specimens. Another anamorphic form, the *Graphium* stage of *S. apiospermum* complex, is less common. It consists of clusters of conidiophores with conidia produced at the ends; it has also been referred to as **coremia** (Fig. 58.3). The teleomorphic form of the organism produces brown to black cleistothecia, which are pseudoparenchymatous, saclike structures containing asci and ascospores. When the latter are fully developed, the large (50 to 200 µm), thick-walled cleistothecia rupture, releasing the asci and ascospores (Fig. 58.1).

Another *Scedosporium* species, *Scedosporium prolificans,* has been associated with infections other than mycetomas, such as arthritis or invasive disease in immunocompromised patients. *S. prolificans* differs from *S. apiospermum* in that it produces inflated, flask-shaped annellophores. The obsolete or previous name for *S. prolificans* was *Scedosporium inflatum,* which more accurately reflects the morphology of the conidiophore. Recognition of this organism also is important, because it is resistant to most if not all the commonly used antifungal agents.

Acremonium spp. develops hyaline hyphae and produces simple, unbranched, erect conidiophores. Single-celled conidia are produced loosely or in gelatinous masses at the tip of the conidiophore (Fig. 58.17). Intercalary and terminal chlamydoconidia may also be produced.

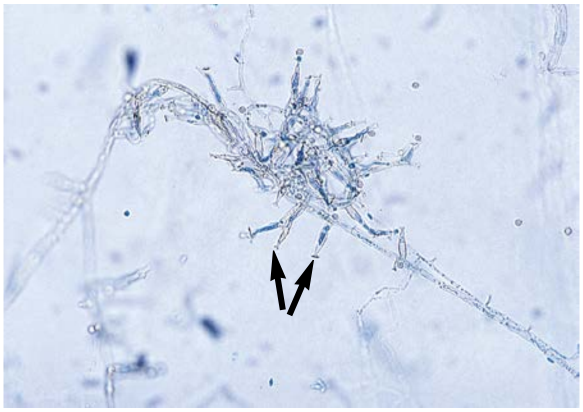
Black Grain Mycetoma: *Exophiala jeanselmei, Curvularia* spp., and *Madurella* spp.

Sterile hyphae are produced when *Madurella* spp. is grown on rich fungal media. Nutritionally poor media may be used to induce sporulation. Long, tapering phialides with collarettes and **sclerotia** may be seen. Temperature tolerance, biochemical hydrolysis, and assimilation studies may be used to differentiate *M. mycetomatis* from *T. grisea.* (See *Phaeohyphomycosis,* later in the chapter, for the description of *E. jeanselmei* and *Curvularia* spp.)

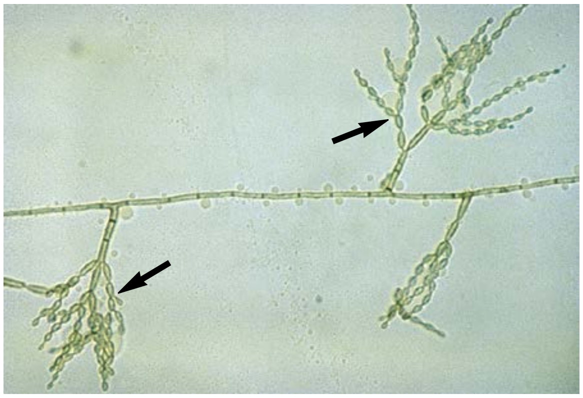
Chromoblastomycosis: *Cladosporium, Phialophora*, and *Fonsecaea* spp.

The taxonomy of the organisms that cause chromoblastomycosis is complex. Their identification is based on somewhat distinct microscopic morphologic features. These are polymorphic fungi that may produce more than one type of conidiation. The genus *Cladosporium* includes species that produce long chains of budding, often fusiform, conidia (blastoconidia) that have a dark septal scar.

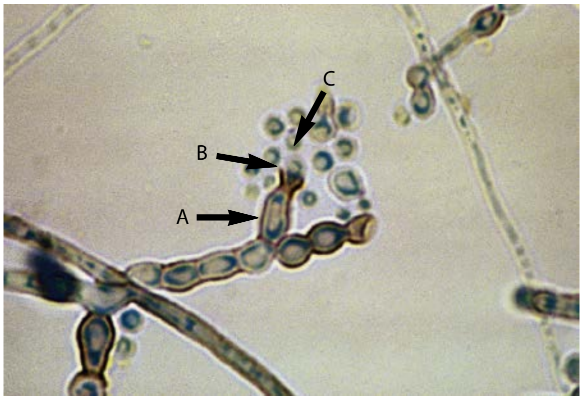
The genus *Phialophora* includes species that produce short, flask-shaped to tubular phialides, each with a well-developed collarette. Clusters of conidia are produced by the phialides through an apical pore and often remain aggregated near the opening in a gelatinous mass. *Phialophora* spp. produce colonies that are wooly and olive-brown to brownish gray; some strains may appear to have concentric zones of color. Microscopically, hyphae are dematiaceous, and sporulation is



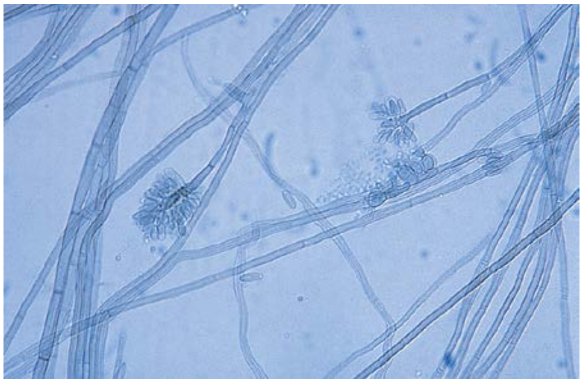
• **Fig. 60.4** *Pleurostomophora richardsiae* (previously *Phialophora richardsiae*) showing phialides with prominent, saucerlike collarette (*arrows*) (×500).



• **Fig. 60.5** *Cladophialophora* spp. showing *Cladophialophora* type of sporulation (*arrows*) with chains of elliptical conidia (×430).



• **Fig. 60.6** *Phialophora verrucosa* showing flask-shaped phialide (*A*) with distinct collarette (*B*) and conidia (*C*) near its tip (×750).



• **Fig. 60.7** Both the *Rhinocladiella* and *Phialophora* types of sporulation may be produced by *Fonsecaea pedrosoi* and are demonstrated here (×430).

common. *Pleurostomophora richardsiae* (previously *Phialophora richardsiae*) produces phialides with distinct flattened or saucerlike collarettes (Fig. 60.4). In contrast, *P. verrucosa* produces deeper, more cup- or flask-shaped phialides. Pleomorphic phialides may also be seen with these species; however, all produce either or both hyaline elliptical conidia or brown elliptical conidia within the phialides.

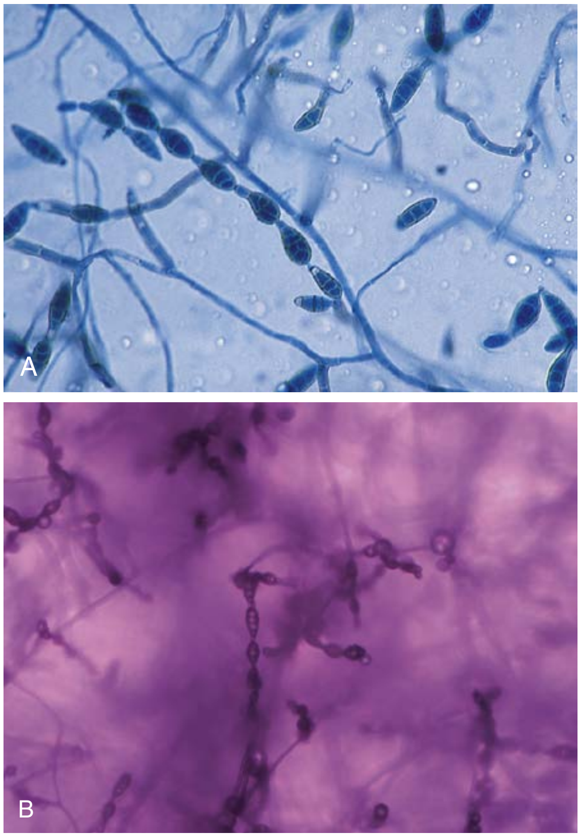
The genus *Fonsecaea* includes organisms that exhibit a mixed type of sporulation. The genus produces a distinct *Fonsecaea*-type conidiophore, which somewhat resembles truncated *Cladophialophora*-type sporulation. It may also produce a *Rhinocladiella*-type sporulation, in which single-celled conidia are produced on denticles that arise from all sides of conidiophores (**sympodically**). A mixture of the *Fonsecaea, Rhinocladiella,* and *Cladophialophora* types may occur, and phialides with collarettes or *Phialophora*-type sporulation also may be present.

The diagnostic features of the *Cladophialophora, Phialophora,* and *Fonsecaea* genera can be summarized as follows:

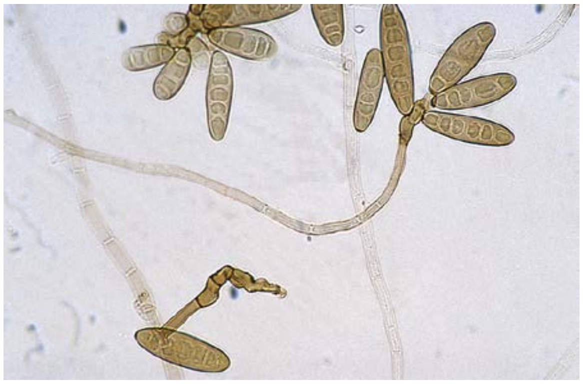
- *Cladophialophora (C. carrionii): Cladophialophora* type of sporulation with long chains of elliptical conidia (2 to 3 µm × 4 to 5 µm) borne from erect, tall, branching conidiophores (Fig. 60.5).
- *Phialophora* spp.: *P. verrucosa* produces phialides, each with a distinct cup- or flask-shaped collarette (Fig. 60.6); *P. richardsiae* produces phialides with a flattened collarette (Fig. 60.4). Conidia are produced endogenously and occur in clusters at the tip of the phialide.
- *Fonsecaea* spp.: Conidial heads with sympodial arrangement of conidia are seen, with primary conidia giving rise to secondary conidia (Fig. 60.7). *Cladophialophora*-type, *Phialophora*-type, and/or *Rhinocladiella*-type sporulation may also occur.

Phaeohyphomycosis: *Alternaria, Bipolaris, Cladophialophora, Curvularia, Exophiala, Exserohilum*, and *Phialophora* spp.

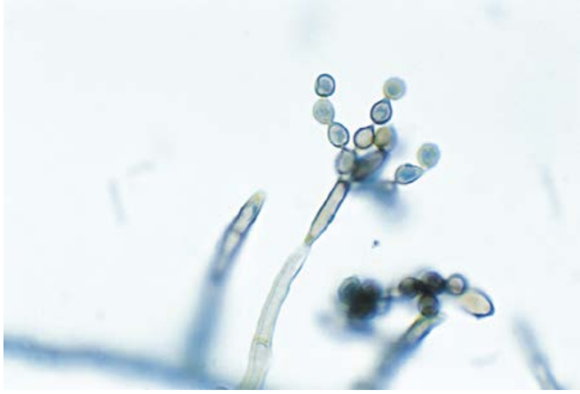
A useful approach to identification of the dematiaceous molds is first to determine whether single-celled or multicelled conidia are produced. If conidia are produced singly, the laboratorian should determine whether they are produced individually or in chains (e.g., *Cladophialophora* spp.). In cellophane tape preparations, the chains of conidia produced by *Cladophialophora* spp. are easily disrupted. If multicellular conidia are produced, examining the septation within the conidium is useful. Multicellular conidia with septation in the horizontal axis of the conidium (i.e., the axis perpendicular to the longitudinal axis of the conidium)



• **Fig. 60.8** (A) *Alternaria* spp. showing chaining multiform dematiaceous conidia with horizontal and longitudinal septa. (B) Microscopic morphology (200× magnification) of *Alternaria* spp. demonstrating growth within Biomed Diagnostics commercially prepared InTray fungal media. The design of the InTray media permits growth and imaging without preparation of microscopic slides, (Photo courtesy Biomed Diagnostics, Inc., White City, OR.)



• **Fig. 60.9** *Bipolaris* spp. showing dematiaceous, multicelled conidia produced sympodically from geniculate conidiophores (×430).



• **Fig. 60.10** *Cladophialophora* spp. showing branching chains of dematiaceous blastoconidia that are easily dislodged during preparation of a microscopic mount (×430).

are characteristic of certain organisms, such as in *Bipolaris* and *Curvularia* spp.; conidia with septation in both the longitudinal and horizontal axes of the conidium are characteristic of other fungi, such as *Alternaria* spp.

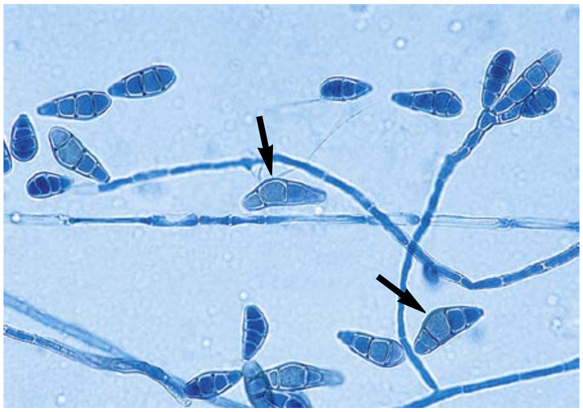
***Alternaria* spp.** Microscopically, hyphae are septate and golden-brown pigmented; conidiophores are simple but sometimes branched. Conidiophores bear a chain of large, brown conidia resembling a drumstick and contain both horizontal and longitudinal septa (Fig. 60.8). Observing chains of conidia sometimes is difficult, because they may be dislodged, as the culture mount is prepared.

***Bipolaris* spp.** Hyphae are dematiaceous and septate. However, conidiophores are characteristically bent (**geniculate**) at the locations where conidia are attached; conidia are arranged sympodically and are oblong to **fusoid.** The hilum protrudes slightly (Fig. 60.9). **Germ tubes** are formed at one or both ends, parallel to the long axis of the conidium, when the fungus is incubated in water at 25°C for up to 24 hours (i.e., from both poles, thus the name *Bipolaris*).

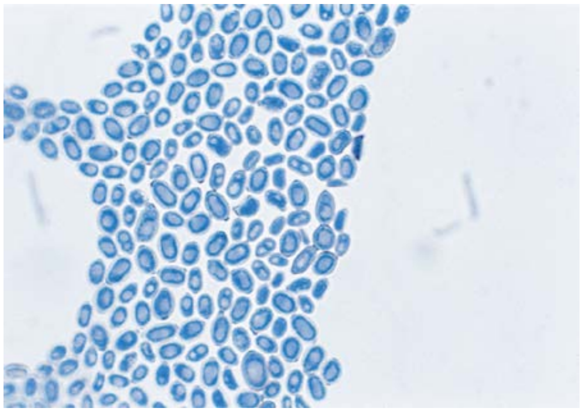
***Cladophialophora* spp.** Microscopically, hyphae are septate and brown. Conidiophores are long, branched, and give rise to branching chains of darkly pigmented, budding conidia. Conidia usually are single-celled and exhibit prominent attachment scars (dysjunctors). The cells that produce the branch points are often referred to as **shield cells** (Fig. 60.10). This organism commonly fails to reveal chains of conidia on wet mounts, because conidia are so easily dislodged.

***Curvularia* spp.** Microscopically, hyphae are dematiaceous and septate. Conidiophores are geniculate (i.e., bent where conidia are attached). Conidia are arranged sympodically and are golden-brown, multicelled, and curved, with a central swollen cell (Fig. 60.11). The end cells are lighter in color than the swollen cell.

***Exophiala* spp.** Only the *Exophiala* species *E. jeanselmei* and *E. dermatitidis* are considered here; although other species exist, they are recovered far less commonly in the clinical laboratory. The microscopic features of young colonies of *Exophilia* spp. exhibit dematiaceous, yeastlike cells (Fig. 60.12). Although these may appear to be budding, close inspection may disclose that the daughter cells are produced by annelides rather than true buds. The microscopic features of young colonies of *Exophilia* spp. exhibit dematiaceous, yeastlike cells. Feltlike, filamentous colonies produce dematiaceous hyphae and conidiophores that are cylindrical and have a tapered tip. Annellations may be visible at the tip, and clusters of oval to round conidia are apparent (Fig. 60.13). Potassium nitrate is



• **Fig. 60.11** *Curvularia* spp. showing twisted conidiophore and curved conidia with a swollen central cell (*arrows*) (×500).



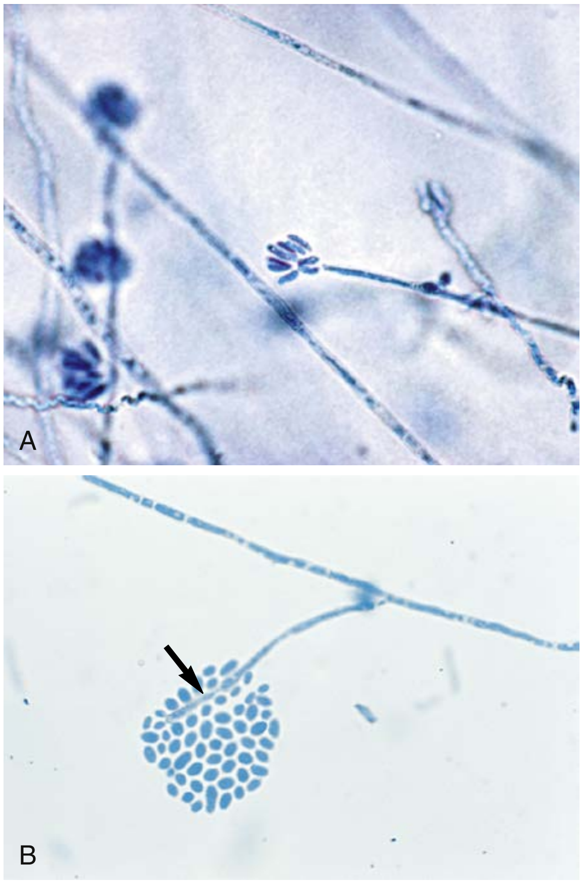
• **Fig. 60.12** *Exophiala dermatitidis* showing dematiaceous, yeast-like cells from a young culture. These forms asexually reproduce via annelides rather than through true budding (blastoconidiation) (×500).

used by *E. jeanselmei* but not by *E. dermatitidis*. Temperature studies are also useful for differentiating the most common *Exophiala* species. Both *E. jeanselmei* and *E. dermatitidis* grow at 37°C, but only *E. dermatitidis* can grow at 40°C to 42°C.

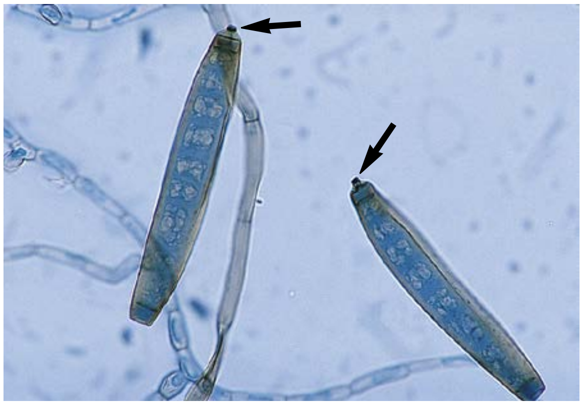
***Exserohilum* spp.** Hyphae are septate and dematiaceous. Conidiophores are geniculate, and conidia are produced sympodically. Conidia are elongate, are ellipsoid to fusoid, and exhibit a prominent **hilum** that is truncated and protruding (Fig. 60.14). The conidia are multicellular, have perpendicular septa, and usually contain five to nine septa.

Antifungal Susceptibilities

Antifungal susceptibilities for melanized fungi for most clinically relevant species are known. However, interpretive breakpoints have not been standardized. Amphotericin B and the azoles have demonstrated clinical effectiveness against infections with melanized fungi. Triazoles, posaconazole, and voriconazole have a broad spectrum of activity against most of these fungi. Occasional treatment failure of mycetoma has been associated with the use of voriconazole.



• **Fig. 60.13** (A) *Exophiala jeanselmei* showing elongated conidiophore (annellophore) with a narrow, tapered tip (×500). (B) *Exophiala dermatitidis* showing elongated tubular annellophores (*arrow*); morphologically very similar to *Exophiala jeanselmei* (×500).



• **Fig. 60.14** *Exserohilum* spp. showing elongated multicelled conidia with prominent hila (*arrows*).

CASE STUDY 60.1

A 54-year-old female presents to her physician with a mildly tender subcutaneous cyst on her right forefinger. She experienced trauma to her hand while gardening 6 weeks earlier. The cyst is punctured, and the exudate is examined microscopically and cultured. Direct microscopic examination reveals yeastlike cells and brown, pigmented, branching, septate hyphae. The culture is slow growing and initially develops a shiny black, yeastlike colony that age to a filamentous, velvety texture with black reverse.

Questions

1. What genus of fungi should be considered?
2. If you saw cylindrical conidiophores that had annellation at the tips and clusters of conidia, what test or tests would you perform next to aid identification?
3. You find that this mold grows at 37°C but not at 42°C. What organism is this?

Chapter Review

1. Brown patches on the palm of the hand or the sole of the foot are caused by:
- **a.** *Cladophialophora* spp.
- **b.** *Exophiala* spp.
- **c.** *Hortae werneckii*
- **d.** *Acremonium* spp.

2. Adding specimen scrapings to 10% KOH to show the presence of sclerotic bodies that resemble copper pennies is useful in the diagnosis of:
- **a** Chromoblastomycosis
- **b** Phaeohyphomycosis
- **c** Mycetomas
- **d** Zygomycosis

3. Which of the following is the causative agent of black grain mycetoma?
- **a** *E. jeanselmei*
- **b** *Curvularia* spp.
- **c** *Madurella* spp.
- **d** All of the above

4. Which of the following is a fungus known to cause chromoblastomycosis?
- **a** *Curvularia* spp.
- **b** *Acremonium* spp.
- **c** *Bipolaris* spp.
- **d** *Fonsecaea* spp.

5. Which laboratory test may be used to differentiate *E. jeanselmei* from *E. dermatitidis?*
- **a.** Urea
- **b.** Growth at 42°C
- **c.** Esculin
- **d.** Germ tube

6. True or False

______ Dematiaceous fungi most commonly involve deeply invasive disease.

______ Most patients with mycetomas live in tropical locations.

______ Serologic assays are routinely used to diagnose infections caused by dematiaceous fungi.

______ *P. boydii* is resistant to amphotericin B.

______ Sclerotic bodies are present in histologic slides of lesions from chromoblastomycosis.

7. Matching: *Match each term with the correct description.*

______ *H. werneckii*
______ *P. hortae*
______ *Acremonium* spp.
______ *Curvularia* spp.
______ Mycetoma
______ Chromoblastomycosis
______ *Cladophialophora* spp.

a. granulomatous infection of the lower extremities
b. conidia (with dark septal scar) in long chains
c. tinea nigra
d. black piedra
e. black grain mycetoma
f. infections acquired via traumatic inoculation
g. white grain mycetoma

61

Atypical and Parafungal Agents

OBJECTIVES

1. Describe the symptoms of *Pneumocystis jirovecii* infection and the cells affected by this organism.
2. List the appropriate specimen types collected for diagnosis of pneumocystis pneumonia.
3. Discuss the laboratory tests used in the diagnosis of *P. jirovecii* infection, including the methodology and biochemical principles.
4. List the diseases and morphologic characteristics used in diagnosing infections of the parafungi *Lacazia loboi*, *Lagenidium* spp., *Pythium insidiosum*, and *Rhinosporidium seeberi.*

GENUS AND SPECIES TO BE CONSIDERED

Current Name	Previous Name
Pneumocystis jirovecii	*Pneumocystis carinii*
Lacazia loboi	
Lagenidium spp.	
Pythium insidiosum	
Rhinosporidium seeberi	

PNEUMOCYSTIS

General Characteristics

In 1999, the name of the organism that causes a pneumonia in immunocompromised humans, commonly called **pneumocystis pneumonia (PCP),** was changed from *Pneumocystis carinii* to *Pneumocystis jirovecii.* One of the causative organisms for the rodent form of pneumocystis is still called *P. carinii;* the other is *Pneumocystis wakefieldiae.* Although there are currently five recognized species of *Pneumocystis, P. jirovecii* is the only species that is known to infect humans. The organism is an opportunistic, atypical fungus that infects immunocompromised hosts and mostly manifests as PCP. However, transmission from infected patients to immunocompetent health care workers has been reported.

P. jirovecii originally was believed to be a trypanosome. Several factors supported the notion that *P. jirovecii* was a protozoan parasite; its morphology is similar to that of protozoa, and clinically it responds to antiprotozoal drugs but not to antifungal drugs in patients with **pneumocystosis.** Inability to maintain and propagate the organism in routine culture has further limited its characterization, although cultivation is possible under special conditions. *P. jirovecii* exists as three forms in its life cycle: the **trophic form (trophozoite), sporozoite (precyst),** and **ascus (cyst),** which is the diagnostic form.

Although *P. jirovecii* has been shown to be a fungus, it differs from other fungi in various aspects. Its cell membrane contains cholesterol rather than ergosterol. The flexible-walled trophic form is susceptible to osmotic disturbances. In addition, *P. jirovecii* contains only one or two copies of the small ribosomal subunit gene, whereas most other fungi contain numerous copies of this gene. Deoxyribonucleic acid (DNA) sequence analysis of the small ribosomal subunit gene in *P. jirovecii* has disclosed a greater sequence homology with the fungi than with the protozoa. Two independent analyses that compared the DNA sequences of *P. jirovecii* with those of other fungi confirmed the placement of *P. jirovecii* in the fungal kingdom, in the phylum Ascomycota.

Epidemiology

P. jirovecii has a worldwide distribution and most commonly presents as pneumonia in an immunocompromised host. Recently, PCP has been shifting toward non–human immunodeficiency virus (HIV)-infected immunosuppressed patients, such as hematologic malignancy and autoimmunity. The use of powerful immunosuppressive therapies has led to this shift. *Pneumocystis* is transmitted person-to-person via airborne particles. Immunocompetent individuals appear to be the reservoir for *P. jirovecii,* which is transmitted to immunodeficient individuals as a pathogen. Most children by age 2 to 4 years have antibodies to *Pneumocystis*, suggesting acquisition early in life. Vargas et al. showed that *Pneumocystis* DNA was present in 24 of 72 infants, as determined from nasopharyngeal specimens, and that seroconversion occurred in 85% of infants by 20 months of age.

Since the onset of the HIV and acquired immunodeficiency syndrome (AIDS) epidemic in the 1980s, *Pneumocystis* has been defined as the most common opportunistic infection among those with HIV or AIDS in the United States. The introduction of highly active antiretroviral therapy (HAART) for patients with HIV has reduced the incidence of disease. However, PCP remains a significant medical problem because numerous patients with HIV do not respond to therapy, do not comply with therapy, or do not know they are infected.

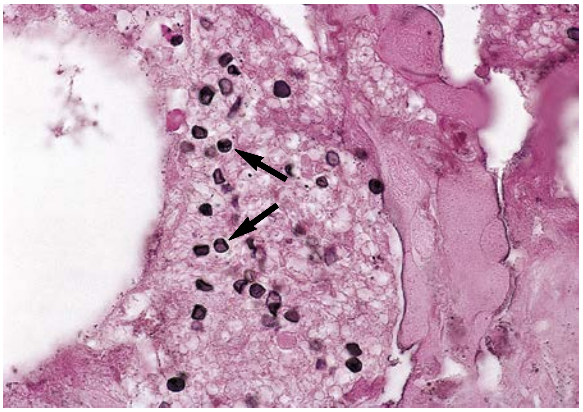
The results of DNA testing demonstrate the detection of *P. jirovecii* in immunocompetent populations as well as additional groups of patients with chronic underlying disease.

Pathogenesis and Spectrum of Disease

After *P. jirovecii* is inhaled, the trophic form of the pathogen is believed to adhere to type I pneumocytes (thin squamous epithelial cells of the lungs). The organisms replicate extracellularly while bathed in alveolar lining fluid. With successful replication of the organism, the alveolar spaces fill with an eosinophilic foamy material, which can be detected with hematoxylin and eosin staining. This technique does not provide direct staining of the organisms. Methenamine silver or another fungal stain may be used to identify the cyst form of the organism in lung tissue. Infection with the organism and the pathophysiologic changes described result in impaired oxygen-diffusing capacity and hypoxemia. A predominantly interstitial mononuclear inflammatory response is associated with this type of pneumonia. When first described, this pneumonia was known as **interstitial plasma cell pneumonia.**

Symptoms of PCP include a nonproductive cough, low-grade fever, dyspnea, chest tightness, and night sweats. In patients without HIV infection, the underlying conditions most commonly seen as risk factors for this opportunistic infection are asthma, chronic obstructive pulmonary disease (COPD), cystic fibrosis, systemic lupus erythematosus (SLE), pregnancy, rheumatoid arthritis, infection with Epstein-Barr virus, ulcerative colitis, and high-dose corticosteroid therapy. During treatment with an antiretroviral medication, patients show an improvement and an increase in CD4+ cells. However, following a brief period of improvement, the patients begin to deteriorate because of an exaggerated immune response referred to as **immune reconstitution inflammatory syndrome.**

Extrapulmonary infection has been reported in 0.6% to 3% of postmortem samples collected from patients who were diagnosed with *P. jirovecii* pneumonia. Extrapulmonary cysts have been identified in lymph nodes, the spleen, bone marrow, and the liver, predominantly. Additional extrapulmonary sites include the adrenal glands, gastrointestinal tract, genitourinary tract, thyroid, ear, pancreas, eyes, and skin. Multiple sites of infection typically indicate a more rapid disease progression and fatal outcome.



• **Fig. 61.1** Cystic forms of *Pneumocystis jirovecii (arrows)* stain well with methenamine silver and hematoxylin and eosin stain (×500).

Laboratory Diagnosis

Specimen Collection and Transport

Respiratory specimens from the deep portions of the lung, such as bronchoalveolar lavage (BAL), are best for detection of *P. jirovecii.* A sputum specimen submitted for direct examination should be induced sputum obtained by a trained respiratory therapist; otherwise, the rate of false-negative results may be unacceptably high. Additional acceptable respiratory specimens include tracheal aspirates, pleural fluid, transbronchial biopsy, or cellular material from bronchial brushings. Nasopharyngeal and oropharyngeal samples have demonstrated high sensitivity and specificity for the diagnosis of PCP when used in nucleic acid–based testing methods for *P. jirovecii.* Collection for the diagnosis of extrapulmonary pneumocystis requires biopsy of the infected organ and histologic staining.

Specimen Processing

See the following section for specific details for specimen processing required for the various test methods.

Direct Detection Methods

Stains

The diagnosis of *P. jirovecii* pneumonia currently is based on the clinical presentation, radiographic studies, and direct or pathologic examination of respiratory samples or biopsy material. The flexible-walled trophic forms are the predominant morphology of the organism, but these are difficult to visualize. They are somewhat discernible in Giemsa-stained material, but their pleomorphic appearance makes this form of the organism difficult to identify. Giemsa stains the nuclei of all the various life cycle stages as reddish purple with a light blue cytoplasm. A firm-walled cyst also exists, although the cysts are outnumbered by the trophozoites 10 to 1. Cysts are more easily recognized than the trophic form and may be definitively identified using a variety of stains, such as calcofluor white, methenamine silver, and immunofluorescent staining (Fig. 61.1). The cysts are spherical to concave, are uniform in size (4 to 7 μm in diameter), do not bud, and contain distinctive intracystic bodies.

A comparison of the four most common staining methods used for *P. jirovecii* (i.e., Giemsa, immunofluorescent, calcofluor white, and methenamine silver) has demonstrated that immunofluorescent staining (Merifluor *Pneumocystis;* Meridian Bioscience, Cincinnati, OH), Monofluo *P. jirovecii* IFA (Bio-Rad, Hercules, CA), calcofluor white staining (Fungifluor; Polysciences, Warrington, PA), and methenamine silver staining (GMS) and Wright-Giemsa (Diff-Quik; Baxter Scientific, McGaw Park, IL) likely represent the best balance between sensitivity and specificity and have the best overall positive and negative predictive values. The immunofluorescent method showed greater sensitivity than the other three but a smaller negative predictive value. Therefore, if this method is used as a screening tool for the presence of *Pneumocystis*, a confirmatory method should be performed because of the high number of false-positive results.

Direct Detection of (1-3)-Beta-D-Glucan

The ascus (cyst) cell wall component, (1-3)-beta-D-glucan, has been used to successfully diagnose infections with *P. jirovecii.* Other fungi also secrete the molecule but in lower amounts. There are several commercial assays available; however, they are not all Food and Drug Administration (FDA) approved for use within the United States. The Fungitell Assay (Associates of Cape Cod, Falmouth, MA) uses patient serum for the detection of (1-3)-beta-D-glucan. Normal human serum contains low levels of (1-3)-beta-D-glucan (10 to 40 pg/mL) from the commensal yeasts that are present in the alimentary canal and gastrointestinal tract. Therefore values less than 60 pg/mL are considered negative, 60 to 79 pg/mL are indeterminate, and greater than 80 pg/mL are positive. It is important to use additional diagnostic information and confirmatory testing in conjunction with this test, because other yeast or fungi also secrete (1-3)-beta-D-glucan during infection.

Nucleic Acid Detection

A variety of nucleic acid amplification assays for *P. jirovecii* have been developed, including, most recently, real-time polymerase chain reaction (PCR) methods and multiplex assays. However, because of the potential for colonization of immunocompetent populations, positive nucleic acid–based testing results must be directly correlated with the patient's history and clinical presentation. As of this writing, no tests have been FDA approved for use in the United States.

Serologic Testing

Serology is useful for epidemiological purposes but not for the diagnosis.

Cultivation

P. jirovecii is very difficult to cultivate outside the lung; therefore routine culture methods are not performed.

Approach to Identification

See Direct Detection Methods.

Treatment

Trimethoprim-sulfamethoxazole (TMP-SMX) and pentamidine isethionate are the predominant agents used to treat PCP. Both drugs have significant side effects including nephrotoxicity. The use of TMP-SMX is also associated with the development of resistant strains.

Rare Atypical and Parafungal Agents

Lacazia loboi

L. loboi is the causative agent of lobomycosis, a rare granulomatous zoonotic fungal infection mostly of the skin and subcutaneous tissue. The lesions and nodules are described as leprosy-like and generally appear in cooler regions of the body, indicating the pathogen does not grow well at body temperature (37°C). The organism has been found in the soil, on vegetation, and in aquatic animals in tropical and subtropical areas, especially the bottlenose dolphins. The transmission to humans is not known but theorized that infection results from traumatic entry or entry into broken skin from contaminated water. Direct dolphin to human transmission has been reported by an aquarium attendant. Human to human transmission has also been reported.

Laboratory Diagnosis and Treatment

L. loboi can be seen in stained tissue biopsies; the organism itself is uncultivable *in vitro.* Morphologically, the organism resembles *Paracoccidioides brasiliensis* (Chapter 62). Biopsied material will show yeastlike cells and an influx of inflammatory cells. The cells are uniform in size, with a thick outer membrane and appear to be chaining, connected by small tubules. The uniformity in size can help to differentiate from *P. brasiliensis*. Treatment of infection with *L. loboi* is difficult because this organism is resistant to most antifungals; therefore surgical removal is required.

Pythium insidiosum

P. insidiosum is a funguslike, aquatic oomycete organism. The organism is found in the tropical, subtropical, and temperate areas. Isolation of *P. insidiosum* can be performed using mycologic media such as Sabouraud dextrose agar. The organism has two phases, a more funguslike, mycelium-producing phase and a biflagellate zoospore, which is the infectious stage. Zoosporogenesis can be initiated only in water cultures *in vitro.* Infections are thought to be acquired by traumatic injection into the skin or the intestinal tract by traumatic lesions from contaminated aquatic environments. Infective keratitis has also been reported. Person to person transmission has not been observed. Infection with *P. insidiosum* includes cutaneous and subcutaneous lesions with the formation of plaques and ulcers. Orbital infections have also been reported. Vascular pythiosis can be seen more commonly in Thailand, especially in patients with thalassemia.

Laboratory Diagnosis and Treatment

Serologic testing is not specific and therefore not recommended. Tissue samples are used for diagnosis and can be examined by direct microscopy. Samples may be stained with a variety of immunohistochemical stains. Stained skin and tissue samples typically demonstrate hyphal structures that are short or long, sparsely septate, tubular structures and inflammatory cells, especially eosinophils and mast cells. A 10% potassium hydroxide (KOH) preparation may also be used to visualize the hyaline hyphal elements in tissue scrapings.

Culture can be used for the diagnosis of infection with *P. insidiosum*. Small pieces of tissue should be embedded into the mycological media and incubated at 25°C and 37°C for 24 to 48 hours. Specimens received more than 24 hours after collection should be placed in a broth tube and incubated at 37°C. Two percent Sabouraud dextrose agar or broth with or without antibiotics is the most common media used to isolate *P. insidiosum.* However, identification of *P. insidiosum* requires the development of the characteristic oogonia (sexual stage) in culture. This is extremely rare. Nucleic acid–based testing has been used to identify the organism and is recommended over culture. Identification is therefore limited by the lack of availability of the molecular test in clinical laboratories.

Treatment

P. insidiosum do not contain chitin and ergosterol similar to yeasts and fungi; therefore, the organism is resistant to antifungals. Combination antibiotics including minocycline, linezolid, and chloramphenicol have been successfully used to treat keratitis associated with *P. insidiosum*.

Lagenidium spp.

Lagenidium spp. is an emerging oomycete similar to *P. insidiosum* and the causative agent of lagenidiosis. As with *P. insidiosum*, *Lagenidium* spp. has two forms, the mycelial form and the biflagellate zoospore. *Lagenidium* cases have been found in wet areas. The organism is found in crabs, mosquito larvae, nematodes, and other organisms. Person-to-person transmission has not been identified. The organism causes invasive skin, subcutaneous, and arterial infections. Additional infection sites have been also noted: cornea, gastrointestinal tract, and extremities. Systemic infections have also been identified in humans and animals.

Laboratory Diagnosis

The organism can be examined using microscopy and isolated on fungal media similar to *P. insidiosum.* On solid media, *Lagenidium* spp. produces white-yellow submerged colonies. The hyphae have spherical structures, which can be seen at the end of the hyphae in liquid cultures. Histopathologic staining of the infective sites cannot differentiate between *Lagenidium* or *P. insidiosum*. Morphology is similar, and both initiate localized eosinophilia. The development of the zoospores and the presence of broad, aseptate hyphae in wet mounts, as well as identification by molecular methods, should be used to confirm the presence of *Lagenidium* spp.

Treatment

Lagenidium spp. lack sterols in their cellular membranes and are therefore resistant to antifungal medications.

Rhinosporidium seeberi

R. seeberi is described as a Mesomycetozoea protistal eukaryote. This organism is similar morphologically to the parasitic form of *Coccidioides*. Infections are usually identified in tropical or subtropical areas. The mechanism of transmission is unknown; however, the pathogen can be found in aquatic environments, and resistant spores are present in terrestrial environments. Infection is likely acquired by exposure to resistant spores through breaks in the skin or mucous membranes. Infection results in the formation of painless polyps in the mucosal areas of the nose, eye, larynx, genitalia, and rectum.

Laboratory Diagnosis

Tissue biopsies are the preferred method used for diagnosis. Wet mounts from the polyps demonstrating sporangia and endospores are usually present in cases of rhinosporidiosis. Confirmation of rhinosporidiosis disease is based on the identification of greater than 300 μm spherical sporangia with endospores and a negative fungal culture.

Treatment

R. seeberi is resistant to antifungals. Surgical removal of the infected tissue and polyps can be used, but recurrence is common.

CASE STUDY 61.1

A 69-year-old male is diagnosed with follicular lymphoma and placed on a 4-week regimen of combination chemotherapy. During the fourth week of treatment, the patient develops a fever that lasts 3 days. On the third day, he is admitted to the hospital. The findings from the initial physical examination are normal except for the fever. The following laboratory test results are obtained:

White Blood Cell (WBC) count	2.5 × 10^9/L	Normal: 4.5–11.0 × 10^9/L
Absolute neutrophil count	1.1 × 10^9/L	Normal: 50%–60% of WBCs
Serum beta-D-glucan	182 pg/mL	Normal: <20 pg/mL
Computed tomography (CT) scan of the lungs	Ground-glass opacities in the lung	

These findings result in a diagnosis of interstitial pneumonia. The patient is treated with intravenous (IV) panipenem/betamipron, micafungin, and ganciclovir.

The patient does not seem to be recovering. After additional testing, he is switched to oral trimethoprim-sulfamethoxazole (TMP-SMX), and the lung infiltrates disappear within 2 weeks.

Questions

1. What additional testing would have been performed to confirm the diagnosis of *Pneumocystis jirovecii*?
2. What patient characteristics would have contributed to the patient's susceptibility to infection with *P. jirovecii*?

Chapter Review

1. A 65-year-old male with HIV presents to the emergency department with night sweats, a nonproductive cough, and a low-grade fever. PCP is suspected. Which of the following is the best specimen for diagnostic staining for *P. jirovecii?*

a. Urine
b. Sputum
c. Bronchial alveolar lavage fluid
d. Blood
e. Nasopharyngeal swab

2. The organism responsible for causing leprosy-like skin lesions and is resistant to antifungal treatment is:

a *P. insidiosum*
b *R. seeberi*
c *L. loboi*
d *Lagenidium* spp.

3. Short Answer

List at least three stains used to detect *P. jirovecii.*

62

The Yeasts and Yeastlike Organisms

OBJECTIVES

1. Explain the etiology and epidemiology of *Candida, Cryptococcus, Trichosporon,* and *Malassezia* spp.
2. Describe the macroscopic phenotypes and microscopic structures used to identify yeasts and yeastlike isolates.
3. Differentiate yeast and yeastlike species based on microscopic, macroscopic, and biochemical test results.
4. Compare and contrast the methods used to identify yeasts, including staining, antigen testing, and biochemical and growth characteristics (i.e., morphology).
5. Diagram an algorithm for identifying the yeasts discussed in this chapter.
6. Describe the limitations associated with the phenotypic and genotypic techniques used for the identification of organisms discussed in this chapter.

GENERA AND SPECIES TO BE CONSIDERED

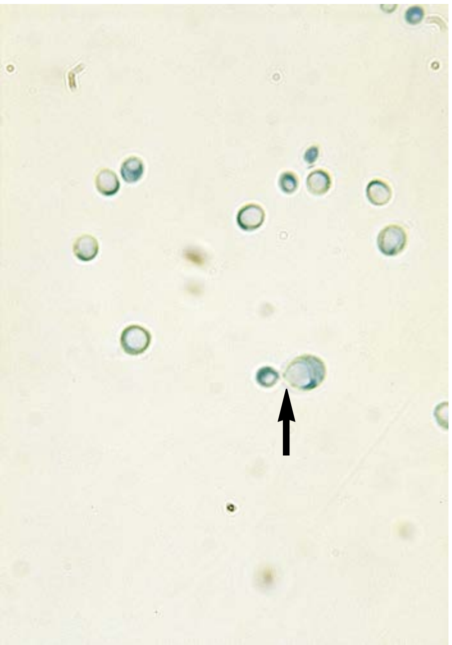
Apiotrichum sp. (previously *Trichosporon* sp.)
Candida spp.
Cryptococcus spp.
Cutaneotrichosporon spp. (previously *Trichosporon* spp.)
Filobasidium sp. (previously *Cryptococcus* sp.)
Geotrichum sp.
Hannaella sp. (previously *Cryptococcus* sp.)
Malassezia spp.
Naganishia spp. (previously *Cryptococcus* spp.)
Papiliotrema spp. (previously *Cryptococcus* spp.)
Prototheca sp.
Rhodotorula spp.
Saccharomyces sp.
Solicoccozyma sp. (previously *Cryptococcus* sp.)
Saprochaete spp. (previously *Blastoschizomyces* spp.)
Sporobolomyces spp.
Trichosporon spp.
Ustilago spp. (previously *Pseudozyma* spp.)

General Characteristics

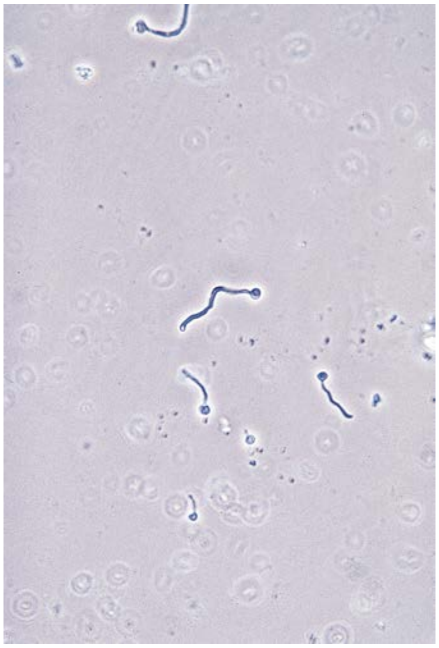
Yeasts are eukaryotic, unicellular organisms that are round to oval and range in size from 2 to 60 µm. They are not a formal taxonomic unit, but rather a group of unrelated fungi that demonstrate the unicellular growth form as yeast. The microscopic morphologic features have limited usefulness in helping to differentiate or identify these organisms. The microscopic morphology on cornmeal or RIOT (rice infusion, oxgall, and polysorbate) agar is useful when considered in conjunction with the biophysical profile (i.e., a combination of the biochemical and physical characteristics used in the identification of a microorganism) obtained using a commercial identification system. It is often impossible to differentiate yeasts in direct microscopic and histopathologic examination of clinical specimens, but occasionally particular characteristics are seen that suggest the identification or are **pathognomonic** (i.e., unique) for a specific organism. Important morphologic characteristics that are useful in differentiating yeasts include the size of the cells, the presence or absence of a capsule, the production of chlamydospores, and broad-based or narrow-necked budding. For example, variability in size with evidence of a capsule and narrow-necked budding are features that can be helpful for distinguishing *Cryptococcus* spp. from *Candida* spp. The medically important yeasts discussed in this chapter have been taxonomically classified as *Ascomycota* or *Basidiomycota.*

In general, yeasts reproduce asexually by **blastoconidia** formation (budding) (Fig. 62.1) and sexually by the production of ascospores or basidiospores. The process of budding begins with a weakening and subsequent outpouching of the yeast cell wall. This process continues until the **bud,** or daughter cell, is completely formed. The cytoplasm of the bud is contiguous with the cytoplasm for the original cell. Finally, a cell wall **septum** is created between mother and daughter yeast cells. The daughter cell often eventually detaches from the mother cell, and a residual defect occurs at the budding site (i.e., a **bud scar**).

With certain environmental stimuli, yeast can produce different morphologies. An outpouching of the cell wall that becomes tubular and does not have a constriction at its base is called a **germ tube**; it represents the initial stage of true hyphae formation (Fig. 62.2). Alternatively, if buds elongate, fail to dissociate, and form subsequent buds, **pseudohyphae** are formed; to some, these resemble links of sausage (Fig. 62.3). Pseudohyphae have cell wall constrictions rather than true intracellular septation delineating the fungal cell borders.

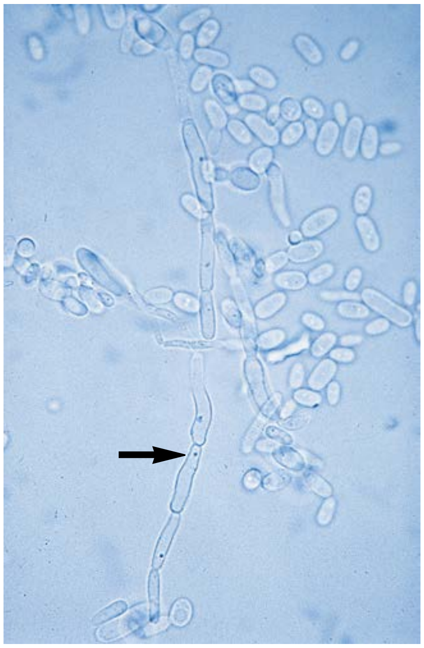


• **Fig. 62.1** Blastoconidia (budding cells *[arrow]*) characteristic of the yeasts.



• **Fig. 62.2** Germ tube test for *Candida albicans* showing yeast cells with germ tubes.

Macroscopically, many yeasts may appear as moist, creamy colonies. The yeast may produce a capsule resulting in a shiny or mucoid colonial appearance. Yeast may produce bright pigments, e.g., *Rhodotorula* spp., or appear hyaline or melanized (dematiaceous). Microscopic and macroscopic morphology along with biochemical analysis has been historically used for yeast identification. Commercial databases containing different phenotypic reactions are often somewhat limited to routinely identify yeasts and can lead to inaccurate results. Most commercial systems can reliably identify commonly encountered organisms, e.g., *C. albicans* complex (*C. albicans, C. africana, C. dubliniensis*) or *C. glabrata.* The worldwide emergence of *Candida auris* presented a global threat as it was often multidrug resistant and no traditional biochemical system could accurately identify the organism. The adoption of matrix-assisted laser desorption ionization time-of-flight mass spectrometry (MALDI-TOF MS) and the decrease in cost of DNA sequencing technology has greatly improved the ability to readily identify infrequently seen organisms in most clinical mycology laboratories. However, not all routine clinical laboratories are equipped with MALDI-TOF MS or other molecular technology. As a result, the commercially available yeast phenotypic identification systems remain available for laboratories of all sizes. Some commercial systems have extensive computer databases that include biochemical profiles of many yeasts. Variations in the reactions of carbohydrates and other substrates utilized are considered in the identification of yeasts provided by these systems.



• **Fig. 62.3** Pseudohyphae consisting of elongated cells *(arrow)* with constrictions at attachment.

Commercially available systems can be used in conjunction with some of the less expensive and rapid screening tests that provide presumptive identification of *Cryptococcus* spp. and definitive identification of *Candida albicans*. Chromogenic agar and *C. albicans* peptide nucleic acid fluorescent in situ hybridization (PNA FISH) (AdvanDX, Woburn, MA) are two examples of diagnostic tools that provide rapid characterization for the identification of *C. albicans* (Fig. 62.4). Because some laboratories continue

to use conventional systems, the information presented in this section discusses rapid screening methods for presumptive identification of yeasts, commercial identification systems, and a conventional schema for identifying commonly encountered yeast.

The number of fungal infections caused by yeasts and yeastlike fungi has increased significantly. This can be attributed to patients living longer with chronic health conditions (i.e., diabetes). Most of these infections have been caused by various *Candida* spp. However, other yeasts also cause significant disease, particularly in immunocompromised hosts (i.e., recipients of hematopoietic stem cell and solid organ transplants). In addition to causing disease in immunocompromised patients, infections are common in postsurgical patients, trauma patients, and patients with long-term indwelling catheters. Some of these yeasts are resistant to commonly used antifungal agents, which emphasizes the need for prompt, appropriate identification and, in some cases, antifungal susceptibility testing. Unfortunately, antifungal susceptibility testing (Chapter 63) is not as widely performed in most clinical laboratories compared to susceptibility testing for bacteria.

Epidemiology

Yeast are ubiquitous in the environment and often are part of the microbiota of both humans and animals. Immunocompromised patients are particularly susceptible to infection from yeasts that are members of the endogenous human microbiota, particularly the skin, upper respiratory, gastrointestinal (GI), and genitourinary tracts. Health care–associated infections can contribute to the increased development of pathogenic yeast infections because of person-to-person transmission.

Candida spp.

The genus *Candida* contains more than 200 species. *Candida* spp. are the yeast identified most commonly in the mycology laboratory and responsible for most opportunistic fungal infections. Currently *Candida* spp. are the fourth most common cause of hospital-acquired bloodstream infections (BSIs), and nonalbicans *Candida* species cause two-thirds of invasive infections in the United States. According to data from the CDC Emerging Infections Program, in some geographic locations, *C. glabrata* complex species are frequently isolated. Yeast infection mortality rates can exceed 50% or more in patients with severe candidemia. Ninety-five percent of all invasive *Candida* infections are attributed to *C. albicans* complex, *C. glabrata* complex (*C. glabrata, C. bracarensis, C. nivariensis*), *C. tropicalis, C. parapsilosis* complex (*C. parapsilosis, C. orthopsilosis, C. metapsilosis*), and *C. krusei*.

Differentiating among the *Candida* spp. in the clinical mycology laboratory is vital as susceptibility to antifungal agents can no longer be reliably predicted due to mutations in drug targets and the acquisition of resistance determinants.

Cryptococcus spp.

Cryptococcus spp. are a basidiomycetous yeast. *Cryptococcus neoformans* and *C. gattii* complex was historically divided into five serotypes. Serotype A has been referred to as *C. neoformans* var. *grubii,* and serotype D as *C. neoformans* var. *neoformans.* Serotypes B and C were the distinct species *C. gattii.* Based on molecular diagnostics the group has been reorganized. The name *C. neoformans* has been retained to describe the species formerly designated *C. neoformans* var. *grubii*, and the new species *C. deneoformans* refers to those serotype D isolates (formerly *C. neoformans* var. *neoformans*). The *C. gattii* complex is composed of five cryptic species: *C. gattii, C. deuterogattii, C. tetragattii, C. decagattii,* and *C. bacillisporus.* An increasing number of non-*C. neoformans* species have also been increasingly isolated from human infections, and many have been reclassified into other genera as discussed in this chapter.

Standard biochemical laboratory tests do not differentiate *C. neoformans* from *C. deneoformans* or the five species in the *C. gattii* complex. *C. neoformans* is widely distributed in nature, and aerosolization is a prerequisite to most infections. *C. neoformans* can infect many organisms including amoebas, flies, other insects, nematodes, and a variety of animals such as dolphins, koalas, and cats. *C. neoformans* is the most commonly isolated species in immunocompromised hosts worldwide, and *C. deneoformans* is more commonly isolated in Europe. These two species are found in pigeon or other bird excreta. *C. gattii* complex occasionally is isolated from immunocompromised patients; however, more infections are identified in immunocompetent individuals in areas where the organisms are endemic. The natural habitat for *C. gattii* complex are gum trees and other plants in temperate and subtropical regions.

Filobasidium sp., *Hannaella* sp., *Naganishia* spp., *Papiliotrema* spp., and *Solicoccozyma* sp.

The organisms in this group are all non-*C. neoformans* species that have been reclassified and are occasionally isolated from a variety of serious human infections. *Filobasidium uniguttulatum* (previously *Cryptococcus uniguttulatus*) has been associated with ventriculitis and meningitis. *Hannaella luteolus* (previously *Cryptococcus luteolus*) has been known to cause tenosynovitis, requiring more than a year of antifungal treatment. The genus *Naganishia* includes four organisms previously included in the *Cryptococcus* genus: *N. adeliensis (C. adeliensis), N. albidus (C. albidus), N. diffluens (C. diffluens)*, and *N. liquefaciens (C. liquefaciens).* The genus *Papiliotrema* includes the previous *Cryptococcus* species, *C. laurentii* and *C. flavescens*. And lastly, *Cryptococcus terreus* is now included in the genus *Solicoccozyma.* These organisms are opportunistic pathogens, and like *Cryptococcus* spp. the reservoir and transmission for the organisms is contaminated excreta from pigeons and other birds. *F. uniguttulatum* has also demonstrated resistance to common antifungal agents including azoles and flucytosine. The nomenclature changes and reorganization have the potential to result in misdiagnosis in the clinical laboratory and treatment failures in the highly susceptible immunocompromised patient populations.

Geotrichum sp.

Geotrichum candidum can be isolated as normal human microbiota and is considered an opportunistic pathogen. The organism is commonly isolated from respiratory infections in immunocompromised individuals.

Malassezia spp.

Malassezia are included in the *Basidiomycota* and are found on the skin of humans and animals. There are more than 15 species of *Malassezia* spp. The organism causes several superficial skin diseases as well as pulmonary and bloodstream infections. Many of the species are lipophilic. *M. furfur, M. globosa, M. obtuse, M. pachydermatis, M. slooffiae,* and *M. sympodialis* are the more commonly isolated species in the clinical laboratory.

Prototheca spp.

The *Prototheca* spp. are considered achlorophyllous algae but are included here as a yeastlike organism because the clinical presentation is fungal-like and they are often confused with yeast. The genus includes six species that are ubiquitous in nature. *Prototheca wickerhamii* and *P. zopfii* are the two species more commonly isolated in the clinical laboratory. An increasing number of *Prototheca* spp. systemic infections are becoming more prevalent in immunocompromised patients.

Rhodotorula spp.

The genus *Rhodotorula* contains numerous species that are ubiquitous in the environment. The organisms are normal inhabitants of the skin and can be found in many different environments from food and beverages to salt and freshwater including bathtubs, showers, and swimming pools. There have been several changes to the taxonomic distribution of species, and it will undoubtedly continue to evolve. Currently there are several species that are clinically relevant including *R. dairenensis, R. glutinis*, and *R. mucilaginosa.*

Saccharomyces sp.

Saccharomyces cerevisiae has long been considered nonpathogenic and rarely associated with human disease. However, recent use of probiotic prophylaxis for treatment of antibiotic-associated diarrhea and contact with health foods containing the organism has resulted in the reports of increasing infections associated with the organism. The organism has also been transmitted in health care settings and is able to persist in the environment. Person-to-person transmission is possible resulting in colonization and infection in immunocompromised individuals.

Saprochaete spp.

Saprochaete (previously *Blastoschizomyces*) belongs to the Ascomycetous yeasts. *Saprochaete* spp. are typically found in the environment in regions where the summers are hot and dry with warm, wet winters. The organisms may also be isolated as normal human microbiota from the skin, respiratory, and GI tract. Although the genus contains approximately 12 valid species, *S. capitata* is the most common clinically isolated species. Infections have been primarily identified in immunocompromised patients.

Sporobolomyces spp.

The organisms within the genus *Sporobolomyces* are also environmental organisms that can be found in aquatic habitats such as freshwater lakes, in association with plants, mammals, or birds. Many of the species have been reassigned to other genera using molecular techniques. However, the three species that are clinically significant have been retained in the *Sporobolomyces* spp. (i.e., *S. holosaticus, roseus*, and *S. salmonicolor*).

Trichosporon spp., *Apiotrichum* spp., and *Cutaneotrichosporon* spp.

The genus *Trichosporon* has been reorganized with several species being moved to the related genera, *Apiotrichum* and *Cutaneotrichosporon*. Many of these organisms are associated with cutaneous and systemic infections that can result in high mortality rates. The organisms are also often isolated in health care–associated infections.

Ustilago spp.

Ustilago spp. (previously *Pseudozyma*) are emerging pathogens and typically found in the environment as plant pathogens. They have been referred to as smuts that cause significant damage to agricultural crops. There are six recognized species that have been isolated from blood specimens and associated with disseminated infection. The organisms are primarily transmitted to humans by the inhalation of spores from the environment. As with other fungal infections, infected patients are typically immunocompromised, thrombocytopenic, and neutropenic.

Pathogenesis and Spectrum of Disease

Candida albicans Complex

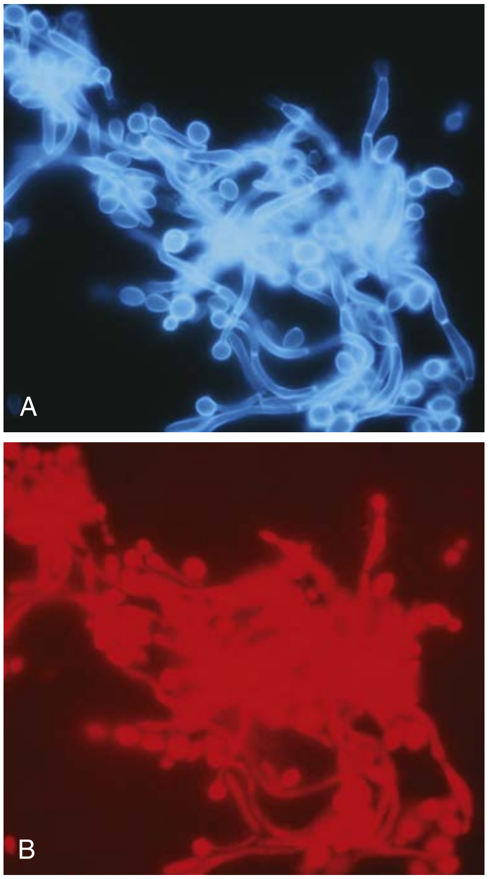
The *C. albicans* complex is composed of three species: *C. albicans, C. dubliniensis,* and *C. africana. C. albicans sensu stricto* is the major pathogen of the *Candida* genus and is commonly identified in the clinical laboratory. **Candidiasis** is a clinical syndrome caused by a *Candida* spp. It may include oroesophageal candidiasis, **intertriginous candidiasis** (in which skin folds are involved), **paronychia** (an infection of the tissues surrounding the nails), onychomycosis (an infection of the nail and the nail bed), respiratory infections, vulvovaginitis, pulmonary infection, eye infection, candidemia, endocarditis, meningitis, or disseminated infection. **Thrush,** an infection of the mucous membranes in the mouth, is considered a localized infection. Thrush can be seen in newborns, patients with HIV infection, individuals with diabetes, and patients undergoing chemotherapy. Creamy patches or colonies appear on the tongue and mucous membranes. *Candida* spp. may be recovered from the oropharynx, GI tract, genitourinary tract, and skin.

The clinical significance of the organisms recovered from respiratory tract secretions is difficult to determine, because *Candida* spp. are considered part of the normal oropharyngeal microbiota in humans. Invasive candidiasis has increased in incidence because of the increase in patients with compromised immunity, expansion of critical care units and outpatient clinics, and delayed therapy. Invasive candidiasis and hematogenous spread has resulted in an increase in BSIs, osteomyelitis, endocarditis, endophthalmitis, meningitis, peritonitis, myositis, and pancreatitis. Meningitis has increased in pediatric cases in association with several risk factors, including gestational age, administration of antimicrobials, central vascular catheterization, parenteral nutrition, and the use of antacids. In addition, an increased *C. albicans* carriage rate has been identified in health care workers. Simultaneous recovery of the same species of yeast from several body sites, including urine, is a good indicator of disseminated infection and fungemia.

The pathogenesis of *Candida* infections is extremely complex and probably varies with each species. Adhesion of organisms to the epithelium of the GI or urinary tract is a crucial factor for colonization with *Candida* spp. Three distinct aspartyl proteases have been described in *C. albicans,* and strains with high levels of proteases have been shown to have an increased ability to cause disease in experimental animal models. Hydrophobic molecules on the surface of *Candida* spp. also appear to be important in pathogenesis, and a strong correlation exists between adhesion and surface hydrophobicity. The yeast also possesses several adhesions that are linked to the β-1,6-glucans of the fungal cell wall. These adhesions are referred to as agglutinin-like sequences (ALS) and are designated ALSp1-7 or ALSp9. Expression of the adhesions varies with the fungal morphology and the site of infection. These adhesions can also interact with each other forming aggregations and facilitate the formation of biofilm. Clinical isolates appear to be adapted to form intricate polymicrobial biofilms with pathogenic bacteria such as *Staphylococcus aureus.* This is associated with the yeasts' ability to undergo phenotypic switching (i.e., the ability to produce pseudohyphae and hyphae). *C. albicans* can switch to a filamentous form (Fig. 62.5), permitting other pathogenic organisms to imbed in the filaments and form a polymicrobial matrix or biofilm. The ability of *C. albicans* to phenotypically switch to a filamentous form is common in patients who are neutropenic, suggesting that chemicals or cytokines produced play a role in the suppression of this phenotype. In addition, commensal strains of *C. albicans* are no longer capable of forming hyphae. *C. albicans* has also been shown to produce a toxin, candidalysin, a cytolytic peptide secreted by the yeast hyphae. This toxin initiates an inflammatory response and initiates epithelial invasion by the yeast. *C. albicans* produces over 225 proteins that facilitate tissue invasion, immune evasion, nutrient acquisition, and other pathogenic mechanisms. Significant research regarding the human microbiome has also uncovered a coevolutionary relationship with the maintenance of the normal human microbiota on mucosal surfaces and the immune system. This dynamic interaction will undoubtedly provide further insight into the fine balance between *C. albicans* and other *Candida* spp. as a commensal versus a pathogen.

Nonalbicans *Candida*

The other *Candida* spp. (also called nonalbicans *Candida*), once believed to not cause disease, are now recognized as agents of infection in certain patient populations. *C. tropicalis* and *C. auris* appear to possess some of the same



• Fig. 62.5 (A) Calcofluor white fluorescent stain of *Candida albicans* (×100) after growth in human serum at 37°C in conjunction with methicillin-resistant *Staphylococcus aureus,* demonstrating phenotypic switching to the filamentous form. Apparent shadowing are areas of imbedded growth of *S. aureus.* (B) Same specimen stained with Texas red. Note the areas from *A* that appear filled in with staining with Texas red because of the presence of a polymicrobial growth with *C. albicans* and *S. aureus.* (Photo courtesy Amanda Graves, BS, MLS [ASCP], Palm Coast, FL.)

virulence factors as *C. albicans*. *C. auris* is also resistant to fluconazole. Numerous species of nonalbicans *Candida* are routinely isolated in association with human infection. The other most common are *C. glabrata* complex, *C. krusei, C. tropicalis,* and *C. parapsilosis* complex. The incidence of infection with *C. glabrata* is higher in older adults than in young adults and children. *C. glabrata* has also demonstrated resistance to common antifungal drugs such as fluconazole and the echinocandins. *C. glabrata* has been isolated from serious infections including endocarditis, meningitis, and disseminated disease. *C. tropicalis* has been shown to be prevalent in patients with hematologic malignancies, especially those who are neutropenic. Because *C. krusei* is intrinsically resistant to the azole class of antifungals, fluconazole, identification of this species is essential to proper clinical management of the patient. *C. parapsilosis* complex is the primary cause of fungemia in the neonatal intensive care unit (NICU). *C. parapsilosis* complex organisms are also the second most commonly isolated *Candida* spp. in positive blood cultures.

A variety of other *Candida* spp. have been identified in infections and should be considered when evaluating an isolated culture of yeast. These include *C. blankii, C. catenulata, C. ciferrii, C. eremophila, C. dubliniensis, C. inconspicua, C. fabianii, C. famata, C. glaebosa, C. guilliermondii, C. haemulonii, C. kefyr, C. lambica, C. lipolytica, C. lusitaniae, C. norvegensis, C. pelliculosa, C. pulcherrima, Candida rugosa* complex, *C. utilis,* and *C. zeylanoides.*

Cryptococcus neoformans

Cryptococcosis is an acute, subacute, or chronic fungal infection that has several manifestations. *C. neoformans, C. deneoformans,* and members of the *C. gattii* complex are considered the major human pathogens. Differences in the infections by *Cryptococcus* spp. appear to be dependent on the host immune status and not the species of yeast. Immune clearance of *C. neoformans* is very efficient in immunocompetent individuals. However, in immunocompromised hosts, especially those deficient in CD4 T cells, the organism travels to the central nervous system, where the yeast can cause cryptococcal meningitis. Patients with a moderately compromised immune system or who are early in the disease process of cryptococcal fungemia may present without concomitant meningitis. Disseminated cryptococcosis and cryptococcal meningitis is well recognized in patients with AIDS and remains an important cause of morbidity and mortality in these patients in resource-poor countries that do not have access to highly active antiretroviral therapy.

Patients with disseminated infection may have painless papular skin lesions that may ulcerate. Other, less common manifestations of cryptococcosis include endocarditis, hepatitis, renal infection, and pleural effusion. The clinical significance of *Cryptococcus neoformans* is somewhat difficult to assess. However, given the severity of disease it can cause, its presence in clinical specimens should be considered significant. In many instances, the clinical symptoms are suppressed by corticosteroid therapy, which is a risk factor for disease. Cryptococcal infection is strongly associated with such debilitating disease as leukemia, lymphoma, and the immunosuppressive therapy that may be required for these and other underlying diseases. In some cases, the presence of the organism in clinical specimens precedes the symptoms of underlying disease. In addition, the introduction of antiretroviral therapy has lowered the incidence of infection rates and death from cryptococcal meningitis in AIDS patients. This treatment has resulted in a paradox, in that as the patient's immune response improves, it can trigger an exaggerated inflammatory response known as immune reconstitution inflammatory syndrome (IRIS). IRIS remains a clinical challenge. Early treatment with ART in cases of cryptococcal meningitis seem to exacerbate the infection and may result in rapid death. The key seems to be the ability to diagnose cryptococcal meningitis early and administer antifungals to reduce the fungal burden in conjunction with immune modulators to block the influx of macrophages to the CNS, preventing IRIS.

Cryptococcus spp. can exhibit a very characteristic polysaccharide capsule. The capsule collapses and protects the yeast from desiccation under dry conditions. The capsule is believed to help the organism survive passage through the pigeon gut before it is excreted. The reduction in the yeast's cell size caused by capsular collapse places the organism in the ideal size range for alveolar deposition in the human host. In addition, the polysaccharide capsule contains compounds that phagocytes do not recognize which prevents clearing of the organism. Acapsular strains of *Cryptococcus,* which possess a very reduced capsule, are more easily phagocytized by inflammatory cells and removed from infected host.

Phenoloxidase, an enzyme found in *C. neoformans,* is responsible for melanin production. Melanin has been demonstrated to act as a virulence factor by making the organism resistant to leukocyte attack. Evidence also has been presented that increased melanin production can decrease immune system functions, such as lymphocyte proliferation and tumor necrosis factor production. *C. neoformans* also produces a wide variety of enzymes including lipases, proteases, and urease. Urease catalyzes the degradation of urea into CO_2 and ammonia promoting adhesion and potentially exerting a toxic effect on the tight junctions of the blood brain barrier to facilitate invasion. The production of urease also promotes the accumulation of immature dendritic cells, making phagocytosis of the pathogen ineffective. *C. gattii* can modulate the host's immune system by reducing the inflammatory response and evading the immune system completely by altering expression of capsular antigens very similarly to *C. neoformans. Cryptococcus* spp. undergo bisexual reproduction. During *Cryptococcus* sexual reproduction, yeast cells undergo a morphological transition to a hyphal form. However, unlike the other cryptococcal species, *C. deneoformans* is capable of very robust unisexual reproduction in the absence of the opposite mating type. Studies have demonstrated that this is regulated by the highly complex calcineurin pathway. This pathway differs slightly in the different *Cryptococcus* spp. and regulates virulence, stress response, and temperature sensitivity. Further studies of this complex system in the various species will lead to a better understanding of the organism's physiology, response to the host immune system, and disease progression. This may lead to novel antifungals that can be used to prevent and treat cryptococcal infections. It is important to note that although there appears to be a different pathobiology associated with *C. deneoformans* than either *C. neoformans* or *C. gattii,* they are all treated the same by primary health care providers.

Filobasidium sp., *Hannaella* sp., *Naganishia* spp., *Papiliotrema* spp., and *Solicoccozyma* sp.

Increasing incidence of infections with the non-*C. neoformans* organisms has been reported in patients with a history of impaired immunity. The clinical manifestations are similar to *C. neoformans* and *C. gattii,* including central nervous system invasion and fungaemia. Additional presentations include reports of pulmonary, GI, ocular, and cutaneous infections.

Malassezia spp.

Malassezia furfur causes tinea versicolor, a skin infection characterized by superficial, brownish, scaly areas on light-skinned individuals and lighter areas on dark-skinned people. The lesions occur on the smooth surfaces of the body, namely the trunk, arms, shoulders, and face. The disorder has a worldwide distribution. *M. furfur* is also a cause of disseminated infection in infants and young children and in adults receiving lipid replacement therapy. *Malassezia slooffiae, Malassezia globosa, Malassezia sympodialis,* and occasionally *Malassezia restricta* have also been recovered from skin lesions associated with pityriasis versicolor. *M. furfur* and *M. pachydermatis* have been associated with fungemia in immunocompromised patients.

Geotrichum and *Prototheca* spp.

Infection with *Geotrichum candidum* is often isolated from patients with impaired immunity. The organism has been isolated from blood, respiratory, GI, oropharyngeal, skin, and vaginal specimens. However, it is important to note it is considered normal microbiota and therefore isolation should be interpreted with care. Disseminated infection with *G. candidum* has been reported.

Prototheca spp. infections are often a result of traumatic inoculation to the eye or subcutaneous tissue. The organism has been associated with cutaneous and subcutaneous tissue infections, keratitis, and systemic protothecosis. Organisms have also been isolated from patients in the absence of disease.

Rhodotorula spp. and *Sporobolomyces* spp.

A resident microbiota of the human skin, *Rhodotorula* spp. resemble *Cryptococcus* spp., appearing as round, oval-shaped, budding yeasts that produce capsules. *Rhodotorula* are associated with cases of human infection, including septicemia, meningitis, peritonitis, and peritoneal dialysis.

Sporobolomyces is included here as it produces a salmon-colored to coral pigment that can be easily confused with *Rhodotorula* on artificial media. As a ubiquitous, environmental organism, *Sporobolomyces* has been associated with rare cases of fungemia and meningitis in immunocompromised patients. Additional reported clinical manifestations include dermatitis and allergic alveolitis. Three species, *Sporobolomyces holsatiscus, Sporobolomyces roseus,* and *Sporobolomyces salmonicolor,* have been associated with human infections.

Saccharomyces cerevisiae

Saccharomyces cerevisiae is the common yeast that is used in baking and the preparation of a variety of food products and is a component in probiotics. The yeast has been linked to human-to-human transmission in association with health foods and baking. Probiotics contain live organisms and are used to prevent and treat antibiotic-associated diarrhea including infection with *Clostridioides difficile,* inflammatory bowel disease, and malabsorption syndrome. Infections have been reported that are the result of intestinal translocation by *S. cerevisiae* and venous catheter contamination in the health care setting. *Saccharomyces* sp. has been isolated from cases of thrush, vulvovaginitis, empyema, and BSIs.

Saprochaete spp.

Saprochaete spp. is an emerging pathogen that is often isolated from patients with debilitating disease such as leukemia, renal transplants, ambulatory dialysis, and osteomyelitis. Isolation is typically from the blood of immunocompromised patients who are neutropenic. The organism has also been isolated in the normal microbiota of the human skin and GI tract.

Trichosporon spp., *Cutaneotrichosporon* spp., and *Apiotrichum* sp.

Trichosporonosis is caused by a variety of *Trichosporon* spp. that have undergone changes in nomenclature based on DNA sequence comparisons. There are approximately 37 valid species with 5 organisms (*Trichosporon inkin, Trichosporon ovoides, Cutaneotrichosporon asahii, C. mucoides, and Apiotrichum loubieri*) primarily associated with human disease almost exclusively in immunocompromised patients, particularly those with leukemia. Skin lesions accompanied by fungemia are common. Endocarditis, endophthalmitis, and brain abscess have been reported. *C. asahii* is the most common organism isolated from systemic infections and invasive trichosporonosis. These organisms occasionally are recovered from respiratory tract secretions, skin, the oropharynx, and the stool of patients with no evidence of infection and may represent transient colonization of those individuals.

White piedra, an uncommon fungal infection of immunocompetent patients, is found in both tropical and temperate regions of the world. It is characterized by the development of soft, yellow or pale brown aggregations around hair shafts in the axillary, facial, genital, and scalp regions of the body. The organisms that cause this disease typically invade the cortex of the hair, causing damage.

Ustilago spp.

Ustilago spp. are primarily associated with infections in patients with one or more risk factors including neutropenia, chemotherapy, thrombocytopenia, or the presence of an indwelling catheter. Several species have been isolated from systemic infections as well as from respiratory and pleural fluids and a brain abscess.

Laboratory Diagnosis

Specimen Collection, Transport, and Processing

See General Considerations for the Laboratory Diagnosis of Fungal Infections in Chapter 58.

Stains

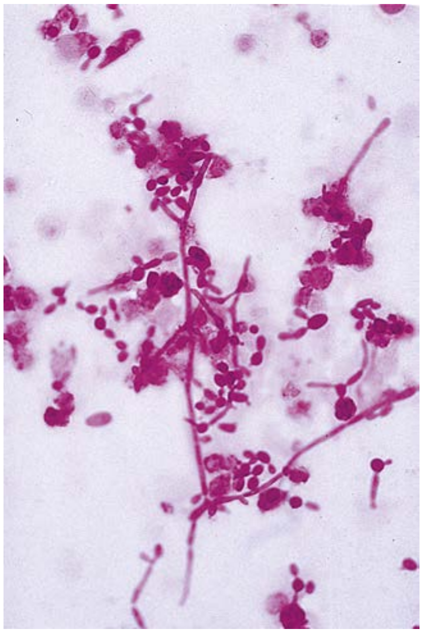
Candida spp.

Direct microscopic examination of clinical specimens containing *Candida* organisms reveals budding yeast cells (blastoconidia) 2 to 4 µm in diameter and/or pseudohyphae (Fig. 62.6) showing regular points of constriction, resembling links of sausage. True septate hyphae (filamentation) may also be produced by *C. albicans, C. africana,* and *C. dubliniensis.* The blastoconidia, hyphae, and pseudohyphae are strongly gram positive. The approximate number of such forms should be reported, because the presence of large numbers in a fresh clinical specimen may have diagnostic significance. Microscopically, *C. glabrata* blastoconidia are notably smaller (at 1 to 4 µm) than those of other medically significant *Candida* spp.

Cryptococcus spp.

Traditionally, the India ink preparation has been a widely used method for the rapid detection of *Cryptococcus* spp. in clinical specimens including CSF, urine, and other body fluids. This method is still used as a rapid and inexpensive assessment tool and has considerable diagnostic value in resource-poor settings. This method delineates the large capsule of *Cryptococcus* spp., because the ink particles cannot penetrate the capsular polysaccharide material. Although useful, many laboratories have replaced the India ink with the more sensitive latex agglutination test that detects cryptococcal antigen (CAD).

Microscopic examination of other clinical specimens, including respiratory secretions, can be difficult to use if they contain a lot of cellular material and debris. *Cryptococcus* spp. appear as a spherical, single- or multiple-budding, thick-walled yeast 2 to 15 µm in diameter. The organism is usually surrounded by a wide, refractile polysaccharide



• **Fig. 62.6** Periodic acid–Schiff (PAS) staining of urine demonstrates blastoconidia and pseudohyphae of *Candida albicans.*

capsule (Fig. 62.7). Perhaps the most important characteristic of *Cryptococcus* spp. is the extreme variation in the size of the yeast cells; this is unrelated to the amount of polysaccharide capsule present. It is important to remember that not all isolates of *Cryptococcus* exhibit a discernible capsule.

Malassezia spp.

Malassezia spp. are often detected through direct microscopic examination of skin scrapings. The organism is easily recognized as oval- or bottle-shaped cells that exhibit monopolar budding in the presence of a cell wall with a septum at the site of the bud scar. Small hyphal fragments also are observed (Fig. 62.8); the morphology is commonly described as "spaghetti and meatballs." In cases of fungemia, the morphologic form seen in direct examination of blood cultures is small yeasts without the presence of pseudohyphae.

Trichosporon spp., *Cutaneotrichosporon* spp., and *Apiotrichum* sp.

Microscopic examination of clinical specimens that contain *Trichosporon* spp., *Cutaneotrichosporon*, and *Apiotrichum* spp. reveals hyaline hyphae, numerous round to rectangular arthroconidia, and occasionally a few blastoconidia. Usually hyphae and arthroconidia predominate. In white piedra, white nodules are removed and observed using the potassium hydroxide (KOH) preparation after light pressure is applied to the coverslip to crush the nodule. Hyaline hyphae 2 to 4 µm wide and arthroconidia are found in the preparation of the cementlike material that binds the hyphae together. The organism may be identified in culture by the presence of true hyphae, blastoconidia, and arthroconidia in conjunction with a positive urease (Fig. 59.40). Although *Cutaneotrichosporon asahii* may be distinguished from other organisms by its biophysical profile (carbohydrate and substrate utilization), these organisms are likely best distinguished at the species level with molecular tools, such as DNA sequencing.

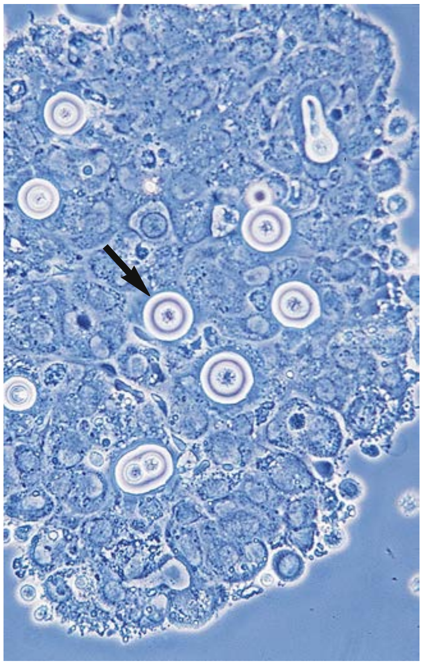
Other Organisms Resembling Yeasts (*Geotrichum, Prototheca*, and *Ustilago* spp.)

Antigen Detection

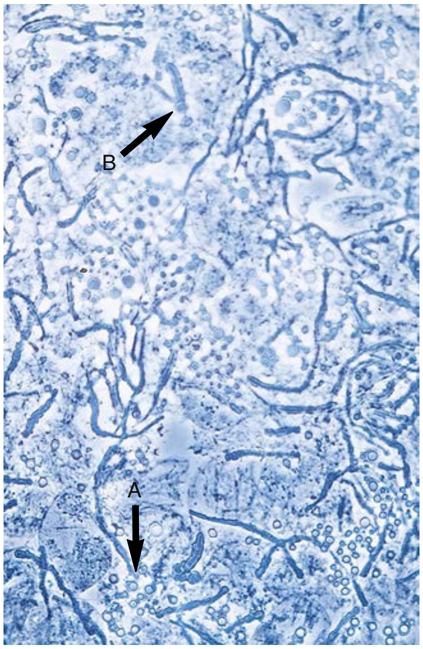
Most systemic fungal infections may be detectable using a common fungal cell wall antigen, beta-1,3-glucan. Several commercial kits as well as automated instrumentation is available for the detection of the fungal antigen in blood samples. *Cryptococcus* spp. do not contain beta-1,3-glucan, and the test has performed poorly in the detection of *Saprochaete* spp.

The CAD test for *C. neoformans* may be performed on cerebrospinal fluid or serum. In many laboratories this assay has replaced the use of India ink to screen for *C. neoformans.* It should be noted that *Trichosporon* spp. produce an antigen similar to that of *C. neoformans.* Sera from patients who have trichosporonosis often yield false-positive CAD tests when latex agglutination methods are used.

In addition, a variety of commercial kits are available for the detection of carbohydrate and protein antigens associated with disseminated *Candida* spp. infections. Sensitivity and specificity vary across systems for these assays. Some correlation with successful antifungal therapy has been reported for the COBAS FARA II analyzer (Roche Diagnostic Systems, Indianapolis, IN) and the test for the fungal antigen D-arabinitol. Specificity of the assays can be



• **Fig. 62.7** Potassium hydroxide preparation of pleural fluid shows the encapsulated, variably sized, spherical yeast cells *(arrow)* of *Cryptococcus neoformans* (phase-contrast microscopy).



• **Fig. 62.8** Potassium hydroxide preparation of a skin scraping from a patient with tinea versicolor demonstrates spherical yeast cells *(A)* and short hyphal fragments *(B)* of *Malassezia furfur.* (Phase-contrast microscopy; ×500.)

improved by the addition of a secondary antigen or in parallel with serological tests for *Candida*-specific antibodies.

Nucleic Acid Detection

Nucleic acid amplification tests (NAATs) have been developed for a variety of yeast species. The US Food and Drug Administration (FDA) has approved several commercially available PNA FISH kits for the detection of *Candida* spp. from positive blood cultures (Fig. 62.4). The assay can detect *C. albicans* complex, *C. tropicalis, C. glabrata*, and *C. parapsilosis* complex. The assay uses fluorescein-labeled PNA probes that target the species-specific 16S rRNA on blood smears made from positive blood cultures. The slides are then reviewed with a fluorescent microscope. The PNA FISH assay has a demonstrated sensitivity and specificity of 100%. All positive tests should be subcultured to ensure that no other yeasts are present.

Additional multiplex PCR assays are also available to detect yeast in positive blood cultures that integrate nucleic acid extraction, amplification detection, and analysis. The BioFire FilmArray (bioMérieux, Durham, NC) includes detection for *C. albicans, C. glabrata, C. krusei, C. parapsilosis*, and *C. tropicalis* in approximately one hour. The Luminex xTAG PCR assay (Luminex Molecular Diagnostics, Ontario, Canada) can detect 23 different fungi including *Candida* spp. in a single sample using microsphere technology.

The FDA-approved Affirm VPIII (Becton Dickinson, Franklin Lakes, NJ) DNA probe assay is available for the direct detection of *Candida* spp. The assay detects *Candida* spp., *Gardnerella vaginalis*, and *Trichomonas vaginalis* nucleic acids in vaginal samples. The T2 *Candida* panel (T2 Biosystems, Lexington, MA) uses a magnetic resonance-based system for the detection of *C. albicans, C. tropicalis, C. glabrata, C. krusei*, and *C. parapsilosis* in whole blood samples. The assay is intended for use in seriously ill patients for rapid and early detection of fungemia.

Cultivation

Candida spp.

The colonial and microscopic morphologic features of *Candida* spp. have little value for making a definitive identification. Most *Candida* spp. produce smooth, creamy white colonies, but some produce dry, wrinkled, dull colonies. In 50% of autopsy-proven cases of invasive candidiasis, organisms could not be isolated from blood culture bottles. Blood culture systems, such as the automated BACTEC (Becton Dickinson, Franklin Lakes, NJ) and BacT/ALERT (BioMérieux, Durham, NC), have increased the recovery of *Candida* spp.

Cryptococcus spp.

C. neoformans is easily cultured on routine fungal culture media without cycloheximide. The organism is inhibited by the presence of cycloheximide at 25°C to 30°C. For optimal recovery of *C. neoformans* from cerebrospinal fluid, a 0.45-mm membrane filter should be used with a sterile syringe. The filter is placed on the surface of the culture medium and is removed at daily intervals so that growth under the filter can be visualized. An alternative to the membrane filter technique is culture after centrifugation.

Colonies of *C. neoformans* usually appear on culture media within 1 to 5 days. The growth begins as a smooth, white to tan colony that may be mucoid to creamy (Fig. 62.9). It is important to recognize the colonial morphology on different culture media, because variation does occur; for example, on inhibitory mold agar, *C. neoformans* appears as a golden yellow, nonmucoid colony. Textbooks typically characterize the colonial morphology as being *Klebsiella*-like because of the large amount of polysaccharide capsule present. Most isolates of *C. neoformans* do not have large capsules and may not have the typical mucoid appearance.

Trichosporon spp., *Cutaneotrichosporon* spp., and *Apiotrichum* sp.

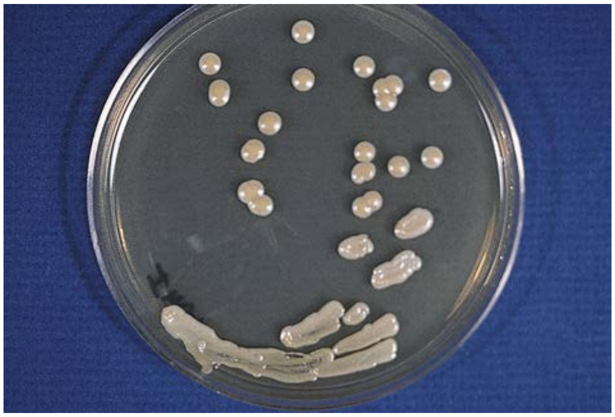
Colonies of the organisms included in these three genera vary in their morphology; however, most are cream-colored, heaped, dry to moist, and wrinkled. Some may appear white, dry, and powdery.

Malassezia spp.

Malassezia spp. are infrequently cultured in the clinical laboratory. Of the 14 valid species, 13 are recognized as being lipid dependent. Recovery of the organism is not required to establish a diagnosis in skin infections, and it is seldom attempted for this purpose. Cultivation requires an agar medium enriched with natural long chain fatty acids (olive oil). The colonies are small compared with the colonies of *C. albicans* and are creamy and white to off-white. Some specialized culture media, for example modified Dixon agar, are available and will support the cultivation of *Malassezia* spp. without the addition of olive oil.

Approach to Identification

The historical approach to yeast identification has consisted of evaluating the carbohydrate and substrate utilization



• **Fig. 62.9** Colonies of *Cryptococcus neoformans* appear shiny and mucoid because of the presence of a polysaccharide capsule.

profile with a commercial identification system and observing the microscopic morphology in a cornmeal or RIOT agar preparation. This latter aspect is particularly important for discovering any errors in identification that may have been made by the commercial system. For example, if a commercial system designates an isolate as *C. glabrata* but pseudohyphae are seen in the cornmeal preparation, additional testing is needed to identify the isolate correctly, as *C. glabrata* does not produce pseudohyphae. It is extremely important that all additional tests be performed on pure cultures. If a culture is prepared from a nonsterile site, it may also be contaminated with bacteria. Cultures can be purified by subculturing to a Sabouraud dextrose agar plate with antibiotics or treated with hydrochloric acid (HCl). The HCl procedure is completed by inoculating a colony to three 5-mL tubes of Sabouraud glucose broth. Then 1 N HCl is added to each tube: four drops to the first tube, two drops to the second tube, and one drop to the third tube. Following incubation at 25°C for 24 to 48 hours, 0.1 mL of the broth cultures are subcultured to Sabouraud dextrose agar. In addition, if more than one yeast is present, subculturing to chromogenic media may be useful. An overall general scheme for yeast identification is provided in Fig. 62.10.

Candida spp.

C. albicans complex may be identified by the production of germ tubes or chlamydoconidia (Fig. 62.11; also see Fig. 62.2). Other *Candida* spp. are most commonly identified by the utilization of specific substrates and the fermentation or assimilation of carbohydrates. For instance, *C. glabrata* ferments and assimilates glucose and trehalose, whereas *C. tropicalis* ferments and assimilates sucrose and maltose. Another method of identifying *C. albicans* and differentiating it from other *Candida* spp. is based on the presence of chlamydoconidia (Fig. 62.11) on cornmeal agar containing 1% Tween 80 and trypan blue incubated at room temperature for 24 to 48 hours. The morphologic features of yeasts on cornmeal agar containing Tween 80 often allow tentative identification of select species (Table 62.1).

Colonies that appear starlike or possess feetlike projections on agar, as previously described on blood agar, may be identified as *C. albicans.* However, this method is not as sensitive, and requires a longer incubation of 24 to 48 hours. In addition, species such as *Trichosporon* spp. may also appear as colonies with the pseudohyphal fringe within 18 to 24 hours of incubation on blood agar. A Gram stain of the isolate would provide a means of differentiation of the isolate as *Trichosporon* spp. by the characteristic presence of arthroconidia.

Germ Tube Test

The germ tube test (Evolve Procedure 62.1) is a simple and economical method used in the clinical laboratory to identify *C. albicans*. Approximately 80% of the yeasts recovered from clinical specimens are *C. albicans,* and results of the germ tube test are available within 3 hours.

Germ tubes appear as early hyphal-like extensions that are produced without a constriction at the point of origin from the yeast cell (Fig. 62.3). *C. dubliniensis and C. africana* also produce germ tubes. Although *C. dubliniensis* and *C. africana* are infrequently encountered in clinical specimens, supplemental biochemical or morphologic testing may be needed to differentiate them from *C. albicans. C. tropicalis* produces what have been called "pseudo–germ tubes," which are constricted at the base or point of germ tube origin on the yeast cell. Unless this is recognized, and the laboratorian has developed the skills to distinguish between germ tubes and pseudo–germ tubes, *C. tropicalis* isolates may be misidentified as *C. albicans.*

C. albicans produces beta-galactose aminidase and L-proline aminopeptidase. Other *Candida* spp. may produce one of the enzymes but not both. Assays such as BactiCard *Candida* (Remel Laboratories, Lenexa, KS) can be used to detect these enzymes. All rapid enzymatic screening methods are sensitive and specific for rapid identification of *C. albicans,* including the BactiCard, Murex *C. albicans*-50, Albicans-sure, and the API 20C AUX yeast identification systems. Compared with the germ tube test, these tests require less time (5 to 30 minutes). Overall, these methods provide a rapid and objective alternative to the germ tube test.

Cryptococcus neoformans

Diagnosis has been historically made by the identification of encapsulated yeast in the spinal fluid using India ink. Cryptococcal meningitis is a serious condition that requires rapid diagnostic testing. One rapid CrAg test (IMMY, Norman, OK, United States) is a lateral flow immunoassay that can be used to qualitatively identify antigen and perform a quantitative titer. This test can be performed directly on serum or cerebrospinal fluid. Results are readily available after a short 10-minute incubation step. If grown in culture, *C. neoformans* may be presumptively identified based on rapid urease production and failure to utilize inorganic nitrate. Final identification of *C. neoformans* usually is based on substrate utilization patterns and pigment production on niger seed (thistle or birdseed) agar (Fig. 62.12).

Rapid Urease Test

The rapid urease test (Evolve Procedure 62.2) is a useful tool for screening for urease-producing yeasts recovered from respiratory secretions and other clinical specimens. Alternatives to this method include use of a heavy inoculum placed on the tip of the slant on Christensen's urea agar and subsequent incubation at 35°C to 37°C. In many instances, a positive reaction occurs within several hours; however, 1 to 2 days of incubation may be required. Interestingly, strains of *Rhodotorula* spp., some *Candida* spp., and *Trichosporon* spp. hydrolyze urea over time, so a distinction should be made between a traditional urease test, which takes an overnight incubation, and the rapid urease test.

Rapid Trehalose Test

The rapid trehalose test can be used for presumptive identification of *C. glabrata.* This test should be used in conjunction with microscopic morphology (small cell size)

and the failure to produce a germ tube. In addition, correlation of appearance on CHROMagar enhances and improves identification. The rapid trehalose test has also been combined with maltose hydrolysis in a 30-second dipstick assay.

Trichosporon spp., *Cutaneotrichosporon* spp., and *Apiotrichum* sp.

Organisms within these genera are indicated in the presence of predominate contiguous arthroconidia that are rectangular, often with rounded ends, along with septate hyaline hyphae. Blastoconidia are sometimes present but are not seen in all cultures. Positive urease production differentiates these genera from *Saprochaete* and *Geotrichum* spp. Final identification is based on the characteristic substrate utilization.

Malassezia spp.

M. furfur may be recovered from the blood of patients who have fungemia. Growth in the presence of a long-chain fatty acid, in conjunction with the "bowling pin" or "pop bottle" morphology, is sufficient for identification. *Malassezia* spp. that do not require long-chain fatty acid supplementation can be identified using substrate utilization analysis and cornmeal agar morphology.

Commercial Yeast Identification Systems

Commercial yeast identification systems have provided laboratories with standardized test methods. The methods are rapid, providing results within 24 to 72 hours. The systems provide an identification based on a database of thousands of yeast biotypes that considers the variation in substrate utilization patterns. The manufacturers also provide computer consultation services to the laboratory for the identification of isolates that produce an atypical result. Although these systems are powerful tools, they should not be used as the sole method of identification; traditionally, they are most effectively used in conjunction with yeast morphology on routine media.

Multiple Species Identification Systems

API-20C AUX

The API-20C AUX yeast identification system (bioMérieux, Marcy I'Etoile, France) has an extensive data set of all commercial systems available. The system consists of a strip that contains 20 microcapsules, 19 of which contain dehydrated carbohydrates for determining assimilation test profiles of yeasts. Reactions are compared with growth (turbidity) in the first cupule, which lacks a carbohydrate substrate. Reactions are read, and results are converted to a seven-digit biotype profile number. Most of the yeasts are identified within 48 hours; however, some *Cryptococcus* and *Trichosporon* spp. may require up to 72 hours. The API-20C AUX yeast identification system, as well as all other commercially available products, requires that the microscopic morphologic features of yeast grown on cornmeal agar containing 1% Tween 80 and trypan blue be correlated with the substrate utilization patterns.

MicroScan Rapid Yeast Identification Panel

The MicroScan Yeast Identification Panel (Beckman Coulter Inc., Brea, CA) is a 96-well, microtiter plate containing 27 dehydrated substrates. It was introduced as an alternative to the API-20C AUX yeast identification system. It uses chromogenic substrates to assess specific enzyme activity, which can be detected within 4 hours. Specific enzyme profiles have been generated for many of the yeasts commonly encountered in the clinical microbiology laboratory.

Vitek Biochemical Cards

The Yeast Biochemical Card (bioMérieux, Durham, NC) is a 30-well, disposable plastic card that contains conventional biochemical tests and negative controls. It is used with the Vitek 2 system. Evaluation of this system showed an overall accuracy of identification near 100% compared with API-20C AUX. Fewer than one fourth of the yeasts required additional biochemical or morphologic tests to confirm the identification. Of all correctly identified yeasts, more than half were reported within 24 hours of incubation.

Chromogenic Agars

Chromogenic agar is a differential medium useful for the recovery of *Candida* organisms in clinical specimens, differentiation of *Candida* spp., and isolation of colonies. Distinct enzymes of different *Candida* spp. react with chromogenic substrates to yield a characteristic colony color. When used with colonial morphologic features, the colored growth on the agar based on enzymatic substrates can provide a presumptive identification. Many of these agars can be used for the identification of *C. albicans, C. tropicalis, C. krusei*, and *C. glabrata.* All manufacturer directions should be followed closely, as differences in temperatures and incubation times can alter the appearance of the colonies.

Matrix-Assisted Laser Desorption Ionization Time-of-Flight

Both commercially available MALDI identification systems the Biotyper CA System (Bruker Daltonics) and the Vitek

TABLE 62.1 **Characteristic Microscopic Features of the Commonly Encountered Yeast and Yeastlike Organisms on Cornmeal Tween 80 Agar**

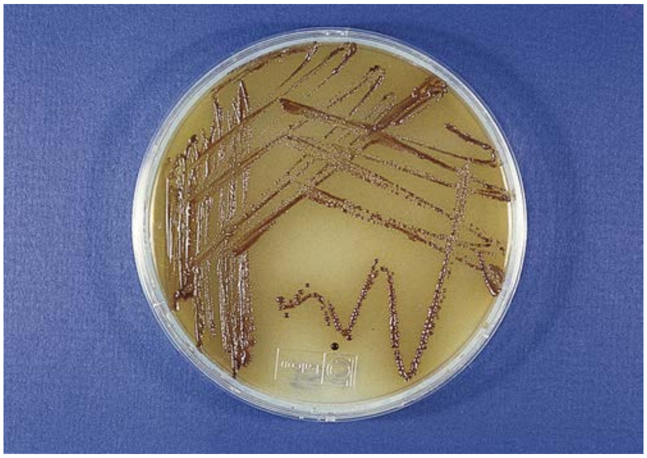
Organism	Arthroconidia/Blastoconidia	Pseudohyphae or Hyphae
Candida albicans complex	Spherical clusters at regular intervals on pseudohyphae	Chlamydoconidia present on hyphae
Candida auris	Round to oval, elongated	Pseudohyphal-like forms
Candida dubliniensis	Ovoid budding yeast cells	Chlamydoconidia present on hyphae
Candida glabrata complex	Small, spherical, and tightly compacted	None produced
Candida kefyr	Elongated, lie parallel to pseudohyphae	Pseudohyphae present but not characteristic
Candida krusei	Elongated; clusters occur at septa of pseudohyphae	Branched pseudohyphae
Candida lusitaniae	Blastoconidia, may appear in short chains	Short, curved pseudohyphae with blastoconidia formed at or between septa
Candida parapsilosis complex	Present but not characteristic	Sagebrush or "shaggy star" appearance; large (giant) hyphae present
Candida rugose complex	Elongated blastoconidia, may be in chains	Pseudohyphae present
Candida tropicalis	Produced randomly along hyphae or pseudohyphae	Pseudohyphae present but not characteristic
Cryptococcus spp.	Round to oval, vary in size, separated by a capsule	Rare; usually not seen
Geotrichum candidum	Rectangular arthroconidia	Coarse true hyphae
Malassezia spp.	Yeastlike cells that are phialides with small collarettes; budlike structures on a broad base	Hyphal elements are generally absent, but rudimentary forms may be present
Prototheca spp.	Sporangia of various sizes containing endospores; budding does not occur	No hyphae
Rhodotorula spp.	Round to oval-shaped, multilateral budding cells with capsules	Rudimentary pseudohyphae may be present
Saccharomyces spp.	Large round to oval with multilateral budding	Rudimentary short pseudohyphae sometimes present
Saprochaete capitatus	Round to oval budding yeastlike cells, few arthroconidia and annelloconidia	Hyphae and pseudohyphae with annellides clustered on the tips
Sporobolomyces spp.	Oval to ellipsoidal cells, blastoconidia; ballistoconidia can produce satellite colonies	Pseudohyphae with blastoconidia on sterigmata (protrusion), true hyphae may be present
Trichosporon, spp.[a]	Numerous arthroconidia, resembling *Geotrichum* spp.; blastoconidia may appear singly or in short chains	May be present but difficult to find, septate hyphae and pseudohyphae
Ustilago spp.	Elongate, irregular, spindle or bean-pod shaped yeastlike cells	Short hyphae with clamp connections may be observed

[a] *Trichosporon, Apiotrichum*, and *Cutaneotrichosporon* spp.

MS (bioMérieux) can identify yeast and fungal isolates with excellent accuracy. See Chapter 7 for more information. MALDI-TOF requires that isolates be cultured overnight and then processed using a standardized extraction procedure. Several studies report the correct identification of yeast to the species level up to approximately 98% compared with traditional culture methods. In addition, some laboratories require the direct isolation of organisms from blood culture systems without subculturing to another medium to facilitate identification, though these methods are not FDA approved and require rigorous independent validation and verification by the individual laboratory. Both Bruker and bioMérieux continuously improve their FDA-cleared databases by adding spectra of additional strains (increasing species diversity) as well as incorporating new species.

Cornmeal Agar Morphology

Cornmeal agar morphology can be used to determine whether the yeast produces blastoconidia, arthroconidia,



• **Fig. 62.12** *Cryptococcus neoformans* colonies are brown when grown on niger seed agar.

pseudohyphae, true hyphae, and/or chlamydoconidia (Evolve Procedure 62.3). Cornmeal agar morphology can be used to detect characteristic chlamydoconidia produced by *C. albicans.* Microscopic morphology on cornmeal agar can be used to differentiate *Cryptococcus, Saccharomyces, Candida, Geotrichum,* and *Trichosporon.* The morphologic features of the common *Candida* spp. are distinct enough to provide a presumptive identification. This can be accomplished for *C. albicans, C. glabrata, C. krusei, C. parapsilosis, C. tropicalis,* and *C. kefyr,* keeping in mind that numerous other species, uncommonly recovered in the clinical laboratory, might resemble microscopically any of the species.

Cornmeal agar morphology is less useful for identification of the uncommonly encountered yeasts. It should be used as an additional test in conjunction with a commercial yeast identification system.

Carbohydrate Utilization

Carbohydrate utilization patterns are the historical conventional methods for the definitive identification of yeasts recovered in a clinical laboratory. Various methods have been advocated for use in determining carbohydrate utilization patterns by clinically important yeasts. Evolve Procedure 62.4 provides a method for determining carbohydrate utilization.

Once the carbohydrate utilization profile has been obtained, reactions may be compared with those listed in tables in most mycology laboratory manuals. In most instances, carbohydrate utilization tests provide definitive identification of the yeast, and additional tests are unnecessary. Some laboratories prefer carbohydrate fermentation tests, which are simply performed using purple broth containing different carbohydrate substrates. In general, carbohydrate fermentation tests are unnecessary and are not recommended for routine use.

Phenoloxidase Detection Using Niger Seed Agar

Use of a simplified *Guizotia abyssinica* (niger seed) medium is a definitive method for detecting phenoloxidase production by yeasts (Evolve Procedure 62.5). Most isolates of *C. neoformans* readily produce phenoloxidase; however, some do not. In addition, in some instances, cultures of *C. neoformans* have been shown to contain both phenoloxidase-producing and phenoloxidase-deficient colonies in the same culture.

If conventional methods are used, all criteria, including urease production, carbohydrate utilization, and the phenoloxidase test, must be met before a final identification of *C. neoformans* is made.

Nucleic Acid Sequencing Methods

Nucleic acid sequencing provides more accuracy than conventional biochemical methods within 12 hours following colony isolation. Multiple genes are needed to develop reproducible, specific, and sensitive sequence data for standardization of identification. Methods including conventional Sanger DNA sequencing, pyrosequencing, and whole genome sequencing will undoubtedly improve the accuracy of classification and identification of yeast and yeastlike organisms as techniques improve for use in the clinical laboratory.

PROCEDURE 62.1

Germ Tube Test

Principle

Strains of *Candida albicans* produce germ tubes from their yeast cells when placed in a liquid nutrient environment and incubated at 35°C for 3 h (similar to the *in vivo* state).

Method

1. Suspend a very small inoculum of yeast cells obtained from an isolated colony in 0.5 mL of sheep serum or rabbit plasma. (Note: Some laboratories have successfully replaced the use of serum or plasma with trypticase soy broth.)
2. Incubate the tubes at 35°C to 37°C for no longer than 3 h.
3. After incubation, remove a drop of the suspension and place it on a microscope slide. Examine it under low-power magnification for germ tubes. A germ tube is an appendage that is half the width and three to four times the length of the yeast cell from which it arises (Fig. 62.2). No point of constriction exists at the origin of the germ tube from the cell.

Quality Control

C. albicans and *Candida tropicalis* are used as positive and negative controls, respectively.

Expected Results

C. albicans produces germ tubes, usually within 2 h, whereas *C. tropicalis* does not.

Performance Schedule

Controls should be performed with each test run.

PROCEDURE 62.2

Rapid Urease Test

Principle

Hydrolysis of urea by the enzyme urease produces ammonia and carbon dioxide. The ammonia produces alkaline conditions in the medium and changes the indicator (phenol red) from yellow to pink.

Method

1. Reconstitute a vial of dehydrated urea broth (Remel Laboratories, Lenexa, KS) with 3 mL of sterile distilled water on the day of use.
2. Dispense 3 to 4 drops into each well of a microdilution plate. Determine the exact number of wells to be used for the day and use only the number necessary.
3. Transfer a heavy inoculum of a yeast colony (not including pink yeasts) to a well containing the urea broth. Colonies tested should be no older than 7 days and should be free of bacterial contamination. In some cases, a subculture may be needed to obtain enough growth to provide the inoculum for the test.
4. Include positive and negative controls using *Candida neoformans* and *Candida albicans,* respectively.
5. Seal the microdilution wells with plastic tape and incubate for 4 h at 37°C.
6. Observe for the production of a pink to purple color, which indicates urease production.

Quality Control

C. neoformans and *C. albicans* are used as the positive and negative controls, respectively.

Expected Results

C. neoformans should produce urease; *C. albicans* does not.

Performance Schedule

Controls should be performed with each test run.

PROCEDURE 62.3

Cornmeal Agar Morphology

Principle

Polysorbate (Tween 80) is added to cornmeal agar to reduce the surface tension to allow the development of pseudohyphal and hyphal growth of yeasts and blastoconidia formation. Certain species of yeast develop characteristic morphologic features on this medium.

Method

1. Obtain an isolated colony from the primary culture medium.
2. Inoculate a plate of cornmeal agar containing 1% Tween 80 and trypan blue by making three parallel streaks cutting into the agar about 0.5-inch apart at a 45-degree angle to the culture medium. A sterile coverslip may be added to one area.
3. Incubate the cornmeal agar plate at 30°C for 48 h.
4. After 48 h remove and examine the areas where the cuts were made for blastoconidia, arthroconidia, pseudohyphae, hyphae, or chlamydoconidia (Table 62.1 for the microscopic morphologic features of the commonly encountered yeasts on cornmeal Tween 80 agar). This method is required for use with commercial systems for yeast identification.

Quality Control

Candida albicans is tested for production of characteristic features.

Expected Results

C. albicans produces chlamydoconidia and clusters of blastoconidia arranged at regular intervals along the pseudohyphae.

Performance Schedule

A strain of *C. albicans* should be tested each time new media are received in the laboratory or produced and monthly thereafter.

PROCEDURE 62.4

Conventional Carbohydrate Utilization Tests

Principle

Yeasts and yeastlike fungi utilize specific carbohydrate substrates. Organisms are inoculated onto a carbohydrate-free medium. Carbohydrate-containing filter paper disks are added, and utilization is determined by the presence of growth around the disk. Characteristic carbohydrate utilization profiles are used to identify species of yeasts; however, this method is rarely used.

Method

1. Prepare a suspension of the yeast in saline or distilled water to a density equivalent to a McFarland no. 4 standard.
2. Cover the surface of a yeast nitrogen base agar plate containing bromocresol purple with the suspension of the yeast cells.
3. Remove the excess inoculum and allow the surface of the agar medium to dry.
4. With sterile forceps, place selected carbohydrate disks on the surface of the agar. These should be spaced approximately 30 mm apart.
5. Incubate the carbohydrate utilization plate at 30°C for 24 to 48 h.
6. Remove the plate and observe for a color change around the carbohydrate-containing disks or for growth surrounding them.

Quality Control

A combination of control yeasts that utilize each of the carbohydrates being tested is used. Often two or three organisms may be necessary to control each carbohydrate (published tables are used for this). Control yeasts are tested with each new lot number of carbohydrate disks and monthly thereafter.

PROCEDURE 62.5

Phenoloxidase Detection Using Niger Seed Agar

Principle

Cryptococcus neoformans is the only species that produces 3,4-dihydroxyphenylalanine-phenoloxidase. When reacted with l-beta-3,4-dihydroxyphenylalanine and an iron compound (ferric citrate), *C. neoformans* oxidizes ó-diphenol to melanin, which produces a brown to black color.

Method

1. Place a heavy inoculum on the surface of a plate of niger seed agar medium.
2. Incubate at 25°C for up to 7 days.
3. Observe daily for a dark brown or black pigment, which indicates phenoloxidase specifically produced by *C. neoformans* (Fig. 62.11). Many isolates of *C. neoformans* produce phenoloxidase on this medium within 2 to 24 h.

Quality Control

C. neoformans and *Cryptococcus albidus* are used as positive and negative controls, respectively.

Expected Results

C. neoformans exhibits a positive test result (brown color develops on the disk surface), whereas *Naganishia albidus* does not.

Performance Schedule

Controls should be performed with each run.

CASE STUDY 62.1

A 48-year-old male recovering from liver transplantation in the intensive care unit (ICU) develops a persistent fever. In the initial physical examination, the only thing of note is inflammation surrounding a catheter. The catheter is removed and sent to the microbiology laboratory.

The diagnosis is systemic candidiasis originating from the catheter. The catheter is changed, and the patient is treated with fluconazole. Blood cultures are negative within 1 week.

Questions

1. What tests were likely performed on the catheter to obtain a definitive diagnosis of candidiasis?
2. Given the limited information about the patient's history, what route of transmission of the organism probably resulted in the patient's infection?
3. Based on the patient history provided, what information would indicate that he is susceptible to yeast infection?

Chapter Review

1. Which of the following is *not* a virulence factor of *Candida* spp.?
- **a.** Phospholipases
- **b.** Chlamydospore production
- **c.** Aspartyl proteases
- **d.** Hydrophobicity
- **e.** Hyphae formation

2. Which method has improved the isolation of *Candida* spp. from positive blood cultures?
- **a.** Vitek
- **b.** CHROMagar
- **c.** PNA FISH kit
- **d.** T2 *Candida* assay

3. The specimen needed to isolate *Trichosporon* spp. is:
- **a.** Urine
- **b.** Tissue biopsy
- **c.** Hair clippings
- **d.** Skin scrapings
- **e.** Cerebrospinal fluid

4. Germ tube formation is seen with which two yeasts?
- **a.** *C. albicans, C. neoformans*
- **b.** *C. albicans, C. parapsilosis*
- **c.** *C. glabrata, C. parapsilosis*
- **d.** *C. albicans, C. dubliniensis*
- **e.** *C. glabrata, C. dubliniensis*

5. Matching: *Match each description in the right-hand column with the correct organism in the left-hand column. More than one answer may be correct.*

______ *Candida* spp.
______ *Cryptococcus* spp.
______ *Trichosporon* spp.
______ *Malassezia* spp.

a. causative agent of thrush
b. neurotropic
c. produces phenoloxidase
d. infection results from inhalation of pigeon droppings
e. causes white piedra
f. develops germ tubes
g. causative agent of tinea versicolor
h. produces arthroconidia

6. Short Answer

(1) If you suspect that an organism is *Cryptococcus neoformans,* what tests would you perform for a positive identification?

(2) Describe the different morphologic structures that *Candida albicans, Candida parapsilosis,* and *Candida glabrata* produce on cornmeal agar.

63

Antifungal Susceptibility Testing, Therapy, and Prevention

OBJECTIVES

1. Name the documents that contain the current guidelines for antifungal susceptibility testing.
2. Identify three circumstances in which antifungal susceptibility testing may be valuable.
3. List three areas of concern that complicate interpretive guidelines.
4. Explain how amphotericin B is produced, how it is administered, and its most significant adverse reaction.
5. Describe the mechanism of action of flucytosine and the drug's therapeutic use.
6. Identify three echinocandins and describe their mechanism of action.

Antifungal Susceptibility Testing

Antifungal susceptibility testing (AFST) is designed to provide information that helps the physician select the appropriate antifungal agent to treat a specific infection. Although AFST perhaps has not advanced as far as methods for determining the susceptibility of bacteria to antimicrobial agents, significant progress has been made. As with performing antimicrobial susceptibility testing, it is imperative to utilize standardized methods to ensure reproducibility between clinical microbiology laboratories. Only by doing so will the laboratory be able to communicate and report accurate test results to guide clinicians in therapeutic decision making.

The Clinical Laboratory Standards Institute (CLSI) sets the standards for AFST. The current guidelines for these tests are provided in the following four documents, which are available on the CLSI website (www.clsi.org):

- M27-A3, *Reference Method for Broth Dilution Antifungal Susceptibility Testing of Yeasts,* Approved Standard. This document covers requirements for use of the broth microdilution method. The standards for susceptibility testing are very specific about the inoculum size, test medium, incubation time and temperature, and end point of yeasts that cause invasive fungal infections.
- M27-S4, *Reference Method for Broth Dilution Antifungal Susceptibility Testing of Yeasts,* Fourth Informational Supplement. This document provides species-specific breakpoints against different antifungal agents.
- M38-A2, *Reference Method for Broth Dilution Antifungal Susceptibility Testing of Filamentous Fungi,* Approved Standard. This standard is a microdilution method for molds that cause invasive and cutaneous infections.
- M44-A2, *Method for Antifungal Disk Diffusion Susceptibility Testing of Yeasts and Molds* (M51-A), Approved Guideline. This standard provides methodology for disk diffusion testing for *Candida* spp., including quality control and interpretation guidelines.

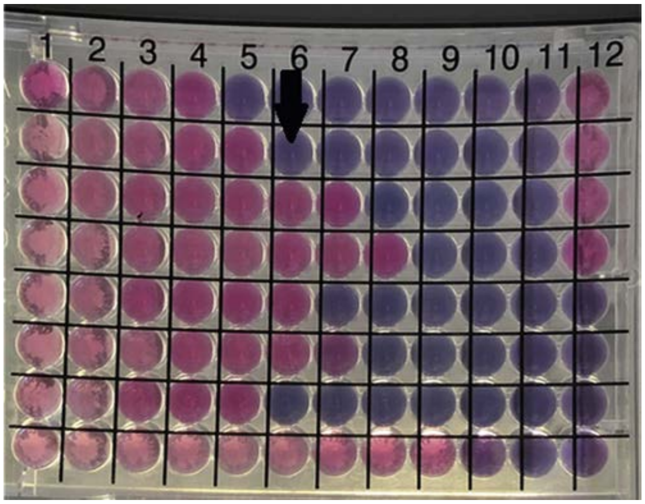
It must be emphasized that the methodology and interpretation of antifungal susceptibility tests continue to evolve, and the laboratory should check for updated standards on a regular basis. Antifungal susceptibility tests are costly and time-consuming, but they may have value in the following circumstances:

- Determining antifungi grams for specific fungi in an institution
- Aid in the management of patients with candidemia, especially those caused by non-albicans *Candida* spp.
- Aid in the management of patients with invasive candidiasis

CLSI considers the previously published breakpoints for itraconazole and 5-flucytosine to all *Candida* spp. obsolete. Breakpoints are published as species-specific for fluconazole, voriconazole, and the echinocandins.

Isolates of the same species may exhibit differences in minimal inhibitory concentrations (MICs) because of previous exposure to antifungal agents or acquisition of a genetic mechanism of resistance. CLSI's most recent interpretative guidelines should be followed whenever possible, as they contain species-specific breakpoints.

The preferred medium for the performance of broth dilution AFST is RPMI 1640 (Roswell Park Memorial Institute 1640). The specific formulation contains the reducing agent glutathione without bicarbonate, high concentrations of vitamins, and phenol red as the pH indicator. The desired



• **Fig. 63.1** A Sensititre YeastOne YO9 (Thermo Fisher Scientific) panel inoculated with *Candida krusei* ATCC 6258. The panel contains alamar blue as a growth indicator. The minimal inhibitory concentrations (MICs) are interpreted as the first blue well. In the example, the MIC for micafungin is 0.25 µg/mL.

pH range for the medium for accurate testing is between 6.9 and 7.1. The recommended buffer to use for adjusting pH is MOPS [3-(N-morpholino) propanesulfonic acid] (final concentration 0.165 mol/L for pH 7.0). Overnight cultures of pure *Candida* isolates grown on Sabouraud dextrose or potato dextrose agar are selected and used to prepare a suspension in 0.85% saline or sterile water equivalent to a 0.5 McFarland turbidity standard. The organism is then diluted 1:100 to make a working stock suspension followed by a subsequent a 1:20 dilution from the working stock in RPMI 1640 broth medium. AFST plates are incubated for 24 hours in ambient air in a 35°C incubator. If there is inadequate growth in the growth control well for the isolate being tested, the plate is incubated for an additional 24 hours. Susceptibility testing for *Cryptococcus neoformans* should be incubated for 70 to 74 hours before interpreting results.

In addition to manual broth dilution susceptibility testing, commercial panels are also available. The Sensititre YeastOne YO9 (Thermo Fisher Scientific) is a 96-well microtiter plate containing nine antifungal agents and can be used for testing *Candida* spp., *Cryptococcus* spp., and *Aspergillus* spp. (Fig. 63.1). The panel contains an alamar blue indicator that can be used to visually interpret MIC results.

Any laboratory that is not equipped to perform CLSI methods, or validated equivalent methods, for susceptibility of clinically important fungal isolates should send the isolates to a reference laboratory for testing. At a minimum an azole agent and an echinocandin should be tested, as azole resistance varies among *Candida* spp.

Antifungal Therapy and Prevention

Numerous antifungal agents have been developed; however, few newer agents are on the horizon. The increasing number of immunosuppressed patients and the expansion of drug resistance of microorganisms make the development and appropriate use of antifungal agents two of the most important areas in microbiology and infectious diseases. This section is meant to provide an overview to commonly used antifungal agents; it is by no means comprehensive.

Azole Antifungal Drugs

The azole group of antifungal agents consists of the imidazoles and the triazoles. These compounds contain six carbon ring structures with conjugated double bonds, chloride residues, and five carbon ring structures that contain at least two nitrogen molecules. Traditionally used agents in this group include fluconazole, itraconazole, and ketoconazole. The newer triazoles are voriconazole, posaconazole, and, most recently, isavuconazole. Azole antifungal agents disrupt the integrity of the fungal cell membrane by interfering with the synthesis of ergosterol.

Fluconazole

Fluconazole, a triazole, is exceptionally soluble in water, which allows either oral or intravenous administration. Fluconazole typically has excellent activity against most *Candida* spp. and *Cryptococcus* spp.; therapeutic levels are easily reached in the central nervous system. There have been reports of resistance in *C. albicans* after short-term treatment in mucosal or deep-seated forms of invasive candidiasis and in *C. neoformans* in patients with AIDS after long-term therapy. Side effects of fluconazole therapy are usually minimal. The susceptibility of *C. glabrata* to fluconazole is not predictable. Isolates of *C. glabrata* may be susceptible at higher doses of drug administration, that is, susceptible dose-dependent (SDD) or resistant to fluconazole. The emerging pathogen, *C. auris*, has also demonstrated resistance to fluconazole. Other notable yeasts or yeastlike fungi resistant to fluconazole are *C. krusei* and *Rhodotorula* spp. In addition, the antifungal has no activity against *Aspergillus* spp., *Fusarium* spp., or Mucorales molds.

Itraconazole

Itraconazole has a spectrum of activity that is similar to ketoconazole but is better tolerated. In addition, itraconazole has been shown to be effective in cases of aspergillosis, onychomycosis, oropharyngeal/esophageal candidiasis, and infections caused by the systemic fungal pathogens, e.g., *Blastomyces, Histoplasma, Paracoccidioides, Talaromyces,* and *Sporothrix* spp. histoplasmosis. Itraconazole may have limited activity against *C. neoformans.* Adverse reactions principally include gastrointestinal disturbances; however, vestibular disturbances, edema, and skin irritations have been reported.

Ketoconazole

Ketoconazole is an imidazole that is available orally for systemic infections, but the main use is as a topical agent. It is useful in mild cases of paracoccidioidomycosis and is an alternative to amphotericin B for infections caused by *Blastomyces, Coccidioides, Sporothrix*, or *Histoplasma* spp. Ketoconazole may be used if prolonged oral therapy for chronic mucocutaneous candidiasis is needed. *In vivo*, ketoconazole is fungistatic because fungicidal levels are not achievable with therapeutic concentrations. Adverse reactions include transient elevations in liver enzymes; nausea; and dose-related gynecomastia, decreased libido, and oligospermia in males. There are several other anti-fungals that are less toxic and therefore other alternatives are generally used except in resource-limited environments.

Voriconazole

Voriconazole has an expanded spectrum of activity compared with itraconazole. In addition to the uses described previously for itraconazole, voriconazole demonstrates useful activity against some *Fusarium* strains as well as activity against *Scedosporium* spp., *Candida* spp. *C. neoformans*, and *Trichosporon* spp. The Mucorales are resistant to voriconazole. This agent is often used as salvage therapy for severe cases of *Coccidioides* meningitis and with other dimorphic fungi, including *Blastomyces, Histoplasma*, and *Talaromyces* spp. Elevated liver enzymes may occur, as may transient visual disturbances, which can significantly alarm the patient if the individual is not forewarned.

Posaconazole

Posaconazole was originally available as an oral triazole structurally similar to voriconazole with activity against *Candida* spp., *Aspergillus* spp., *C. neoformans, Trichosporon,* and the Mucorales. The antifungal is also now available as an intravenous formulation that can be used in treatment of seriously ill patients. The antifungal appears less effective against *Fusarium* spp. and *Scedosporium* spp. It is commonly prescribed as prophylaxis to prevent invasive *Aspergillus* and *Candida* infections in high-risk patients including hematopoietic stem cell transplant recipients with graft-versus-host disease or those with neutropenia following chemotherapy for hematologic malignancies. Posaconazole is also very effective in systemic infections with the thermally dimorphic fungi.

Isavuconazole

Isavuconazole is a triazole available as an oral or parenteral agent and is primarily used for the treatment of invasive aspergillosis (IA) or invasive mucormycosis (IM). There is documentation, however, that panazole-resistant isolates of *Aspergillus fumigatus* are also resistant to isavuconazole. Common side effects include nausea, diarrhea, headache, increased liver enzymes, and peripheral edema. Considering the favorable outcomes for IA and IM infections, use of isavuconazole was investigated for candidemia and invasive candidiasis; however, the results of that study were unable to demonstrate noninferiority of isavuconazole relative to caspofungin for the primary treatment of candidemia and invasive candidiasis.

Echinocandins

The echinocandins (anidulafungin, caspofungin, micafungin) are semisynthetic lipopeptide antifungal agents that inhibit the 1,3-beta-D-glucan synthase that is involved in fungal cell wall synthesis. The drug is effective against *Candida* spp., including strains that are resistant to fluconazole. They are typically used for the prophylaxis and treatment of *Candida* spp. infections in adult and pediatric patients. The echinocandins are only available as intravenous medications. In addition to the treatment of candidiasis, they are also effective against *Aspergillus* spp. They are ineffective against fungi that lack 1,3-beta-D-glucan, including *C. neoformans, Trichosporon* spp., *Fusarium* spp., and the Mucorales. Side effects are minimal.

Polyene Macrolide Antifungals

Polyene macrolide antifungal agents consist of a group of complex organic molecules, most of which contain multiple, conjugated, double-bond, and one- to three-ring structures. This group includes many of the most commonly used antifungal agents, such as amphotericin B, the colloidal and liposomal preparations of amphotericin B, nystatin, and griseofulvin.

Amphotericin B

Amphotericin B is produced by the actinomycete *Streptomyces nodosus.* It is commonly infused intravenously to treat deep-seated fungal infections, e.g., IA, and those caused by *Candida* spp., *Cryptococcus* spp., and members of the Mucorales. Amphotericin B binds the ergosterol component of the fungal cell membrane and alters the selective permeability of this membrane. The most significant adverse reaction associated with amphotericin B therapy is renal insufficiency. The liposomal amphotericin B formulation diminishes this adverse reaction. Although amphotericin B is active against a wide variety of fungi, resistant organisms exist that the laboratory must be able to identify. Clinical failures in cases treated with amphotericin B include infections caused by *Pseudallescheria boydii, Scedosporium prolificans, Aspergillus terreus, Trichosporon* spp., and most cases involving *Fusarium* spp. CLSI has not published clinical breakpoints for any *Candida* spp. against amphotericin B. Instead, they publish an epidemiologic cutoff value (ECV) based on the MIC distribution for the organism against the drug in question. For *Candida* spp., the amphotericin B ECV has been set at ≥4 μg/mL. *Candida* isolates with MICs at or above this cutoff are presumed to contain some acquired mechanism of resistance.

Nystatin

Nystatin, an antifungal agent produced by *Streptomyces noursei,* is not absorbed in the gastrointestinal tract. It is principally used locally to treat oral or vulvovaginal candidiasis. The toxicity of this drug is prohibitive to parenteral use.

Griseofulvin

Griseofulvin is an antifungal antibiotic produced predominantly by *Penicillium griseofulvum*. Its mechanism of action consists of binding microtubular proteins, which are required for mitosis. Griseofulvin is an oral agent used to treat dermatophytoses, which are not responsive to azole antifungal therapy. Headache, gastrointestinal disturbances, and photosensitivity are a few of the adverse reactions that limit the usefulness of this drug.

5-Fluorocytosine (Flucytosine)

Flucytosine is a pyrimidine base, which is fluorinated in the fifth position. Flucytosine is metabolized to 5-fluorouracil, which is incorporated into fungal ribonucleic acid (RNA). This subsequently inhibits protein synthesis. Flucytosine is also metabolized into fluorodeoxyuridine monophosphate, a potent inhibitor of DNA synthesis. Flucytosine and amphotericin B act synergistically and have been used in combination therapy for treating infections caused by *Candida* spp. and *Cryptococcus* spp. Side effects and the emergence of resistance among *Candida* spp. and *C. neoformans* occurs in approximately 2% to 3% of all isolates.

Allylamines

Terbinafine and Naftifine

Terbinafine and naftifine are synthetic allylamines that are highly lipophilic, allowing them to accumulate in the skin, nails, and fatty tissue. The drugs interfere with fungal cell wall synthesis and are effective topical treatments for infections. Terbinafine is available as an oral or topical medication, whereas naftifine is only available in topical form. These antifungals are typically used in dermatophyte infections, and the development of resistance is rare even after prolonged exposure.

Selenium Sulfide

Selenium sulfide shampoos, available commercially, provide antifungal activity against *Malassezia furfur,* the causative agent of tinea versicolor. Additionally, selenium sulfide is sporicidal for *Trichophyton tonsurans*.

Chapter Review

1. Current guidelines for AFST are found in which CLSI document?
  a. M27-Ed4
  b. M38-Ed3
  c. M44-Ed3
  d. All of the above

2. Flucytosine should be used synergistically with which of the following to prevent drug resistance?
  a. Nystatin
  b. Amphotericin B
  c. Griseofulvin
  d. Ketoconazole

3. Which antifungal drug is the therapy of choice for pulmonary histoplasmosis?
  a. Caspofungin
  b. Itraconazole
  c. Fluconazole
  d. None of the above

4. Which of the following antifungal agents disrupts the integrity of the fungal cell membrane by interfering with the synthesis of ergosterol?
  a. Miconazole
  b. Fluconazole
  c. Voriconazole
  d. All of the above

5. True or False

_____ AFST does not need to be performed because results are predictable.

_____ Isolates of the same species always have the same MIC.

_____ Nystatin is an antifungal antibiotic produced by a species of *Penicillium.*

6. Matching: *Match each term with the correct description.*

_____ MIC
_____ amphotericin B
_____ micafungin
_____ fluconazole
_____ nystatin

a. used locally to treat candidiasis
b. minimal inhibitory concentration
c. infused intravenously to treat deep-seated infection
d. tridazole
e. glucan synthesis inhibitors

64

Overview of the Methods and Strategies in Virology

OBJECTIVES

1. Describe the physical components that make up a virion, and list a function for each component.
2. Define the viral infectious cycle, including naming the six steps in this process.
3. Explain viral tropism and provide a specific example related to a human pathogen.
4. Define the properties used to classify viruses and how these properties can be used to predict infection before a confirmed laboratory result.
5. Explain the general steps in viral pathogenesis (e.g., of a respiratory virus).
6. List some of the reasons for the increase in demand for clinical viral services in the field of infectious disease diagnostics.
7. Name some of the equipment necessary to set up a clinical virology laboratory and give the function of each piece.
8. List some of the viruses associated with the following clinical specimens: throat or nasopharyngeal swab or aspirate, urine, stool, lesion, blood, bone marrow, and stool or rectal swab.
9. List some of the most commonly used laboratory tests for detecting the following viruses: enterovirus, herpes simplex virus, influenza virus, norovirus, and respiratory syncytial virus (RSV).
10. Describe the Tzanck test procedure and list the viruses for which the test is used.
11. Define monolayer, primary cells, semicontinuous (low passage) cells, and continuous cells. Explain the incubation conditions for routine cell cultures.
12. Explain the types of cell lines used in viral cell culture; describe their similarities and differences, and how cytopathic effects (CPEs) are rated when reading cell cultures.
13. Describe a shell vial cell culture and explain its advantages over conventional cell culture.
14. Define the hemadsorption procedure and name the viruses for which the test is used.
15. Name the virus family capable of establishing viral latency in the human dorsal nerve root ganglion and explain the possible consequence of the latency.
16. Name the preferred tissue type of cell culture for growth of the following viruses: influenza A virus, varicella-zoster virus, herpes virus, and cytomegalovirus (CMV).
17. Associate an appropriate viral pathogen with the following viral syndromes: infant croup, infant bronchiolitis, adult gastroenteritis, parotitis, infectious mononucleosis, and meningitis.
18. Outline the benefits of mass spectrometry for viral pathogen identification versus other viral detection methods.

The survival of viral infectious agents depends on their ability to infect and reside in a living organism. These tiny organisms are believed to have evolved alongside humans and in conjunction with the domestication of animals. Throughout history, evidence shows that viruses are able to survive when stable host populations are available to provide a means for continued propagation. Viruses that established a long-term relationship with their host (i.e., did not kill the host immediately upon infection) were the first to become adapted and coevolve with the host species. Some of these earliest viruses in humans were believed to be retroviruses, such as the herpes viruses and papillomaviruses, which will be discussed in more detail in this chapter and Chapter 65.

A **virus** is an obligate intracellular parasite, that is among the smallest of all infectious agents and capable of infecting an animal, insect, plant, or bacterial cell. Viruses are found in every ecosystem. As strict obligate intracellular parasites, they are incapable of replication without a living host cell. Virus types are very specific, and each has a limited number of hosts it can infect; this is referred to as **viral tropism.**

Much is still unknown about the origins of viral agents, although most speculation indicates that viruses affecting humans established themselves in the human population via direct transmission of an animal virus to a human. Transmission of viruses from animals to humans still occurs, as demonstrated in the more recent viral outbreaks associated with the severe acute respiratory syndrome (SARS), West Nile, and influenza A H5 viruses, as well as the 2009 H1N1 virus, formerly known as the “swine flu.” The influenza virus has been known to infect humans since the 1700s in Italy and has proven to be one of the deadliest viruses to affect humans. The virus was named to indicate disease resulting from the “influence” of miasma (bad air).

The emergence of a new viral disease across a very large geographic region (worldwide) with prolonged human-to-human transmission is called a **pandemic.** Most of the pandemics recorded had been caused by an influenza virus. Influenza virus pandemics result when the virus undergoes a **genetic shift**, and the reassortment of genes combines with those of another organism, usually an animal. The resulting virus emerges as a completely new or “novel” virus. The genetic changes in viral genomes may result from **antigenic shift** (major changes that result in novel viral antigens) and/or **antigenic drift** (minor changes that occur continuously over time as the virus replicates). One of the most deadly influenza outbreaks was the Spanish flu pandemic of 1918 to 1919. This pandemic was associated with infection with a novel influenza virus of avian origin. After a period of adaptation in humans, the virus emerged in pandemic form and was responsible for more than 50 million deaths worldwide, including 500,000 in the United States. What was so different about this pandemic was that it affected young and healthy individuals, not just the very young or very old. The more recent influenza pandemic of the 20th century was associated with a human influenza virus in which genes reassorted in combination with an avian influenza virus. The most recent pandemic began in December 2019 and is caused by SARS-CoV-2, also known as COVID-19. This is a novel coronavirus originating in Wuhan, China and causes an acute respiratory distress syndrome, an extreme proinflammatory response, and multiorgan dysfunction.

Protection from viral infection has been successful for some viral pathogens. Vaccination (immunization) has proven to be a valuable tool in the control of viral diseases such as yellow fever and rabies and has been instrumental in the eradication of one of the most lethal viruses, smallpox. However, many viral diseases such as influenza, acquired immunodeficiency syndrome (AIDS), and hepatitis continue to pose challenges in treatment, prevention, and control.

The science of clinical virology has seen a rapid expansion in the past few years as new and emerging pathogenic viruses continue to evolve. The science of virology will continue to evolve, and clinicians will continue to rely on the laboratory scientist for the development and implementation of testing to diagnose, treat, and prevent viral disease.

General Characteristics

Viral Structure

Virus particles, referred to as **virions**, consist of two or three parts:

- An inner nucleic acid core, consisting of either ribonucleic acid (RNA) or deoxyribonucleic acid (DNA)
- A protein coat that surrounds and protects the nucleic acid (the **capsid**)
- In some of the larger viruses, a lipid-containing envelope that surrounds the virus

Because enveloped viruses are very susceptible to drying and destruction in the environment, they typically are transmitted by direct contact, such as respiratory, sexual, or parenteral contact. This prevents exposure to the environment and successful propagation of the viral agent to another susceptible host. Viruses that do not have an envelope are often referred to as **"naked" viruses.** Naked viruses are very resistant to environmental factors. Because of their stability, they typically are transmitted by the fecal-oral route. Many viruses have **glycoprotein spikes** extending from their surface. The term **nucleocapsid** is often used to describe the nucleic acid genome surrounded by a symmetric protein coat (Fig. 64.1).

The function of the nucleic acid genome is to encode the proteins required for viral penetration, transmission, and replication. The viral genome structure determines the mechanism for viral replication. A variety of viral genome structures exist, including (+) sense–strand RNA, (–) sense–strand RNA, and DNA genomes. In addition, viral genomes may be single- or double-stranded molecules. The structural implications of variation in genome organization are discussed in more detail in the section on viral replication.

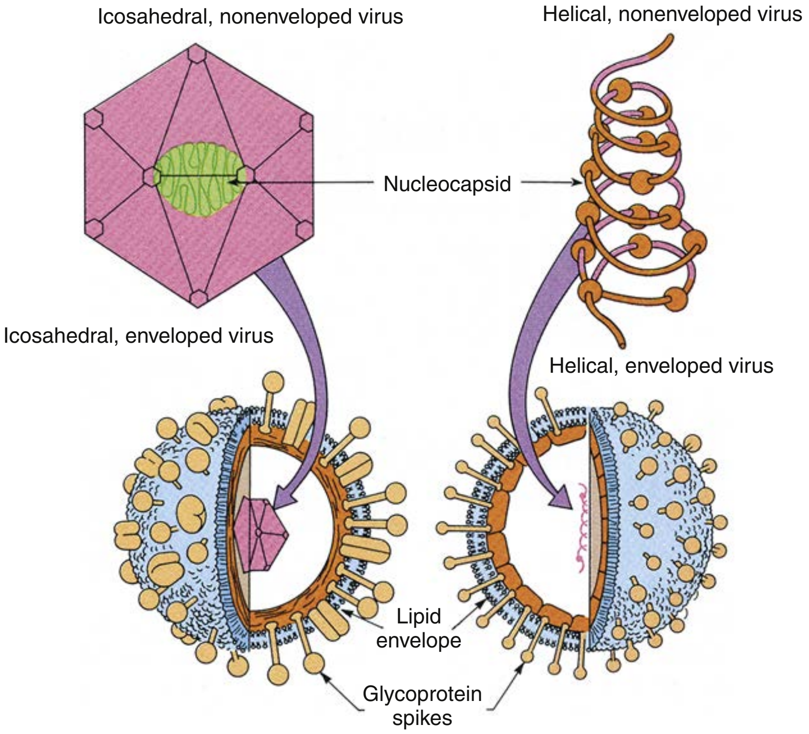
The viral capsid protects the viral genome and is responsible for the tropism to specific cell types in naked viruses. Viral capsids typically are composed of repeating structural subunits referred to as **capsomeres.** The capsomeres associate to form the capsid and a characteristic symmetric structure. The most common capsid structures geometrically form a helical or icosahedral structure (Fig. 64.1). Icosahedral capsids are cubical and have 20 flat sides; irregularly shaped capsids usually assume a helical form and are spiral-shaped.

As mentioned, in some viruses the nucleocapsid is enclosed in a lipid envelope. The envelope is responsible for viral entry into the host cell (Fig. 64.1). During the infectious process, enveloped virions bud from a host cell's cytoplasmic, nuclear, or endoplasmic reticular membrane, and a portion of the membrane remains attached to the virion as the viral envelope. Inserted into this viral envelope are viral proteins, such as hemagglutinin (HA), neuraminidase, or glycoprotein spikes. The glycoprotein spikes assist in stabilization of attachment for the lipid envelope and for attachment to the host cell to facilitate viral entry. Some enveloped viruses also contain a **matrix protein** that lies between the envelope and the nucleocapsid. The matrix protein may have enzymatic activities or biologic functions related to infection, such as inhibition of host-cell transcription.

Viruses that cause disease in humans range from approximately 20 to 300 nm. Even the largest viruses, such as the poxviruses, cannot be detected with a light microscope, because they are less than one fourth the size of a staphylococcal cell (Fig. 64.2). Virus particles can be visualized using an electron microscope. This assists in the classification of viruses based on structural components.

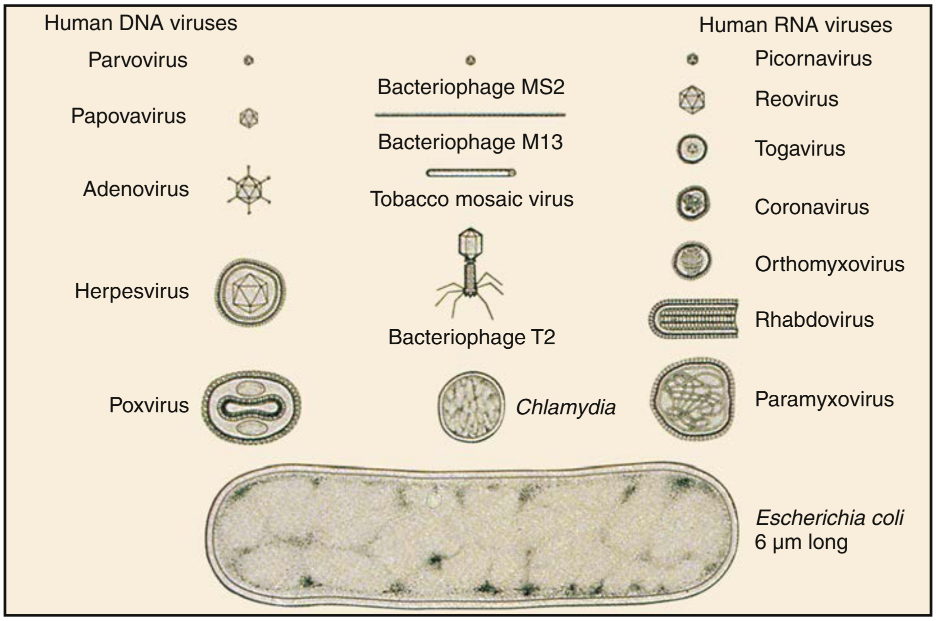
Virus Taxonomy

Viral taxonomy is determined by the International Committee on Taxonomy of Viruses (ICTV) of the Virology Division of the International Union of Microbiological Societies. The ICTV report indicates that viral taxonomy consists of 14 Orders (name ending in -virales), 150 Families (-viridae), 79 Subfamilies (-virinae), 1019 Genera (-virus), and 5560 Species. Classification of viral species can be problematic and therefore is often polythetic; that is, the members of a group share common characteristics but may not



Icosahedral, nonenveloped virus
Helical, nonenveloped virus
Nucleocapsid
Icosahedral, enveloped virus
Helical, enveloped virus
Lipid envelope
Glycoprotein spikes

• **Fig. 64.1** A viral particle. Enveloped and nonenveloped virions have an icosahedral or irregular (usually helical) shape. (Modified from Murray PR, Drew WL, Kobayashi GS, et al, eds. *Medical Microbiology,* St Louis: Mosby; 1990.)

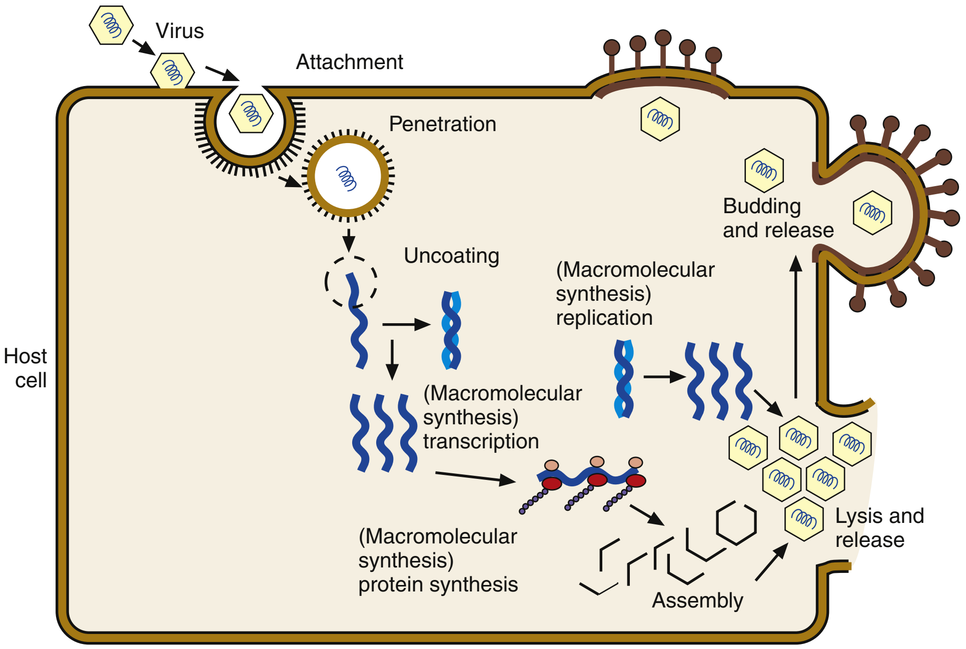


Human DNA viruses
Parvovirus
Papovavirus
Adenovirus
Herpesvirus
Poxvirus
Bacteriophage MS2
Bacteriophage M13
Tobacco mosaic virus
Bacteriophage T2
Chlamydia
Human RNA viruses
Picornavirus
Reovirus
Togavirus
Coronavirus
Orthomyxovirus
Rhabdovirus
Paramyxovirus
Escherichia coli
6 µm long

• **Fig. 64.2** Relative sizes of representative viruses, bacteriophages (bacterial viruses), and bacteria, including chlamydia. *DNA,* Deoxyribonucleic acid; *RNA,* ribonucleic acid. (From Murray PR, Drew WL, Kobayashi GS, et al, eds. *Medical Microbiology,* St Louis: Mosby; 1990.)

have a single defining characteristic. In addition, some viral families currently are not assigned to an order, and some species are not assigned to a family.

Complex viral taxonomy incorporates a variety of categories, including information related to host range, transmission, disease pathology, antigenicity, and viral particle properties, such as size, envelope, capsid structure, physical properties, genome type, and configuration. For simplicity purposes, many texts limit viral classification to three basic properties: (1) viral morphology; (2) method of



Virus
Attachment
Penetration
Uncoating
Host cell
(Macromolecular synthesis) transcription
(Macromolecular synthesis) replication
(Macromolecular synthesis) protein synthesis
Budding and release
Lysis and release
Assembly

• **Fig. 64.3** The viral infectious cycle. (Modified from Murray PR, Drew WL, Kobayashi GS, et al., eds. *Medical Microbiology,* St Louis: Mosby; 1990.)

replication, including genome organization (whether the genome is RNA or DNA and single- or double-stranded); and (3) presence or absence of a lipid envelope. The phrase "means of replication" refers to the strategy the virus uses to duplicate the viral genome. For example, **enteroviruses** have single-stranded RNA genomes that synthesize additional strands of RNA, whereas **retroviruses** make RNA molecules in a two-step process by first synthesizing DNA, which subsequently is converted to RNA.

Characterization of viral genomes has increasingly improved because of advances in molecular techniques. Sequencing of viral nucleic acids, including entire DNA or RNA genomes, has become a routine procedure in the clinical research setting and has specific applications in the clinical diagnostic laboratory as well. Next-generation sequencing for the monitoring of viral therapy, resistance testing, outbreak management, characterization, and surveillance will continue to evolve. This is not without challenges to the clinical laboratory including the need for technical expertise, the cost of instrumentation, data analysis, and interpretations.

Viral Replication

Viruses are strict intracellular parasites that rely upon components of the host cell to replicate, and therefore are capable of replication only within a host cell. The six steps of virus replication, called the **infectious cycle,** proceed as follows (Fig. 64.3):

1. **Attachment,** also referred to as adsorption, is the first step of the infectious cycle. It involves recognition of a suitable host cell and specific binding between viral capsid proteins (often the glycoprotein spikes) and the carbohydrate receptor of the host cell. Each type of virus specifically recognizes and attaches to a specific type of host cell, allowing infection of some tissues but not others (viral tropism, as described previously).
2. **Penetration** (also referred to as virus entry) is the process by which viruses enter the host cell. One mechanism of penetration involves fusion of the viral envelope with the host cell membrane. This method not only provides a mechanism for internalizing the virus, but also leads to fusion between the infected host cell and additional nearby host cells, forming multinucleated cells called **syncytia.** Detection of syncytia can be used to determine the presence of virus in cell cultures or stained smears of clinical specimens. Other mechanisms of viral penetration include phagocytosis by host cells (endocytosis) or injection of viral nucleic acids into the host cell.
3. **Uncoating** occurs once the virus has been internalized. It is the process by which the capsid is removed; this may be by degradation of viral enzymes or host enzymes or by simple dissociation. Uncoating is necessary to release the viral genome for delivery of the viral DNA or RNA to its intracellular site of replication in the nucleus or cytoplasm.
4. **Macromolecular synthesis** involves the production of nucleic acids and protein polymers. Viral transcription leads to the synthesis of messenger RNA (mRNA), which encodes early and late viral proteins. Early proteins are nonstructural elements, such as enzymes, and late proteins are structural components. In addition, replication of viral nucleic acid is necessary to synthesize genomes that are incorporated into progeny virus particles. The mechanics of macromolecular synthesis varies depending on the organization of the viral genome (i.e., positive or negative sense RNA, single- or double-stranded nucleic acid genome).

5. **Viral assembly** is the process by which structural proteins, genomes, and in some cases viral enzymes are assembled into virus particles. Envelopes are acquired during viral "budding" from a host cell membrane. Nuclear endoplasmic reticulum and cytoplasmic membranes are common areas for budding. Acquisition of an envelope is the final step in viral assembly.
6. **Release** of intact virus particles occurs after cell lysis (**lytic virus**) or by virus particle **budding** from cytoplasmic membranes. Release by budding may not result in rapid host cell death, as does release by cell lysis.

Epidemiology

Viruses are transmitted from person to person by the respiratory, fecal-oral, and sexual contact routes; by trauma or injection with contaminated objects or needles; by tissue transplants (including blood transfusions); by arthropod or animal bites; and during gestation (transplacental transmission).

Pathogenesis and Spectrum of Disease

Once introduced into a host, the virus infects susceptible cells and the infectious cycle begins. Viral infections may produce one of three characteristic clinical presentations: (1) **acute viral infection,** displaying evident signs and symptoms; (2) **latent infection,** which has no visible signs and symptoms, but the virus is still present in the host cell in a **lysogenic state** (inserted into the host genome in a resting state) or maintained as a nuclear or cytoplasmic **episome;** and (3) **chronic or persistent infection,** in which low levels of virus are detectable and the degree of visible signs or symptoms varies.

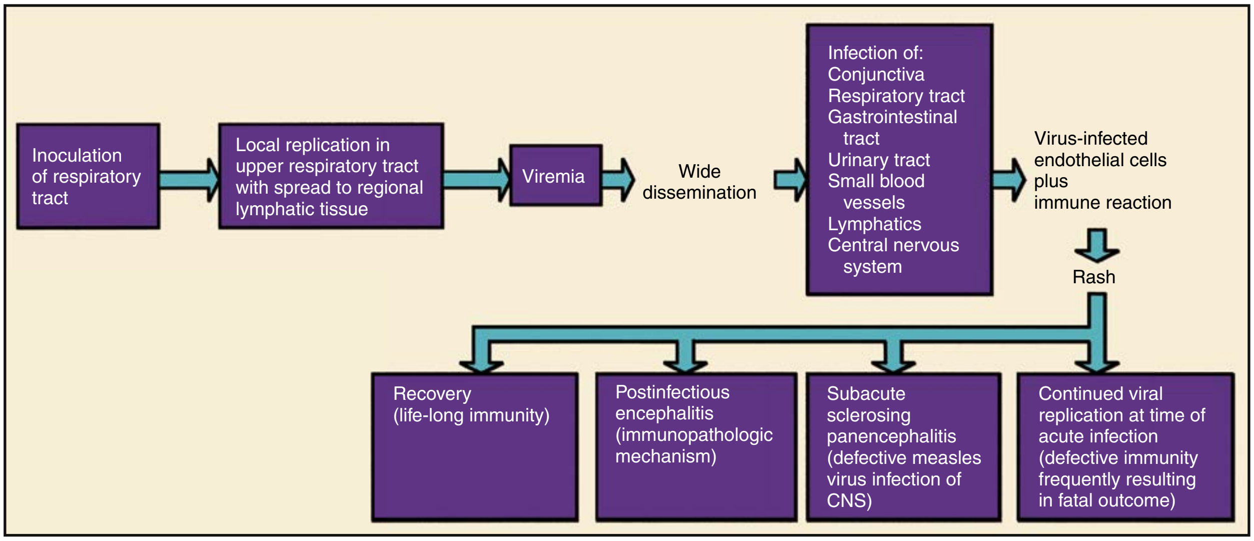
After viral infection at a local, often mucosal site, **viremia** may occur (viruses disseminated in peripheral blood), which may serve to inoculate secondary target tissues distant from the primary site of infection. Secondary viremia may occur in a variety of tissues, such as the skin, salivary glands, kidneys, brain, and other central nervous system (CNS) tissues including the meninges. After peripheral dissemination, symptomatic disease may ensue. Disease resolves when specific antibody and cell-mediated immune mechanisms prevent continued replication, spread of the virus, and associated host immune responses (i.e., inflammation). Tissue is damaged during lysis of virus-infected cells or by immunopathologic mechanisms directed against the virus that are also destructive to neighboring tissue. Most DNA-containing viruses, such as those in the herpesvirus group, remain latent in host tissues with no observable signs or symptoms of disease. Retroviruses and most DNA viruses establish a latent state after primary infection. During the latent state, the viral genome is often integrated into the host cell's chromosome and no viral replication occurs. Latent viruses can reactivate silently, resulting in viral replication and shedding but no clinical symptoms, or they can reactivate and cause symptomatic, even fatal, disease. Reactivation may accompany immune suppression, resulting in the recurrence of clinically apparent disease.

Occasionally, pathogenic viruses stimulate an immune reaction that cross-reacts with antigenically similar components of the host tissues, resulting in impairment to host function; this is called **autoimmune pathogenesis.** When present, it occurs well after the acute viral infection has resolved and after antibodies are generated in response to viral antigens; this process takes several weeks to occur. In some cases, viral infection can promote **transformation** or **immortalization** of host cells through expression of specific viral proteins that affect the cell cycle, ultimately resulting in dysregulation or uncontrolled cell proliferation. Viruses with the ability to stimulate uncontrolled growth of host cells are referred to as **oncogenic viruses** (also known as **oncoviruses**). Several high-risk subtypes of human papillomaviruses (HPV) are oncogenic and are responsible for dysregulation of normal epithelial differentiation leading to cervical cancer and certain types of oral cancer.

The diverse variety of pathogenic mechanisms associated with viral infections is illustrated in the spectrum of disease caused by the measles virus. After replication in the upper respiratory tract and subsequent viremia, the virus infects many susceptible cell types throughout the body, including endothelial cells in capillaries of the skin. This is accompanied by local inflammation and results in the characteristic rash of measles. The immune system of immunocompetent individuals eradicates the virus, resolving the infection, resulting in lifelong immunity to reinfection. In some, antibody produced in response to the measles infection cross reacts with tissue in the CNS, causing a post-infectious encephalitis. In others, slow but continuing replication of damaged virus in the brain gives rise to **subacute sclerosing panencephalitis (SSPE)**. In severely immunocompromised individuals, ongoing primary infection is not aborted by the usual immune mechanisms, and the outcome is death (Fig. 64.4).

Prevention and Therapy

Vaccines are a safe and reliable method for prevention of many disease-causing viruses. Immunizations are available for some human disease-causing viruses. In some cases, the vaccine produces a life-long immunological response that protects the individual from disease. Widespread vaccinations also provide population-level benefits, referred to as **herd immunity**, that protects individuals who are unable to be vaccinated due to age, allergies, or other health condition. Loss of herd immunity due to declines in vaccination rates can have severe consequences as demonstrated by recent outbreaks of measles across the United States. From January to April 2019, the Centers for Disease Control (CDC) reported 465 cases of measles in 19 states, from a virus that was completely eradicated endemically in the year 2000, as indicated by a zero incidence of cases over a 12-month period or longer.



Inoculation of respiratory tract
Local replication in upper respiratory tract with spread to regional lymphatic tissue
Viremia
Wide dissemination
Infection of: Conjunctiva Respiratory tract Gastrointestinal tract Urinary tract Small blood vessels Lymphatics Central nervous system
Virus-infected endothelial cells plus immune reaction
Rash
Recovery (life-long immunity)
Postinfectious encephalitis (immunopathologic mechanism)
Subacute sclerosing panencephalitis (defective measles virus infection of CNS)
Continued viral replication at time of acute infection (defective immunity frequently resulting in fatal outcome)

• **Fig. 64.4** Viral pathogenesis is illustrated by the mechanisms through which the measles virus spreads in the body. *CNS,* Central nervous system. (From Murray PR, Drew WL, Kobayashi GS, et al., eds. *Medical Microbiology,* St Louis: Mosby; 1990.)

However, for viruses for which there are no available vaccines, effective prevention involves regular, thorough hand washing and avoiding contact with others during episodes of evident signs of disease, such as fever, cough, diarrhea, and respiratory distress. For sexually transmitted viruses, prevention may also involve the use of condoms (male and female versions) during vaginal, anal, or oral sex.

Antiviral Agents

An increased understanding of viral structure and replication has improved the availability of therapeutic agents for the treatment of viral infections. More than 70 antiviral drugs are formally licensed for clinical use in the United States, and more than half of these are used in the combination treatment, termed **antiretroviral therapy (ART),** of human immunodeficiency virus (HIV) infections. Antivirals also are used in the treatment of hepatitis C virus (HCV), herpes viruses (herpes simplex virus [HSV], varicella-zoster virus [VZV], and cytomegalovirus [CMV]), hepatitis B virus (HBV), respiratory syncytial virus (RSV), and the influenza viruses. (Antiviral agents are reviewed in more detail in Chapter 65.)

Viruses That Cause Human Diseases
